Abstract

The present study was carried out to evaluate the antibacterial and antioxidant activity of extract and chemical constituents of *Usnea rubrotincta*, *Ramalina dumeticola* and *Cladonia verticillata.* Acetone extract of *U. rubrotincta* showed promising antibacterial activity against Gram positive bacteria *Bacillus subtilis* with the lowest Minimal Inhibitory Concentration (MIC) value of (15.63 µg/mL). Six secondary metabolites were isolated using Preparative High Performance Liquid Chromatography (PHPLC) method from the two bioactive lichens *U. rubrotincta* and *R. dumeticola* (compound 1 – 6). Among all six compounds, compound (1) exhibited strongest activity against both the tested Gram positive bacteria at 7.81 µg/mL. Compound (6) had 69.57% scavenging activity against DPPH free radical while the rest only showed below 50% scavenging activity. This is the first evaluation of antibacterial activity of lichens found in Malaysia and to our knowledge, this is the first report of antibacterial and antioxidant activity of compound (3) and (5).

Keywords: antibacterial, antioxidant, *Usnea rubrotincta*, *Ramalina dumeticola*, *Cladonia verticillata*, usnic acid

Abstrak

Kajian ini dijalankan bagi menilai aktiviti antibakteria dan antioksidan sebatian kimia liken yang diekstrak iaitu *Usnea rubrotincta*, *Ramalina dumeticola* dan *Cladonia verticillata*. Ekstrak aseton terhadap *U. rubrotincta* telah menunjukkan aktiviti antibakteria yang memberangsangkan terhadap bakteria Gram positif *Bacillus subtilis* dengan nilai Kepekatan Perencatan Minimum (KPM) sebanyak (15.63 µg/mL). Enam metabolit sekunder telah dipencilkan daripada 2 liken bioaktif iaitu *U. rubrotincta* dan *R. dumeticola* menggunakan kaedah Kromatografi Cecair Prestasi Tinggi Preparatif (KCPTP) (sebatian 1 – 6). Daripada 6 sebatian, sebatian (1) telah memaparkan aktiviti yang paling kuat terhadap kedua-dua bakteria Gram positif yang dikaji pada kepekatan 7.81 µg/mL. Sebatian (6) mempunyai peratus pemerangkapan radikal bebas DPPH pada 69.57% manakala sebatian lain hanya menunjukkan aktiviti pemerangkapan kurang daripada 50%. Ini adalah penilaian pertama terhadap aktiviti antibakteria bagi liken yang dijumpai di Malaysia dan kepada pengetahuan kita, ini adalah laporan pertama bagi aktiviti antibakteria dan antioksidan sebatian (3) dan (5).

Kata kunci: antibakteria, antioksidan, *Usnea rubrotincta*, *Ramalina dumeticola*, *Cladonia verticillata*, asid usnik

Introduction

Lichens are self-supporting symbiotic association between a mycobiont and a photobiont. The mycobiont which is the fungus is unique and dominates the association while the photobiont is the algae or cyanobacteria. Many lichens are able to endure extreme environmental conditions hostile to the survival of the individual partners [1]. They are able to grow as scattered patches on stones, outcrops, on tree trunks or shrubs. Lichens mostly expose their vegetative parts to sunlight to enable the photobiont which harvest energy from solar radiation. These vegetative bodies are called thalli or lichenized stroma which contains characteristic secondary compounds [2].

To date approximately 1050 secondary metabolites have been identified [3] and most of them are considered to be very unique. The secondary metabolites found in lichens were reported to have multiple functions. They are light filters that protect the photobionts from excessive radiation [4], prevent damage from grazing by herbivores and have antibiotic properties to protect against microbial degradation [5]. Compounds like atranorin, fumarprotocetraric acid, gyrophoric acid, lecanoric acid, physodic acid, protocetraric acid, stictic acid and usnic acid have showed comparatively strong antimicrobial properties against bacteria and fungi, amongst which were human, animal and plant pathogens, mycotoxin-producers and food-spoilage organisms [6]. Several depsides (sekikaic acid, lecanoric acid and lobaric acid) are known exhibited radical scavenging activity comparable to rutin [7].

There are compelling reasons for the search of new antimicrobial agents, including from natural product drugs mainly because of the emergence of multi drug-resistant pathogens and the reduced effectiveness of currently used drugs. Besides, the rise of various diseases related to oxidative stress implicates the dire need of discovery of new antioxidant agents. Lichens can be a good source for the search due to the ability to survive in extreme conditions. Malaysia is abundant of highland and lowland lichens. Din et al. [8] profiled several types of chemical compounds derived from lichens collected from Bukit Larut, Peninsular Malaysia some of which have been reported previously to possess strong antibacterial and antioxidant activity. Four lichen species namely *Ramalina peruviana, Parmotrema tinctorum, Bulbothrix isidiza* and *Cladia aggregata* from Penang Hill, Malaysia were found to have significant antioxidant activity [9]. Hitherto there is no report on the antimicrobial activity of the lichens found in Malaysia. This study investigated antibacterial and antioxidant potential of various extracts of three different lichens from the species, *Usnea rubrotincta, Ramalina dumeticola and Cladonia vercillata* collected from the Malaysian highland area. Further to this, work was undertaken to isolate the chemical constituents from the active lichen extracts.

Materials and Methods

Lichen samples

Lichen *Ramalina dumeticola* was collected from Fraser Hill, Pahang, 3° 46 N' 111° 43 E', 1300m above sea level, voucher specimen number (F.H 1). Lichen *Usnea rubrotincta* and *Cladonia vercilata* were collected from Bukit Larut, Perak, 4° 50N', 100° 48 E', 1035m above sea level, voucher specimen number (B.L 1, B.L 2). Voucher specimens of these lichens have been deposited at the School of Chemical Sciences and Food Technology, Universiti Kebangsaan Malaysia.

Microorganisms and media

The bacteria used as test organisms are as follows: *Staphylococcus aureus* (ATCC 29213), *Bacillus subtilis* (ATCC 19659) and *Escherichia coli* (ATCC 25922) obtained from American Type Culture Collection/USA). Bacterial cultures were maintained on Muller Hinton agar substrates (Oxoid Ltd., Hampshire, England) and were stored at 4 ^{o}C.

Preparation of lichen extracts

The lichen samples were air dried at room temperature. Powdered lichen samples of 250 g were subjected to sequential soxhlet extraction with two types of solvent, acetone and methanol. All the extractions were repeated twice. The extracts were then filtered, concentrated *in vacuo* and air-dried under fume hood to obtain dry powdered extracts which were stored at 4°C.

Antibacterial studies

The minimal inhibitory concentrations (MIC) of methanol and acetone extract of the lichens were determined using the 96 well plate methods as described by Eloff [10] with some modification. Bacterial inoculums were obtained from bacterial cultures incubated for 24 hours at 37 °C on Müller-Hinton agar and diluted to 0.5 McFarland standard of approximately 10^8 CFU/mL. The extracts were screened for antibacterial potentials at 500 µg/mL. Extracts showing bacterial growth inhibition were further tested to evaluate its MIC. A two fold serial dilution of acetone extracts (500 – 7.81 µg/mL) in DMSO and methanol extracts in methanol were prepared in a sterile 96-well plate respectively. The percentage of solvent was kept below 1% throughout the experiment.

Bacterial suspensions (100 mL) were added to each well and the plates were incubated for 24 hours at 37 °C. After the incubation time, 50 mL of *p*-iodonitrotetrazolium *(p*-INT) (0.2 mg/mL) was added into all the wells, including the blank wells (containing methanol or DMSO), and further incubated for 1 hour. These plates were then observed for color changes. Wells with yellow color were interpreted as no growth, whilst purple color was interpreted as presence growth. The minimum inhibitory concentration (MIC) was determined as the lowest concentration of samples which inhibit any visible growth of bacteria. Chloramphenicol and vancomycin were used as positive controls (500 – 7.81 µg/mL). All experiments were performed in triplicate.

Antioxidant assay: Total phenolic content

Total phenolic content (TPC) were estimated by using the Folin – Ciocalteu method [11] with some modification. Stock solutions of 1 mg/mL extracts and gallic acid were prepared in DMSO and distilled water respectively. A series of gallic acid concentrations were prepared by diluting the stock solution with distilled water. Gallic acid of 250 µL was added into individual test tubes followed by addition of 1 mL of distilled water and 250 µL of Folin – Ciocalteu reagent. After thoroughly shaken, the test tubes are allowed to sit in room temperature for 6 minutes. Later, an amount of 2.5 mL of Na_2CO_3 was added and allowed to sit for another 2 hours in a dark room at room temperature. A 200 µL of solution from each test tube is transferred into 96-well plate and the absorbance were measured at 760 nm using a microplate reader. The experiments were performed in triplicates. Gallic acid (0–500 µg/mL) was used for calibration of a standard curve. The result was expressed as gallic acid equivalents (GAE)/g dry weight of lichen material.

Total flavonoids

The total flavonoid content (TFC) was determined using colorimetric method as described by Sakanaka et al. [12]. An amount 125 µL of 1 mg/mL extract or standard solution (quercetin) were mixed with 625 µL of distilled water in a test tube. Sodium nitrite (5%) solution of 37.5 µL is then added and incubated for 6 minutes. Aluminium chloride (10%) solution of 75 µL was later added and the mixture was allowed to stand for another 5 minutes. Thereafter, 250 µL of 1M sodium hydroxide was added. The mixture was brought up to 1.25 mL with distilled water and mixed well. The absorbance at 510 nm was measured immediately. Quercetin (0.5–0.02 mg/mL) was used to construct a standard curve. The results were expressed as quercetin equivalent (QE) per gram dry weight of lichen extract. The experiments were performed in triplicates.

1, 1-diphenyl-2-picryl-hydrazyl (DPPH) free radical analysis

A quantitative determination of free radical scavenging activity was measured by using DPPH assay as described by Shimada et al. [13]. The antioxidant activity was expressed as percentage scavenging of DPPH by extract compared to standard, Trolox. An amount of 20 µL extract (1 mg/mL) was added into 180 µL of 0.2 mM of DPPH solution in 96-well plate. The plate was incubated for 20 minutes and kept in the dark. The same steps were repeated for standard Trolox. The percentage of scavenging was calculated from the absorbance of decolorization which obtained spectrophotometrically at 550 nm. Scavenging of the DPPH radical by the sample was calculated according to the following Equation (1).

$$\text{DPPH scavenging activity (\%)} = [A0 - A1 / A1] \times 100 \quad (1)$$

where $A0$ is the absorbance of the control and $A1$ is the absorbance of the sample. Free radical scavenging activity is expressed as the percentage of DPPH scavenging activity. The experiments were performed in triplicates.

Isolation of chemical constituents from the bioactive extracts: Liquid-liquid extraction
2 g of bioactive extracts were subjected to liquid-liquid extraction using hexane and methanol at 1:1 ratio. The process was performed in a triplicate. The resulting fractions were pooled and dried. It was noticed that there were crystals formed, which was filtered and purified further by recrystallization.

Thin layer chromatography (TLC)
The fractions were dissolved in appropriate solvent before being spotted onto the TLC plate. Solvent systems used in this thin-layer chromatography were according to Culberson [14] and Culberson et al. [15] namely (a) benzene-dioxane-acetic acid (180:45:5, 230 mL), (b) hexane-diethyl ether-formic acid (130:80:20, 230 mL), (c) toluene-acetic acid (200:30, 230 mL) and (d) toluene-ethyl acetate-formic acid (139:83:8, 230 mL). The spots were viewed under long and short ultraviolet light before sprayed with 10% sulphuric acid and heated at 110 °C.

Column chromatography
Fractions that showed good separation on the TLC plate was subjected to column chromatography. The solvent system used was similar to the one used for TLC. An approximately 0.5 g of the fraction was dissolved in a small amount of solvent system to avoid solubility problems inside the column. Small amounts of solvent were filled into the column every 15 minutes. The sub-fractions were collected according to the bands formed in the column and air-dried before subjected to TLC.

Preparative high performance liquid chromatography
The column used for separation was a Phenomenex Hypersil 5µ C18 column (150 x 21.2 mm) with the gradient mobile phases of methanol (A) and 1% orthophosphoric acid (B) with a flow rate of 4 mL/min. The run started with 100% B and was lowered to 50% B within 5 minutes then to 40% B within a further 10 minutes, followed by 20% B within the next 30 minutes. Then 500 µg/ml of sample with the injection volume of 100 µl was injected. A photodiode array detector was used to detect the compound peaks and recorded at three different wavelengths of 222 nm, 230 nm and 280 nm. The fractions were collected according to the retention time.

Identification of chemical constituents
An analytical HPLC method adapted from Din et al. [8] was used to evaluate the purity of the compounds obtained. A Phenomenex Hypersil 3µ C18 column (250 by 4.6 mm) with a flow rate of 1mL/min was used. The mobile phases were 1% aqueous orthophosphoric acid (A) and methanol (B). The gradient system started with 100% A and was raised to 58% B within 15 minutes, then to 100% B within next 16 minutes, followed by isocratic elution in 100% B for a further 10 minutes. The compounds were further subjected for mass (LC-MS ToF), 1D NMR FT-NMR 600MHz Cryo (Fourier Transform Nuclear Magnetic Resonance 600MHz Cryoprobe) and 1D NMR FT-NMR 500MHz (Fourier Transform Nuclear Magnetic Resonance 500MHz) spectrometry.

Bioassay for isolated chemical constituents
The isolated chemical constituents were evaluated for antibacterial and antioxidant activity at 500 µg/mL using the methods described in section Antibacterial studies and Antioxidant assay. The active chemical constituents were further tested for their (MIC).

Results and Discussion

Chemical Constituents
Usnic acid, (1) was obtained as yellow needles from acetone extract of *U. rubrotincta*, (1190 mg, 6.62% yield); HPLC retention time: 28.76 minutes; Mass spectrometry data showed 345 m/z; ^{1}H NMR data and ^{13}C NMR data, see Table 1; Structure, see Figure 1.

Barbatic acid, (2) was obtained as colorless needles from methanol extract of *U. rubrotincta*, (0.13 mg, 0.31% yield); HPLC retention time: 29.02 minutes; Mass spectrometry data showed 360m/z; ^{1}H NMR data and ^{13}C NMR data, see Table 2; Structure, see Figure 1.

Bioassay of extracts

The antibacterial activity and the (MIC) of extracts are summarized in Tables 7 and 8 respectively. Acetone extracts of *Usnea rubrotincta* and *Ramalina dumeticola* and methanol extracts of *Usnea rubrotincta* exhibited inhibitory activity against gram positive bacteria *S. aureus* and *B. subtilis*. However no activity against *E. coli*, gram negative bacterium was observed. The remaining lichen extracts were not active against the three test bacteria. The acetone extract of *R. dumeticola* exhibited highest activity against *S. aureus* followed by acetone and methanol extracts of *U. rubrotincta*. For negative control, DMSO did not exhibit any inhibition against all test organisms.

Table 7. Antibacterial activity of acetone and methanol extracts of various lichens at 500 µg/mL concentration

Test Organisms	***Usnea rubrotincta***		***Ramalina dumeticola***		***Cladonia verticillata***		**Chloramphenicol**	**Vancomycin**
	A	**M**	**A**	**M**	**A**	**M**		
S. aureus	+	+	+	-	-	-	+	+
B. subtilis	+	+	+	-	-	-	+	+
E. coli	-	-	-	-	-	-	+	+

Notes: A, acetone extract; M, methanol extract; +, had inhibitory activity against tested bacteria; -, had no inhibitory activity of extract against tested bacteria

Table 8. Minimal Inhibitory Concentration of bioactive extracts against selected gram positive bacteria

Test Organisms	***Usnea rubrotincta***		***Ramalina dumeticola***	**Chloramphenicol**	**Vancomycin**
	A	**M**	**A**		
	Minimal Inhibitory Concentration (µg/mL)				
S. aureus	125	500	31.25	31.25	7.81
B. subtilis	15.63	250	31.25	15.63	7.81

Notes: A, acetone extract; M, methanol extract

Both acetone and methanol extracts of *U. rubrotincta* showed activity against gram positive bacteria. The lowest MIC (15.63 µg/mL) was observed for acetone extract of *U. rubrotincta* against *B. subtilis* comparable to chloramphenicol. A similar activity against *B. subtilis* and *S. aureus* was reported for *Usnea barbata* acetone extract with MIC value of 0.1 mg/mL [16]. *R. dumeticola* acetone extract showed good antimicrobial activity against both gram positive bacteria with MIC values though it was approximately four times less potent than vancomycin (Table 8). Lichen from the same genus, *Ramalina farinacea* was also reported active against some gram positive bacteria including *B. subtilis* and *S. aureus* at MIC value of 264 µg/mL and 132 µg/mL respectively [17]. All the lichen extracts in this study showed no activity against gram negative bacteria. These findings are closely in agreement with report by Burkholder et al. [18] whom reported no activity of 42 tested lichens against gram negative bacteria *E.coli.*

The phenol and flavonoid contents of all three lichens were in the range of 43.12 – 101.62 mg of GAE/g extract and 24.92 – 165.03 mg of QE/g extract respectively. The DPPH assay showed scavenging activity lower than 50% of for all the studied lichens at 500 µg/mL. Results are summarized in (Table 9).

Table 9. Total phenolic content (TPC), Total flavonoid content (TPC) and DPPH radical scavenging activity of the lichen extracts

	Sample	**TPC (mg) of (GAE)/g dry weight of extract**	**TFC mg of (QE)/g dry weight of extract**	**% Scavenging** of **DPPH at 500µg/mL**
Acetone	RD	101.62 ± 3.51	24.92 ±1.06	27.21 ± 1.61
	U.R	63.05 ± 3.27	165.03 ±0.62	19.31 ± 0.25
	C.V	101.37 ± 3.31	108.09 ±3.95	33.09 ± 0.84
Methanol	R.D	48.74 ± 0.84	42.77 ± 1.13	16.4 ± 2.99
	U.R	43.12 ± 1.14	98.48 ± 2.13	11.42 ± 1.96
	C.V	48.61 ± 0.87	79.20 ± 1.65	17.25 ± 2.98
Trolox				98.19 ± 0.66

Another study [19] recorded (TPC: 115mg of (GAE)/g dry weight of extract) and (TFC: 1.625mg of rutin equivalent/g dry weight of extract) values of a different species of *Usnea* lichen which is *Usnea longissima.* The same study also reported high antioxidant activity (IC50 = 0.10 mg dry material). Phenolic compounds are a type of antioxidant agents which can adsorb and neutralize the free radicals [20], in which the phenol content in present study is lower than reported study [19]. This explains the low antioxidant activity of *U. rubrotincta* compared to *U. longissima. Cladonia foliacea* was investigated for its TPC and DPPH scavenging activity [21], which also reported low phenolic content (TPC: 78.12mg of (GAE)/g dry weight of extract) and weak scavenging activity at (IC50: 1000 µg/mL) which is in accordance with the present study. Lichen from the genus *Ramalina, Ramalina peruviana* was investigated for its phenolic content, as well as its free radical scavenging activity [9]. They also reported lowest total phenolic content in *R. peruviana* (27.1 mg GAE/g extract) compared to a few other lichen species studied, however the free radical scavenging activity was found to be relatively strong at (IC50 = 60.66 mg dry material). *R. dumeticola* was found to contain higher phenolic content but the free radical scavenging activity was only 27.21%. This can be due to different types and concentrations of phenolic compounds present in *R. peruviana* and *R. dumeticola*.

Since the antioxidant activity of the extracts was moderate compared to the antibacterial activity, the extracts selected for subsequent purification and isolation was based on the antibacterial assay results. A total of six secondary metabolites were isolated from acetone and methanol extract of *R. dumeticola* and *U. rubrotincta.* Compound (1) and (4) were found in both the lichen acetone extracts which were identified as usnic acid and atranorin respectively. Compounds (5) and (6) were isolated from acetone extract of *R. dumeticola* which was determined to be hyperhomosekikaic acid and sekikaic acid. With regards to the methanol extract of *U. rubrotincta,* two more compounds were isolated which were (3), 8-hydroxybarbatic acid and (2), barbatic acid.

Among all isolated chemical constituents, (1) exhibited highest inhibitory activity against both gram positive bacteria at (MIC: 7.81 µg/mL) which is comparable to standard vancomycin. Atranorin and (2) also showed active inhibitory potential at (MIC: 31.25 µg/mL) and (MIC: 15.63 µg/mL) against *B. subtilis.* The high antimicrobial activity of (1) has been reported previously by Tay et al. [17] in which the lowest inhibitory concentration against *S. aureus* was at (MIC: 3.1 µg/62.5 µl) and *B. subtilis* at (MIC: 0.78 µg/62.5 µl). Compound (1) has been observed to be present in high levels in both the active lichens which could partly explain the potency of the extracts comparable to the standard.

Lauterwein et al. [22] reported a MIC value range from 2 to 16 µg/mL for (1) against gram positive bacteria *S. aureus.* In this study, compound (4) has exhibited stronger activity than the report by Yilmaz et al. [23], where the inhibition potential was only at (MIC: 500 µg) against *S. aureus* and (MIC: 15.63 µg) against *B. subtilis*. Thadani et al. [24] reported similar activity of (4) and (6) against *B. subtilis* with inhibition at 100 µg/mL in a disk diffusion assay.

However, they also reported inhibition activity of (4) and (6) against gram negative bacteria *E. coli* and no inhibition of (4) and (6) against *S. aureus*. Both reports by Yilmaz et al. [23] and Thadhani et al. [24] have significant difference with this study due to method difference where the reported studies used disk diffusion assay compared to this study which uses the MIC method. Besides that, the bacteria strains are also different between this investigation and Yilmaz et al. [23]. Martins et al. [25] reported MIC values of 50-100 µg/mL for (2) against various strains of *S. aureus* which is similar to this study where we obtained MIC value of 62.50 µg/mL concentration. Disk diffusion method has its own disadvantages where zone sizes are affected by the media used and by the different growth rates of organisms being tested therefore MIC tests are more accurate with anaerobic bacteria [26].

All compounds exhibited below 50% scavenging activity against DPPH free radicals except compound (6). Sisodia et al. [27] reported close activity between the standard and compound (6) against DPPH free radical but in this study only 69.57% scavenging activity was recorded compared to standard Trolox. They also reported minimum scavenging activity of (4) in which is in agreement with this study. Compound (1) which is a phenolic compound, poorly scavenged the DPPH free radical which is in accordance with the findings of Devehat et al. [28] and Thadhani et al. [7]. The radical-scavenging effect of antioxidants on DPPH is a method to quantify the hydrogen donating potency of chemicals and compound (1) does not seem to have the labile hydrogen atoms to bind with the DPPH ions. Devehat et al. [28] studied the antioxidant capacity of compound (2) alongside other lichen compounds but did not report any scavenging activity which is in agreement with our findings where the activity was also very low in contrast to standard. Results are summarized in Table 10.

Table 10. Antibacterial and radical scavenging activity of the isolated compounds

Test Compounds	**MIC (µg/mL)**		**% DPPH radical scavenging at 100µg/ml**
	S. aureus	***B. subtilis***

Notes: - mean no activity detected against tested bacteria

Conclusion

This is the first report on biological study in of lichens *Usnea rubrotincta*, *Ramalina dumeticola*, and *Cladonia verticillata* from Malaysia. Among the chemical constituents isolated in this study, 8-hydroxybarbatic acid from *U. rubrotincta* and hyperhomosekikaic acid from *R. dumeticola* has been investigated for its antibacterial and antioxidant capacity for the first time and were found to be considerably active against tested bacteria. Usnic acid and atranorin have been identified as active antibacterial agents while sekikaic acid as a considerable antioxidant agent. Further work should be done to enhance the knowledge on these chemical constituents.

Abstract

According to International Agency for Research on Cancer (IARC), most of Polycyclic Aromatic Hydrocarbons (PAHs) known as genotoxic human carcinogen and mutagenic. PAHs represent as poorly degradable pollutants that exist in soils, sediments, surface water and atmosphere. A simple, rapid and sensitive extraction method termed modified Dispersive Liquid-Liquid Microextraction (DLLME) using green solvent was developed to determine PAHs in vegetable samples namely radish, cabbage and cucumber prior to Gas Chromatography Flame Ionization Detection (GC–FID). The extraction method is based on replacing chlorinated organic extraction solvent in the conventional DLLME with low toxic solvent, 1-bromo-3-methylbutane without using dispersive solvent. Several experimental factors such as type and volume of extraction solvents, extraction time, confirmation of 12 PAHs by GC-MS, recovery percentages on vegetable samples and the comparative analysis with conventional DLLME were carried out. Both DLLME were successfully extracted 12 types of PAHs. In modified DLLME, the recoveries of the analytes obtained were in a range of 72.72 – 88.07 % with RSD value below 7.5 % which is comparable to the conventional DLLME. The use of microliter of low toxic extraction solvent without addition of dispersive solvent caused the method is economic and environmental friendly which is fulfill the current requirement, green chemistry based analytical method.

Keywords: polycyclic aromatic hydrocarbons, modified dispersive liquid-liquid microextraction, gas chromatography flame ionization detection

Abstrak

Menurut agensi antarabangsa bagi penyelidikan kanser (IARC), kebanyakan Polisiklik Aromatik Hidrokarbon (PAHs) dikenali sebagai karsinogen genotoksik terhadap manusia dan mutagen. PAHs mewakili sebagai pencemar degradasi rendah yang wujud dalam tanah, enapan, air permukaan dan atmosfera. Satu kaedah pengekstrakan yang mudah, pantas dan sensitif yang digelar sebagai pengekstrakan mikro cecair – cecair serakan (DLLME) yang terubahsuai dengan pelarut hijau telah dibangunkan bagi penentuan PAHs dalam sampel sayur – sayuran iaitu lobak, kubis dan timun sebelum diukur menggunakan gas kromatografi – pengesan nyala pengionan (GC–FID). Kaedah pengekstrakan ini adalah berdasarkan penggantian pelarut pengekstrakan organik berklorin di dalam DLLME konvensional dengan pelarut rendah toksik, 1-bromo-3-metilbutana tanpa menggunakan pelarut penyebar. Beberapa factor eksperimen seperti jenis dan isipadu pelarut pengekstrakan, masa pengekstrakan, pengesahan 12

PAHs dengan GC-MS, peratusan perolehan semula sampel sayur – sayuran dan perbandingan analisis dengan DLLME konvensional telah dijalankan. Kedua – dua teknik DLLME telah berjaya mengekstrak 12 jenis PAHs. Bagi DLLME terubahsuai, perolehan semula analit berada dalam julat 72.72 – 88.07 % dengan nilai RSD adalah kurang daripada 7.5 % iaitu setanding dengan teknik DLLME konvensional. Penggunaan mikroliter pelarut pengekstrakan yang rendah toksik tanpa penambahan pelarut penyebar menyebabkan kaedah ini ekonomik dan mesra alam yang memenuhi keperluan semasa iaitu kaedah analisis berasaskan kimia hijau.

Kata kunci: polisiklik aromatik hidrokarbon, pengekstrakan mikro cecair-cecair serakan yang terubahsuai, gas kromatografi-pengesan nyala pengionan

Introduction

Polycyclic aromatic hydrocarbon (PAH) is a complex mixture of an end product, resulted from incomplete combustion of organic materials. It represents as poorly degradable pollutants that exist in soil, sediments, surface water and atmosphere [1]. Sixteen PAHs have been classified as genotoxic human carcinogen and mutagenic by the International Agency for Research on Cancer (IARC) and selected by US Environmental Protection Agency (EPA) as Constant Degree priority pollutants for regulatory process [2]. They are anthracene, fluoranthene, pyrene, benzo(b)fluoranthene, benzo(k)fluoranthene, acenaphthylene, acenaphthene, benzo(a)anthracene, benzo(a)pyrene, benzo(g,h,i)perylene, chrysene, cyclopenta(c,d)pyrene, dibenz(a,h)anthracene, dibenzo(a,l)pyrene, indeno(1,2,3-c,d)pyrene and 5-methylchrysene.

To assess the penetration of PAHs or their metabolites in the plant, it is important to develop a sensitive, rapid, simple, economic and environmental friendly extraction method. Various conventional extraction methods such as Liquid-liquid extraction (LLE) and Solid-phase extraction (SPE) have been implemented [3]. However, the presences of various plant pigments and the limitations of conventional extraction method lead to the failure of developing a compatible, efficient, economical and miniaturize extraction method. The discovery of Dispersive Liquid-Liquid Microextraction (DLLME) method by Assadi and teammates solved the drawbacks of conventional method and it is known to be rapid and low cost method [4]. In this procedure, the mixture of extraction solvent and dispersive solvent is rapidly injected into aqueous sample results the formation of fine droplets. These droplets increase the surface area between extraction solvent and sample solution and speed up the extraction [2, 4]. However, there are few drawbacks on this method as it acquired toxic halogenated solvents used as extraction solvent and dispersive solvent. DLLME also restricts implication on vegetable matrices due to interferences [5].

In this study, modified DLLME was developed to determine the PAHs from the vegetable samples followed by gas chromatography-flame ionization detector (GC–FID). In this procedure, only minimal amount (100µl) of low toxic extraction solvent is added into the vegetable sample compared to that two types of solvent (e.g. water immisicble and water miscible solvent) are needed in original DLLME to form the emulsion consist of fine droplets.

Materials and Methods

Reagents and Materials

Twelve types of PAHs (acenaphthylene, acenaphthene, fluorene, anthracene, phenanthrene, fluoranthene, pyrene, benzo(a)anthracene, chrysene, benzo(b)fluoranthene, benzo(k)fluoranthene and benzo(a)pyrene) were purchased from Supelco. 1-bromo-3-methylbutane, hexanol, heptanol, octanol, nonanol were purchased from Sigma-Aldrich. Acetone and Acetonitrile (HPLC Grade) were obtained from Merck. Deionised water (D.I.) was purified on a Milli-Q water system. Stock solution of PAH standards were prepared by dissolving PAHs standard at 10 ppm in acetonitrile. Working standard solutions of 12 types of PAHs were prepared in acetonitrile at concentration of 5 ppm to 0.1 ppm. The solutions were stored at 4 °C in a refrigerator. Vegetables namely radish (*Raphanus sativus),* cucumber *(Cucumis sativus) a*nd cabbage (*Brassica oleracea*) were purchased from the local organic market. The vortex agitator model no. VELP Scientifica ZX^3 (Usmate, Italy) and the centrifuger with a model no. Hettich ROTOFIX 32 Benchtop centrifuge (Tuttlingen, Germany) were used in this experiment.

Instrumentation

The chromatographic analysis was performed by using Gas Chromatography model Agilent 7890A equipped with a split/splitless injection inlet, flame ionization detector (FID) and a 7683 automatic liquid sampler. The optimization

of gas chromatography (GC-FID) condition was carried out and set up in which runtime of a sample requires 25 minutes. The 12 PAH compounds were separated by using HP-5 (5% phenyl-methylpolysiloxane) capillary column (30m x 320µm x 0.25µm). The optimum condition of the GC-FID for separation of 12 PAHs was oven temperature commenced at 100°C for 1 min and was raised by 15 ^{o}C min^{-1} to 280 ^{o}C for 10 mins. Helium as carrier gas in a constant flow of 1 mL min^{-1}, injector temperature of 290 ^{o}C and in splitless mode.

Gas Chromatography–Mass spectrometry (GC-MS Shidmazu QP2010) was used to perform the confirmation of 12 types of PAH. The applied column comprises of 30m x 0.25mm i.d. x 0.25µm firm thickness known as DB-5MS. The injection for analyte separation was made in splitless mode, injector temperature was maintained at 290°C and the injection volume was 1µL. Ultra-pure helium gas (99.9995%) was used as carrier gas with flow rate of 1.2 mL min^{-1}. The oven temperature programmed, where the initial temperature was 100°C and held for 1 min and ramp to 290 °C at 15°C min^{-1} and held for 20 minutes. Total run time was 33.67 min.

Sample Preparation

The vegetable sample was weighed, homogenized, centrifuged, filtered and spiked at 50 µL of 10 ppm of mixture of individual standard. The homogenized sample (5 ml) was transferred into conical centrifuge tube.

An appropriate amount of extraction solvent (e.g. 100 µL) was added into the sample and gently shaken. A cloudy solution formed due to tiny droplets of extraction solvent dispersing in the sample solution. After homogenization (vortex) and centrifugation process at rate of 3000 rpm for 10 minutes, the sedimented layer formed at bottom of the conical tube. The sediment layer further transferred into the glass insert in a 2 ml of vial using of microsyringe. 1 µL of the sediment solution was injected into GC–FID using autosampler for the analysis at optimized GC-FID condition. Three replicates were done for each trial.

The Selection of Extraction Solvent

The selection of an extraction solvent is crucial for the determination of extraction efficiency of the modified method. Five types of low toxic solvents namely hexanol, heptanol, octanol, nonanol and 1-bromo-3-methylbutane have been tested to obtain an optimal extraction solvent. The selection of low toxic extraction solvent was made based on few criteria's. The extraction solvent must be (a) high density than water, (b) low solubility in water, (c) achieves high percentage recovery of target analyte and (d) achieve good chromatographic behaviour. Besides, the toxicity level of the selected extraction solvent must be less hazardous compared with conventional DLLME extraction solvent (e.g. tetrachloroethylene, chloroform, chlorobenzene) and also an environmental friendly solvent in order to achieve the aim of green chemistry. The behaviour of toxicity and solubility in water of two conventional DLLME extraction solvents (tetrachloroethylene and chlorobenzene) and five selected extraction solvents (hexanol, heptanol, octanol, nonanol and 1-bromo-3-methylbutane) are tabulated in Table 1. Among all the tested solvents, 1-bromo-3-methylbutane has lowest toxicity and lowest solubility in water.

Table 1. Lethal Dose (LD_{50}) Toxicity of 7 types of Extraction Solvents

No	Extraction Solvent	$LD_{50\ (mg/kg,oral)}$ on rat	Solubility in water	Ref.
1	Tetrachloroethylene	2600/2629	206 mg/L at 25°C	[6]
2	Chlorobenzene	1437-3400	400 mg/L at 20 °C	
3	Hexanol	720	5000 mg/L at 20°C	
4	Heptanol	500	2850 mg/L at 100°C	
5	Octanol	5000	1000 mg/L at 20°C	
6	Nonanol	3.56	1000 mg/L at 20°C	
7	1-Bromo-3-methylbutane	6150	196 mg/L at 16.5°C	

The percentage of recovery (%) calculated based on the ratio of the concentration of peak area after extraction to the initial spiked concentrations of analyte in the sample solution.

Results and Discussion

Experimental parameters for the modified DLLME, including the types of low toxic solvent and its volume as well as the extraction time were optimized. From the Figure 1, 1-bromo-3-methylbutane yield the highest average recovery percentage (75.53 %) compare to other extraction solvents. Meanwhile, other extraction solvents failed to obtain the acceptable recovery range (70 – 120 %) set up by the International Conference on Harmonisation (ICH) on the validation of analytical procedures [7]. 1-bromo-3-methylbutane solvent was able to extract all the desired analytes well in the acceptable recovery range from the liquid matrices. Therefore it was ideal to select 1-bromo-3-methylbutane solvents as an extraction solvent in modified DLLME on the extraction of 12 PAHs in vegetable samples. Other four extraction solvents (hexanol, heptanol, octanol and nonanol) have the low recovery percentages. This may due to they are high solubility in water which exposed to the interferences that presence in water and caused the solvents loss interaction with analytes as 12 PAHs are immisible in water. Besides, these four extraction solvents are less dense (0.8 g/mL) than water leaded the failure of the formation of sedimented extraction phase. The droplets formation of extraction solvent floats on the surface of the sample solution causes the difficulties to extract the analytes from the sample solution. These are prove that the density of the solvent and its solubility in water are the important criteria's when selecting the extraction solvent as mentioned above.

Results showed that the sedimented extraction phase obtained is depending on the amount of extraction solvent used. The higher volume of extraction solvent used the larger amount of sedimented phase was obtained. However, the aim of the study is to find out the minimal usage of extraction solvent to extract all 12 PAHs. In fact, 50 µL of the extraction solvent produced minimal amount of sediment layer and caused the difficulties to transfer the sediment layer into the vial as the sediment layer was mixed up with the sample precipitate even though after long period of centrifugation process. In order to reduce the solid matrix interference problem, 100 µL was selected as an ideal volume as the study focuses on the minimal usage of solvent upon extracting 12 PAHs from solid matrices.

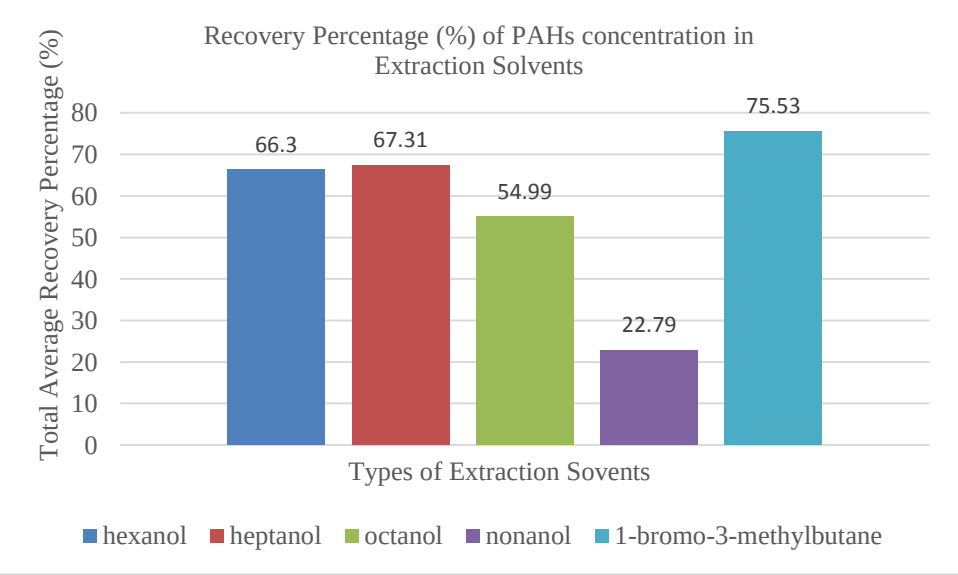

Figure 1. Recovery Percentage (%) of PAHs concentration in extraction solvents

Extraction time

In conventional DLLME, fine droplets of organic solvent are formed in the sample solution with the mixture of extraction solvent and dispersive solvent [8]. This may due to the quick mass transfer of analytes from the aqueous phase to the extraction solvent. Meanwhile in modified DLLME, homogenous fine droplets were formed reproducibly with aid of gentle shaken without addition of dispersive solvent. The extraction time is defined as shaking time. The results showed that there was no significant difference in the extraction recoveries for all the PAHs during the shaking time range (1, 2, 4, 6, 8 and 10 minutes). Since the extraction recovery with extraction time of 2 min lies within the acceptable range (70 to 120 %) with the low relative standard deviation (< 5%), 2 min shaking time was considered as optimal time for modified DLLME. Short extraction time required in modified DLLME is one of the most remarkable advantages of modified DLLME.

Confirmation of 12 PAHs by GC-MS

The mass spectrometry detector can be used for detection and identification purpose as well as for quantitation of analytes. In this study, gas chromatography couple with mass spectrometry detector was implemented only for analyte identification and confirmation. The sediment extraction phase was withdrawn and injected into GC-MS for full scan analysis. The total ion chromatogram of the target analytes under optimized GC-MS conditions was obtained and shown in Figure 2.

In MS full scan mode, all ions produced from each analyte peak in the MS was employed in confirmation of the targeted analytes. High reliability of identification was achieved by making comparison of the MS of the targeted analyte at the top of its chromatographic peak with the best matching compound in the standard mass-spectral libraries. From the results, it was known that all the 12 types of PAHs were successfully extracted using modified DLLME. The 12 types of PAHs were successfully identified and confirmed to be present in the sedimented extraction phase. The initial ion fragments for the first peak were formed at 7.27 minutes and ends at 18.604 minutes. The range of the ion fragments forms between 152.10 m/z to 276.15 m/z. The existing of molecular ions with highest m/z ratio similar to their respective molecular weight was shown to present in individual PAHs mass spectrum.

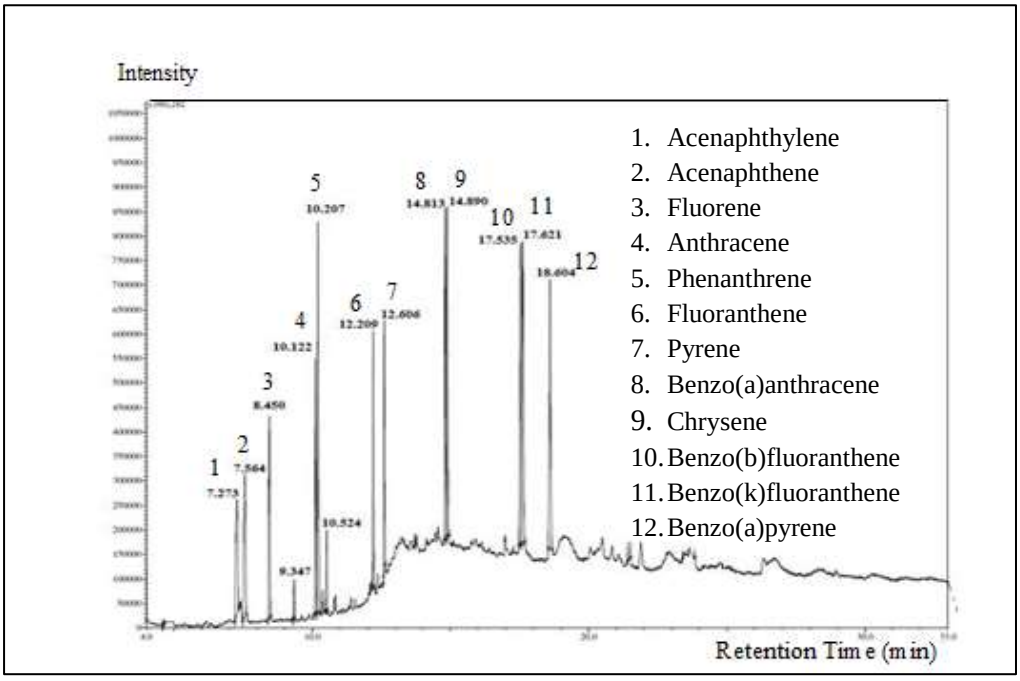

Figure 2. Chromatogram of 12PAHs obtained from modified DLLME in GC-MS Full Scan Mode

Comparison between Modified DLLME and Conventional DLLME

The modified DLLME was compared with conventional DLLME using the same three types of vegetable (e.g. radish, cabbage and cucumber). The purpose of this comparison is to determine the efficiency of the modified DLLME towards the vegetable matrix compared to the conventional DLLME. In conventional DLLME, the common implemented extraction solvent was tetrachloroethylene at 50 µL and the dispersive solvent was acetone at 100 µL. In modified DLLME, 1-bromo-3-methylbutane was used as extraction solvent at 100 µL and there is no addition of dispersive solvent. Each sample was injected three times and the recovery percentage and RSD value of both methods on three vegetable samples were calculated and tabulated in Table 2.

Table 2. Comparison of Recovery Percentage (%) of Modified DLLME with Conventional DLLME in the vegetable samples

PAH	Radish		Cucumber		Cabbage	
	Modified DLLME (%) (RSD%)	**Conven. DLLME (%) (RSD%)**	**Modified DLLME (%) (RSD%)**	**Conven. DLLME (%) (RSD%)**	**Modified DLLME (%) (RSD%)**	**Conven. DLLME (%) (RSD%)**
Acenaphthylene	83.05 (0.1)	76.83 (0.3)	85.29 (1.1)	82.35 (3.2)	80.47 (3.5)	75.64 (4.5)
Acenaphthene	87.88 (0.2)	86.48 (0.2)	81.94 (4.0)	78.32 (6.7)	78.18 (2.7)	76.26 (3.1)
Fluorene	88.07 (0.5)	80.39 (1.8)	80.26 (3.0)	79.92 (4.2)	76.67 (3.5)	74.35 (3.9)
Anthracene	82.14 (0.6)	77.27 (1.7)	76.40 (3.7)	73.43 (3.8)	77.96 (2.7)	72.50 (2.8)
Phenanthrene	81.81 (0.4)	76.36 (1.8)	75.64 (3.4)	71.89 (5.0)	76.29 (3.2)	71.64 (3.8)
Fluoranthene	78.02 (0.3)	74.24 (2.3)	78.53 (2.1)	74.35 (4.1)	77.86 (1.9)	74.11 (2.7)
Pyrene	78.68 (3.3)	72.65 (2.5)	77.29 (7.5)	75.90 (7.7)	75.08 (0.6)	72.60 (0.7)
Benzo(a)anthracene	77.18 (0.5)	75.41 (4.0)	74.37 (7.1)	71.13 (7.4)	74.23 (4.4)	73.08 (4.6)
Chrysene	75.79 (0.2)	73.85 (3.9)	78.52 (5.1)	75.76 (6.0)	74.61 (1.5)	70.44 (1.8)
Benzo(b)fluoranthene	80.94 (1.9)	75.64 (4.7)	74.68 (3.3)	72.50 (3.4)	75.56 (3.6)	73.81 (4.6)
Benzo(k)fluoranthene	75.38 (3.1)	71.34 (4.7)	73.05 (3.0)	71.28 (5.3)	74.25 (2.6)	70.36 (3.9)
Benzo(a)pyrene	72.72 (0.9)	71.93 (5.0)	72.45 (6.2)	70.59 (6.5)	75.62 (2.8)	71.08 (3.4)

From the results obtained, both methods successfully extracted all the 12 PAHs from the respective vegetables. However, modified DLLME yielded higher recovery percentages ranged from 72.72 % to 88.07 % in radish, 72.45 % to 85.29 % in cabbage and 74.23 % to 80.47 % in cucumber with minimal of RSD values from 0.1 % to 7.5 % compared to the conventional DLLME that yielded the recovery percentages ranged from 71.34% to 86.48% in radish, 70.59% to 82.35% in cabbage and 70.36% to 76.26% in cucumber with RSD values (%) from 0.2 % to 7.7 %.

1-bromo-3-methylbutane has higher density than water and low solubility in water leads to high extraction efficiency compared to tetrachloroethylene which used as extraction solvent in conventional DLLME. Without the addition of dispersive solvent, 1-bromo-3-methylbutane capable of forming the fine droplets and enhances the contact surface area between analyte and extraction solvent whereas chlorosolvents acquired dispersive solvent to extract the analyte (12 PAHs) from the vegetable sample. Low recovery of tetrachloroethylene in conventional DLLME may due to the low solubility of tetrachloroethylene towards the analyte [9].

Conclusion

A novel sample preparation method designated as Modified DLLME has been developed for the determination of PAHs in vegetable samples with only using minimal amount of low toxic solvent as extraction solvent without addition of dispersive solvent. Compared to conventional DLLME, modified DLLME yields higher efficiency recovery range from 72.72 – 88.07 % at minimal RSD value range from 0.1 – 7.5 %. Thus modified DLLME is a reliable alternative technique for sample pre-concentration in terms of performance and speed. Major advantages of this modified method are present at low cost and only usage of minimal amount of low toxic extraction solvent to form fine droplets. This method was applied on solid matrices as conventional DLLME majorly focused on the liquid matrices due to the inteference problems.

Abstract

This paper reported the optimization of glucose production from ammonia pre-treated oil palm trunk biomass via enzymatic saccharification process using response surface methodology (RSM). A set of experiment was computed by face centered central composite design (FCCCD) using Design Expert software to statistically evaluate the findings. Three independent variables namely: temperature (35 – 55 °C), pH (4.5 – 6.5) and enzyme ratio (cellullase: *β*-glucosidase; 3:1 – 7:1) were investigated under the given conditions designed by RSM. The experimental result (4.964 ± 0.006 $g.L^{-1}$) was in good agreement with RSM model prediction (4.958 $g.L^{-1}$) with an error less than 0.2 %. The RSM design has been proven to successfully predict the glucose response in this study.

Keywords: oil palm trunk biomass, enzymatic saccharification, lignocellulosic substrate, ammonia pre-treament, response surface methodology

Abstrak

Kertas kerja ini melaporkan pengoptimuman hasilan glukosa daripada prarawatan ammonia biomas batang kelapa sawit melalui proses sakarifikasi enzim dengan menggunakan kaedah gerak balas permukaan (RSM). Satu set eksperimen telah dibentuk iaitu kaedah muka berpusat reka bentuk komposit dengan menggunakan perisian Design Expert bagi menilai penemuan kajian secara statistik. Tiga pembolehubah bebas iaitu: suhu (35 – 55 ° C), pH (4.5 – 6.5) dan nisbah enzim (selulase: β-glukosidase; 3:1 – 7:1) telah disiasat di bawah situasi yang direka oleh RSM. Hasil eksperimen (4.964 ± 0.006 $g.L^{-1}$) yang diperoleh berada dalam persetujuan yang baik dengan ramalan model RSM (4.958 $g.L^{-1}$) iaitu pada ralat kurang daripada 0.2 %. Reka bentuk RSM telah terbukti berjaya meramalkan respon glukosa dalam kajian ini.

Kata kunci: biomas batang kelapa sawit, sakarifikasi enzim, substrat lignoselulosa, pra-rawatan ammonia, kaedah gerak balas permukaan

Introduction

Oil palm (*Elaeis guineensis*) is broadly established in tropical countries such as Malaysia, Indonesia, and Thailand for its comestible oil [1]. In general, the oil palm starts bearing its oil in 2.5 years after being planted, and become

lower in productivity after 20-25 years [2, 3]. Therefore, it is necessary to cut the old oil palm tree and to replant new seedlings for sustainable palm oil.

This practise would generate abundance of felled oil palm trunk (OPT). As reported in 2013, Malaysia possesses an oil palm plantation area up to 5.038 million hectares and the oil palm industries have generated 59 million ton of solid biomass annually [4]. These oil palm residues (dry weight, %) include oil palm empty fruit bunch (30 %); oil palm frond (44 %) and oil palm trunk (26 %) respectively. The oil palm trunk like others part oil palm, consists of lignocellulosic biomass which rich in cellulose, hemicellulose and lignin. Consequently, the felled oil palm trunks can be used as one of vital biomass resource to generate beneficial products such as animal feed, biofertilizer, biodiesel, bioplastic and etc. [5].

Generally, the conversion of lignocellulosic biomass into fermentable monosaccharide (sugars) is inevitably through two major steps i.e. pre-treatment of raw materials and enzymatic hydrolysis of pre-treated material [4]. The pre-treatment step is aimed to breaking up the complex structure of lignocellulosic matrix so as to disrupt the crystalline structure of cellulose and thus enhance the enzyme digestibility during the hydrolysis reaction [6]. Up to date, pre-treatment processes such as chemical, physiochemical and biological have been employed to pre-treat the raw lignocellulosic biomass. However, none of the pre-treatment protocol is universal and economically viable to pre-treat different cellulosic biomass. Hence, the proper pre-treatment is essential for the efficiency of biomass conversion [7]. The pre-treatment objective is to eliminate lignin, detached cellulose and hemicellulose, increase the surface area accessibility and subsequently improving the accessibility of hydrolytic enzymes for the maximum emanation of fermentable monosaccharide.

To take full advantage of plentiful OPT residues, the present study has used OPT as a substrate candidate for glucose emanation. This study has utilized the hot dilute aqueous ammonia (7 %) to pre-treat the OPT biomass. The ammonia treated OPT was then subjected to enzymatic hydrolysis for glucose production. The main objective of this investigation is to determine the best hydrolysis conditions for the maximum glucose production. Hence, the RSM based on face centered central composite design (FCCCD) was employed as to identify the optimal enzymatic saccharification conditions in present study.

The response surface methodology (RSM) was used in the present study to analyse the effects of different independent variables (temperature, pH and enzyme ratio) and to optimise the response (glucose production). Generally, the RSM could be used to simplify the optimization by study the multi-parameters simultaneously [8]. By setting up the three dimensional plots, the overall behaviour reaction of experimental data could be easily understood as well as the interaction effects. The software also provides the statistical ANOVA analysis to identify the significant or insignificant factor in the experiment.

Materials and Methods

Raw material

The oil palm trunk (OPT) biomass was used as a substrate in present study. It was collected from Concept Renewable Energy Sdn. Bhd., Macap, Johor. The fresh pulverized OPT was dried at 45 ºC for 3 consecutive days and then it was sieved to get the particle size with less than 1.0 mm [4].

Ammonia pre-treatment method

The 5.0 g of sieved OPT biomass was soaked in 7 % ammonia solution at 80 °C for 8 hours [7]. Once completed, the slurry was recovered by passed thru the filter cloth and then followed by washing with plenty of distilled water until the pH of wash liquid has reached at neutral value. The treated OPT was dried at 45 ºC to constant weight. The chemical compositions of treated OPT contained 38.7 %, 14.7 %, 9.1 % 6.4 %, 2.3 % 19.4 % and 5.4 % (w/w) of glucan, xylan, arabinan, mannan, galactan, acid-insoluble lignin and ash, respectively on a dry weight basis [7].

Enzymes

Two commercial enzymes were used in this study namely: cellulase (Celluclast 1.5) from *Trichoderma reesei* ATCC 26921 and *β*-glucosidase (Novozym 188) from *Aspergillus niger*. The activity of both enzymes was

measured at 80.41 FPU.mL^{-1} and 134.68 CBU.mL^{-1}, respectively [9, 10]. The 40 FPU.g^{-1} and 100 CBU.g^{-1} of substrate were used throughout the study.

Buffer preparation

The sodium citrate buffer was made by mixing of citric acid monohydrate and trisodium citrate dihydrate. The 0.1 M concentrations for both solutions were prepared by dissolving 21.01 g.L^{-1} of citric acid and 29.41 g.L^{-1} of trisodium citrate dehydrate, respectively. The desired pH value could be attained by mixing both solutions to a total of 100 ml [11]. The 0.1 M sodium citrate buffer was then further diluted to desire 50 mM concentration for the whole investigation.

Experimental design

The response surface methodology (RSM) was employed to design the experiment. Three independent variables, namely: temperature, pH and enzyme ratio (cellulase: β-glucosidase) were examined to determine the effect of each factor on glucose production response. The total of 20-run was computed using face centered central composite design (FCCCD) with six center points of replicates and the alpha value of 1.0. The ranges and the designed levels of process variables are given in Table 1.

Table 1. Actual values of independent variables

Factors	Low level, (–1)	Center level, (0)	High level, (+1)
A: Temperature, °C	35	45	55
B: pH	4.5	5.5	6.5
C: Enzyme ratio (cellulase: β-glucosidase)	3:1	5:1	7:1

The quadratic model equation for predicting the optimal point is expressed by Eq. (1) as followed:

$$Y = \beta_0 + \Sigma \beta_i X_i + \Sigma \beta_{ii} X_i^2 + \Sigma \beta_{ii} X_i X_j + \mathcal{E} \quad (1)$$

where Y is the predicted response (glucose amount, g.L^{-1}), β_0 is constant coefficient, β_i, β_{ii} and β_{ij} are coefficient for the linear, quadratic and interaction effects, X_i and X_j are factors (independent variables) while $\mathcal{E}$ is the error.

The Design Expert 6.0.4 software was used for regression and graphical analyses of the attained data. Generally, a full second-order model with linear, quadratic and interaction term was fitted in order to conclude the optimum combinations of factors level [2]. Meanwhile, the main and interaction effects of model term were also statistically analysed using analysis of variance (ANOVA).

Enzymatic hydrolysis of treated OPT

The treated OPT substrate, 1 % (w/v) was added into a glass jar which contained 100 ml of 0.05 M buffer solution (pH 4.5 – 6.5) and 100 µl 0.2 % (w/v) of sodium azide. The glass jar was then transferred into water bath and heat-up to 35 - 55 °C for 15 min according to RSM design. Lastly, both enzymes with certain ratio (3:1 to 7:1) were discharged into glass jar to initiate the enzymatic hydrolysis reaction. All enzymatic hydrolysis reaction was performed in triplicate and the errors were within ± 5 %.

Glucose analysis

The withdrawal hydrolysate was mixed with 3, 5-dinitrosalicylic (DNS) reagent in ratio of 1:1 and brought to heating at 100 °C for 15 min to cease the enzyme activity. The mixture was cool-down to room temperature prior to read spectrophotometrically at wavelength of 540 nm [12]. The reducing sugars formed during the enzymatic hydrolysis were represented with glucose equivalent [10]. All hydrolysis experiment was conducted in triplicate and the obtained glucose data was presented in an average value.

Validation of RSM prediction points

The optimization predicted points, i.e. temperature, 44.23 ^{o}C; pH, 5.22 and cellulase: β-glucosidase 3:1 were recommended by the RSM software. These suggested parameters were tested in subsequent confirmation run in order to validate the RSM prediction points.

Results and Discussion

Optimization of glucose production

A total of 20-set run which divided into 3 blocks was computed based on face centered central composite design (FCCCD) protocol as shown in Table 2. The enzymatic hydrolysis reaction on ammonia pre-treated OPT biomass was conducted as per each set point as described. Table 2 also tabulates the glucose response for both experimental and predicted values.

The run-11 shows the highest glucose concentration up to 5.73 g.L^{-1} when the experimental conditions were set to temperature, 45 °C; pH, 5.5 and enzyme ratio 5:1, respectively. It was noticed that when the experiment was conducted in conditions at temperature, 55 °C; pH, 6.5, and enzyme ratio 3:1, the lowest glucose concentration was attained i.e. 0.20 g.L^{-1}.

Table 2. RSM design of experiment: experimental and predicted value

Run	Block	Factor A: Temperature	Factor B: pH	Factor C: Enzyme ratio	Response, Glucose (g.L^{-1})	
					Experimental	Predicted
1	Block 1	45.00	5.50	5:1	4.28	4.65

A full quadratic regression model based on actual values was as shown in Eq. (2). The Eq. (2) has a high coefficient of determination, R^2 and adjusted coefficient of determination, R^2_{Adj} at 0.9057 and 0.7997, respectively. This

indicates the quadratic model could be well explained. There is merely 9.43 – 20.03 % of the variation occur might due to noise that cannot be explained by the model it self [14].

$$\text{Glucose} = -82.94287 + 2.31023*\text{Temp} + 14.78740*\text{pH} - 0.87010*\text{Enzyme} - 0.027414*\text{Temp}^2 - 1.49843*\text{pH}^{2+} 0.086392*\text{Enzyme}^2 + 0.020438*\text{Temp}*\text{pH} + 2.93125\text{x}10^{-3}*\text{Temp}*\text{Enzyme} - 0.018187*\text{pH}*\text{Enzyme} \quad (2)$$

The analysis of variance (ANOVA) for glucose content after enzyme hydrolysis was used to estimate the glucose response as a function of temperature, pH and enzyme ratio is shown in Table 3. Mathematically, when the Prob > F values greater than 0.05, those factors are considered statistically insignificant. Meanwhile when Prob > F values less than 0.05, it could be defined as a significant factor [14]. In present study, the quadratic model with 0.003 was significant. The "lack-of-fit" F-value of 4.52 implies that the "lack-of-fit" was insignificant relative to the pure error. There is a 12.2 % chance for the model that a "lack-of-fit" F-value of this large could occur due to noise. In general, the non-significant lack-of fit was good and implied that all data in this experiment were adequated as well as good predicatibility of the model [2].

Note: A: Temperature; B: pH; and C: Enzyme ratio; $R^2 = 0.9057$, $R_{Ajd}^2 = 0.7977$

In present study, only the main effect, pH was significant where the value of Prob>F equal to 0.015. Others significant terms were of square effect of temperature (Prob>F = 0.001) and square effect of pH (Prob>F = 0.025). On the other hand, those insignificant factors were the main effect: temperature (Prob>F = 0.320) and enzyme ratio (Prob>F = 0.860); square effect of enzyme ratio (Prob>F = 0.5442); and all three interactive effects: temp*pH (Prob>F = 0.53), temp*enzyme ratio (Prob>F = 0.856) and pH* enzyme ratio (Prob>F = 0.911), respectively. Based on the ANOVA analysis, those insignificant factors whether main, square or interaction effect can be eliminated and therefore the new reduced quadratic model could be expressed in Eq. (3) as followed:

$$\text{Glucose} = -82.94287 + 14.78740*\text{pH} - 0.027414*\text{Temp}^2 - 1.49843*\text{pH}^2 + 0.020438*\text{Temp}*\text{pH} + 0.018187*\text{pH}*\text{Enzyme} \quad (3)$$

Although interaction effects such as temp*pH and pH*enzyme were insignificant, but they were still maintained in new model (Eq. 3) to retain the model hierarchy [13].

Normality test and predicted versus actual analysis

A graphical technique uses to regulate the relevance of assumption on normality is by plotting the data points on a normal probability paper. If a straight line can be draw through the plotted points, the assumption of normality is reflected to be rational. Figure 1 showed the obtained data were fall on the straight line.

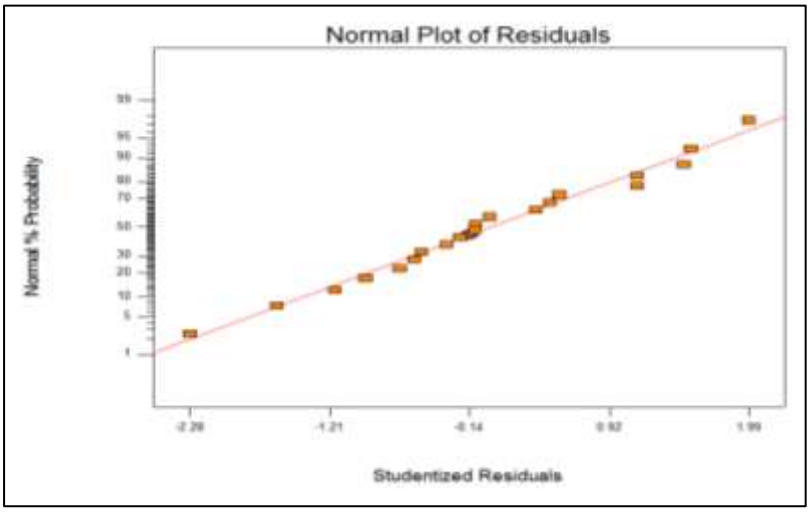

Figure 1. Normality plot of residuals

On the other hand, the data in Table 2 shows that the predicted values were in good agreement with the experimental values for glucose response. The results could be further corroborated as illustrated in Figure 2 which graphically depicts the correlation between the actual and predicted responses. All data point was closed to the straight line, demonstrating that no significant violations of the model were found. Moreover, the model should adequate to predict the glucose amount during enzymatic hydrolysis within the range in present study as it was highly significant, where the Prob > F value is 0.003. In fact, the coefficient of determination, R^2 = 0.9057, considered sufficient to identify the correlation between the actual and the predicted values [15].

Three-dimensional (3D) response surface plots

As shown in Table 3, the main factor: pH was statistically significant. Therefore, the interaction effects which involve Temp*pH and pH*Enzyme ratio should be remained. Further analysis on these interaction effects were carried out. The three-dimensional (3D) response surface plots of both interaction effects were illustrated in Figure 3 and Figure 4, respectively.

Interaction effects of temperature versus pH (temp*pH)

Figure 3 demonstrates the 3D response surface plot for the interaction effects of temperature versus pH. Both of the interaction effects were temperature and pH (varying from 35 – 55 ºC and 4.5 – 6.5, respectively) on the glucose production, while holding the enzyme ratio at its center point, *viz.* 5:1.

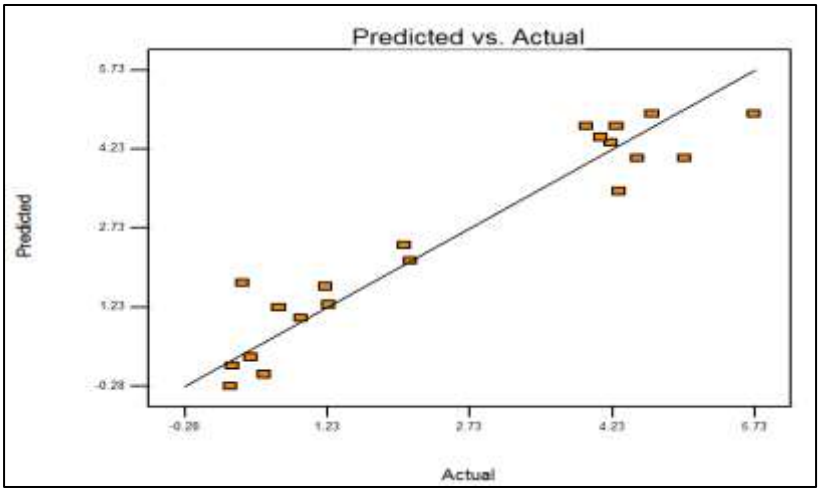

Figure 2. Actual and predicted plot of glucose response

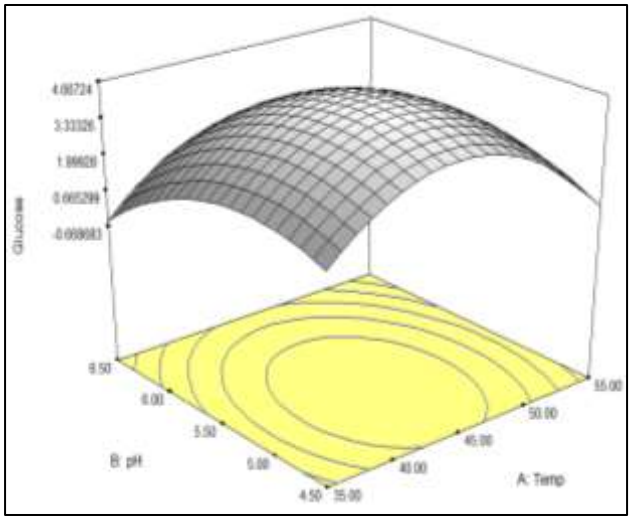

Figure 3**.** 3D response surface plot for interaction effects of temperature versus pH

It was noticed that the highest glucose concentration > 4.39 $g.L^{-1}$ could be attained when temperature at 45 ºC and pH in the range of 5.0 – 5.5, respectively. The pH range of 4.5 – 6.0 is favour the glucose production in all tested temperature ranging from 35 – 50 ºC. The glucose concentration was increased when the temperature was raised from 35 to 45 ºC. This could be explained as the enzyme-catalyzed reaction behaves like most chemical reaction, proceed at a faster velocity as the temperature is raised. An increase in temperatures, it would impart more kinetic energy to the reactant molecules resulting in more productive collision per unit time [16]. As a result, more glucose released when the temperature was raised from low to mid-point in present study. However, further increased of temperature (> 45 ºC), the glucose concentration was decreased. Figure 3 has obviously showed the raising of glucose amount from 35 – 45 ºC and sharply declined when the tested temperature was in range of 45 – 55 ºC. In general, an enzyme molecule is a very delicate and fragile structure. If the molecule absorbs too much energy, the

tertiary structure will be disrupted and the enzyme will lose its catalytic activity and eventually denatured. This is the main reason why low glucose concentration was detected when at higher temperature. In short, both cellulase and β-glucosidase enzymes were performed well and reach their optimum temperature point at 45 °C.

Interaction effects of pH versus enzyme ratio (pH*enzyme ratio)

Figure 4 reveals the interaction between pH and enzyme ratio on glucose production. When temperature was fixed at 45 °C, enzyme ratio and pH were set to 5:1 and 4.8 – 5.6; 4.65 $g.L^{-1}$ of glucose concentration is obtainable. Meanwhile, when the pH value greater than 5.6 the glucose amount was decreased.

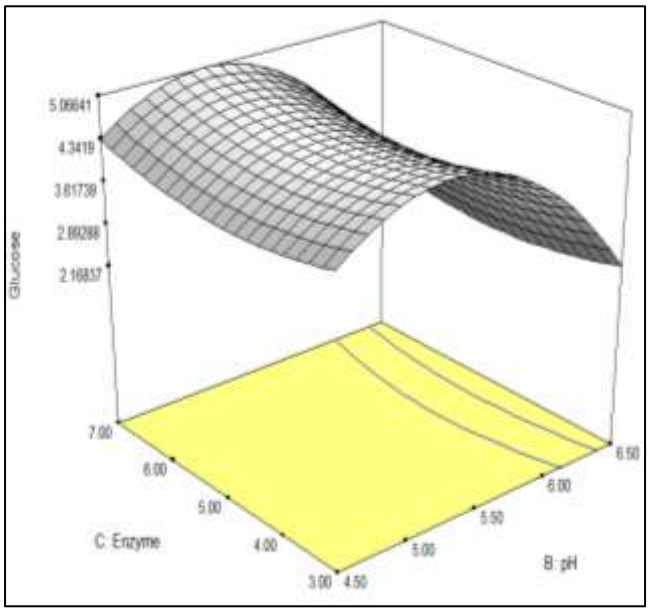

Figure 4. 3D response surface plot for interaction effects of pH versus enzyme ratio

Generally, enzymes have ionic groups on their active sites and must be in suitable environment either acid or base to function. A change of pH in the medium would lead to modification of enzyme in the ionic form of active site and its three-dimensional shape [17]. For these reasons, enzymes are only active over a certain pH range. Hence, the enzyme activity would be retarded once it is beyond the suitable pH range and thus impede the reaction rate. It was noticed that both cellulase and β-glucosidase was active at low acidic pH condition ranging from 4.5 – 5.5. The higher pH value (pH > 5.6) did not favour the enzyme hydrolysis in this study. This is a reason why the glucose content was lower at high pH condition compared to low pH circumstance. Figure 4 shows the 3D response surface plot where the glucose amount was increased from 4.5 to its optimum point 5.5 and declined with increment of pH values.

Prediction and verification of optimization conditions

Response optimizer function has provided a set of solutions that were used to predict the optimum conditions of glucose production from enzymatic saccharification of ammonia treated OPT substrate. The criteria of the variables were set accordingly as to maximize the response, i.e. glucose production. By following RSM prediction, ones could obtain the glucose at 4.958 $g.L^{-1}$ when the parameters were set to temperature, 44.23; pH 5.22 and enzyme ratio, 3:1, respectively. Moreover, the desirability value of this response is 1.00. It means when running the pre-set conditions, the experimental value should be the same as prediction. In order to ascertain the prediction, three replication runs were performed as to verify the RSM prediction. Table 4 tabulates both of the RSM prediction and experimental values for glucose production.

Table 4. Optimum conditions suggested by the RSM for glucose production

A Temperature	B pH	C Enzyme ratio	Glucose production, $g.L^{-1}$		Error, %
			RSM prediction	Experimental	
44.23	5.22	3:1	4.958	4.964 ± 0.006	0.12

In present study, the glucose concentration of 4.964 ± 0.006 $g.L^{-1}$ was obtained. Both predicted and experimental values were in closed agreement to each other with the error less than 0.2 %. Last but not least, the RSM model has successfully modelled the glucose production on ammonia pre-treated OPT substrate in present study.

Conclusion

This investigation studied three independent variables on glucose emanation from enzymatic saccharification of ammonia pre-treated OPT substrate using response surface methodology (RSM). Statistical optimization of enzyme hydrolysis for glucose production has been successfully carried out. The attained data could fit the second order equation well with an R^2 up to 90.57 %. The RSM optimization of glucose response, 4.958 $g.L^{-1}$ was achieved when the experiment was performed according to the software optimizing settings. The model suggested the best conditions when temperature, pH and enzyme ratio were set at 44.23 °C, 5.22 and 3:1, respectively.

Abstract

Biosurfactant produced by *Pseudomonas aeruginosa* UKMP14T was optimized by growing the isolate in mineral salt medium (MSM) supplemented with 1% (v/v) glycerol and 1.3 g/L ammonium sulphate with C/N ratio of 14:1. The culture medium was incubated at 37°C, with an agitation speed of 150 rpm for 7 days. *P. aeruginosa* UKMP14T produced biosurfactant at 0.8 g/L after 7 days incubation. Anthrone assay proved biosurfactant was glycolipid. The biosurfactant was characterized by scanning electron microscope-energy dispersive X-ray spectroscopy (SEM-EDX) in addition to Fourier transform infra-red (FT-IR), nuclear magnetic resonance (NMR) and electrospray ionization-mass spectrometry (ESI-MS). The SEM-EDX analysis indicated the presence of carbon and oxygen elements by 78% and 22% (atomic %), respectively. FT-IR absorption spectra indicated the functional groups of rhamnolipid were located at 3308.46, 2922.91, 2857.09 and 1730.96 cm^{-1}. ESI-MS/MS analyses identified *P. aeruginosa* UKMP14T produced rhamnolipid with two fatty acids-nine congeners, L-rhamnosyl-L-rhamnosyl-β-hydroxydecanoyl-β-hydroxydecanoate (Rha-Rha-C_{10}-C_{10}) (*m/z* 649) which formed the main compound. The critical micelle concentration (CMC) of this rhamnolipid was established at 30 mg/L (32 dynes/cm). The characteristics of biosurfactant produced by *P. aeruginosa* UKMP14T indicated it has a high potential in industrial dan bioremediation application.

Keywords: biosurfactant, *Pseudomonas aeruginosa*, rhamnolipid, spectroscopic analysis, CMC value

Abstrak

Biosurfaktan dihasilkan oleh *Pseudomonas aeruginosa* UKMP14T dioptimumkan dalam medium garam mineral (MSM) yang ditambahkan dengan 1% (i/i) gliserol dan 1.3 g/L ammonium sulfat dengan nisbah C/N iaitu 14:1. Medium kultur ini dieram pada 37°C, dengan kelajuan goncangan pada 150 psm selama 7 hari. *P. aeruginosa* UKMP14T menghasilkan biosurfaktan sebanyak 0.8 g/L selepas 7 hari pengeraman. Asai antron membuktikan biosurfaktan terhasil adalah glikolipid. Biosurfaktan tersebut dicirikan oleh mikroskop pengimbasan elektron-spektroskopi tenaga serakan sinaran-X (SEM-EDX), dengan penambahan Infra-merah transformasi Fourier (FT-IR), resonan magnetik nuklear (NMR) daknn spektrometri jisim-pengionan elektrosemburan (ESI-MS). Analisis SEM-EDX menunjukkan kehadiran unsur karbon dan oksigen masing-masing sebanyak 78% dan 22% (% atomik). Spektrum penyerapan FT-IR menunjukkan kumpulan berfungsi ramnolipid pada 3308.46, 2922.91, 2857.09 dan 1730.96 cm^{-1}. Analisis ESI-MS/MS mengenalpasti *P. aeruginosa* UKMP14T menghasilkan ramnolipid dengan sembilan kongener-dua asid lemak, L-ramnosil-L-ramnosil-β-hidroksidekanoil-β-hidroksidekanoat (Rha-Rha-C_{10}-C_{10}) (*m/z* 649) sebagai sebatian utama. Kepekatan misel kritikal (CMC) ramnolipid ini dikesan pada 30 mg/L (32 dynes/cm). Ciri-ciri biosurfaktan yang dihasilkan oleh *P. aeruginosa* UKMP14T menunjukkan ia mempunyai potensi tinggi untuk di aplikasi dalam industri dan bioremediasi.

Introduction

For decades, efforts have been made to find alternative surfactants to those chemically synthesized and as a result biosurfactants are more harmony with current trends towards global environmental awareness. There are several features that make biosurfactants commercially promising for industrial applications; their lower toxicity, higher biodegradability and effectiveness at extreme temperature, salinity and pH conditions. Their most important advantages are their ecological applicability, biodegradable and biosynthesized by a variety of microorganisms [1].

Among the different classes of biosurfactant such as glycolipids, lipopeptides, phospholipids, fatty acids, neutral lipids and polymeric compounds [2], ramnolipids members of glycolipid group, are the most extensively studied and characterized. The typical structure of rhamnolipid is determined by the number of rhamnose, fatty acids and the combination of fatty acids components. Two known major types of rhamnolipid species are L-rhamnosyl-3-hydroxyldecanoyl-3-hydroxydecanoate or mono-rhamnolipid (Rha-C_{10}-C_{10}) and L-rhamnosyl-L-rhamnosyl-3-hydroxyldecanoyl-3-hydroxydecanoate or di-rhamnolipid (Rha-Rha-C_{10}-C_{10}) [3]. Now, over 40 different ramnolipid congeners have been described and bacteria from genus *Pseudomonas* were found to be the most common producers of this compound [4].

Biosurfactant production including rhamnolipid is generally associated with the utilization of hydrocarbons by microbial community. The function of biosurfactants is often related to hydrocarbon uptake. Therefore, they are predominantly synthesized by hydrocarbon-degrading microorganisms. At low concentration, surfactant are soluble in water and with increasing concentrations, they form micelle in solution. The concentration at which micelle begins to form is called the critical micelle concentration (CMC); above the CMC, biosurfactants can solubilize hydrocarbons in soil-water system. Therefore, the biosurfactants may be useful in degradation of oil-contaminated area [5].

This study attempted to define the structures of these compounds by using a number of analytical methods such as Fourier transform infrared spectroscopy (FTIR) and mass spectrometry [6] and by utilizing SEM-EDX for the purposes of analysis. It is of interest to note SEM-EDX for the purposes of analysis had not been used in previous studies that were carried out. Therefore, the main objective of this study is to identify the rhamnolipid congeners produced by *P. aeruginosa* UKMP14T by using spectroscopic analyses including SEM-EDX and determination of CMC value of this surface active compound.

Materials and Methods

Biosurfactant-producing bacterium

P. aeruginosa UKMP14T used in this study were selected from 20 hydrocarbon-degrading bacteria for its potential in producing biosurfactant. These hydrocarbon-degrading bacteria were isolated from oil-contamined soil and water from oil refinery petroleum plants [7].

Media

The nutrient parameters such as carbon and nitrogen sources as well as the physical parameters (pH and temperature) have been optimized in a previous study [7]. The growth medium used in this study was mineral salt medium (MSM) [8] containing 0.1% (v/v) trace elements [9] and added with ammonium sulphate ($(NH_4)_2SO_4$) as a nitrogen source at 1.3 g/L with a C/N ratio of 14:1. The medium was adjusted to pH 9.0 and then autoclaved at 121°C, 15 psi for 15 minutes, cooled to room temperature (± 25°C) before added with 1% (v/v) of glycerol as a carbon source.

Production of biosurfactant

An amount of 10% (v/v) of standardized bacterial suspension of *P. aeruginosa* UKMP14T was prepared [10] and inoculated into a 250 mL conical flask containing 50 mL of MSM and added with 1% (v/v) glycerol. The culture was incubated at 37°C in an orbital shaker (Multitron, Infors HT, Switzerland) with an agitation speed of 150 rpm for 9 days. The culture medium was then centrifuged at 8022 g (RC5C Sorvall Centrifuge Instrument, USA) at 4°C

for 30 minutes. The supernatant was assayed with anthrone [11] and Bradford [12] methods for detection of sugar and protein, respectively. L-rhamnose solutions with a range of concentrations, 0.02-0.10 g/L for anthrone assay and bovine serum albumin (10-50 µg/mL) for Bradford assay were used for the standard curves. The bacterial growth was determined by spread plate method and pH was monitored using pH meter (Delta 320, Mettler-Toledo, China). Specific growth rate of this bacterial isolate was determined [13].

Scanning electron microscope – energy dispersive X-ray spectroscopy (SEM-EDX)
Samples of the culture medium for the production of biosurfactant by *P. aeruginosa* UKMP14T were taken after 4 and 7 days of incubation and centrifuged at 760 g for 10 minutes (IEC MicroCL 17 Centrifuge, Thermo Electron Corporation, Germany). The samples was then prepared [14] and viewed under SEM (LEO-SEM1450VP, UK) with integrated EDX spectroscopy (Incax-Sight, Oxford Instrument, UK).

Extraction of biosurfactant
To recover biosurfactant, cell free supernatant was subjected to an acid precipitation [15]. The supernatant was treated by acidification to pH 2.0 using 1.0 M HCl and left for four weeks at 4°C to complete the precipitation of the biosurfactant. After centrifugation at 8022 g at 4°C for 30 minutes, the precipitate was dissolved in 0.1 M $NaHCO_3$, pH 8.0, and then reacidified and recentrifuged. Later, the precipitate was extracted using chloroform-methanol (2:1, v/v). The organic phase was evaporated to remove the solvent, yielding a viscous dark-brown biosurfactant product.

Thin layer chromatography (TLC)
About 30 µL of the biosurfactant extract dissolved in chloroform was spotted onto TLC plates (silica gel 60 G Merck, USA) and developed in chloroform:hexane:methanol (5:4:1, v/v/v) as solvent system. For detection of glycolipid and protein, the plates were air dried, sprayed with anthrone and ninhydrin reagent, and heated at 100°C for 2 minutes. The appearance of yellow spots was regarded as positive for the glycolipid biosurfactant. On the other hand, red spots would be detected when protein was present in the sample.

High performance liquid chromatography (HPLC)
The extract was further partially purified by HPLC (Waters Alliance e2695 Separation Module, USA) equipped with C18-RP Waters Symmetry column and Waters 2998 Photodiode Array Detector. The mobile phase consists of aqueous solution of (A) water with 0.1% (v/v) formic acid and (B) 100% (v/v) methanol. The gradient system was used, starting with 10% to 90% B in 20 minutes and reversed from 90% to 10% in 10 minutes. The flow rate of the mobile phase was set at 1 mL/min and the sample injection volume was 50 µL. The fractions were collected with a fraction collector and then concentrated to dryness using centrifugal concentrator. After this process, spectroscopic analyses were done for the characterization of rhamnolipid congeners.

Fourier transform infra red (FT-IR) spectroscopy
The chemical bonds and functional groups present in the fractions collected from HPLC were elucidated using FT-IR spectrometry (Perkin Elmer Spectrum 400 FT-IR and spotlight 400 imaging system, USA). The spectrum was recorded at the range of 4000-650 cm^{-1}, resolution of 4 cm^{-1} with 4 times scans.

Nuclear magnetic resonance (NMR)
The extracted biosurfactant was redissolved in deuterated methanol (MeOD) and analyzed using 1D ^{1}H and ^{13}C NMR and 2D NMR experiments (Bruker/AVANCE III 600MHz cryoprobe, USA). Correlation spectroscopy (COSY), heteronuclear single quantum coherence (HSQC) and heteronuclear multiple-bond correlation spectroscopy (HMBC) were determined.

Electrospray ionization-mass spectrometry (ESI-MS and ESI-MS/MS)
The analyses were performed in Bruker MicroToF Q, USA in the negative-ion mode. The extracted biosurfactant was dissolved in methanol and introduced using direct infusion technique with a syringe pump at flow rate of 0.3 µL/min. ESI tandem mass spectra (ESI-MS/MS) were acquired by mass-selecting the target ion using a quadruple mass analyzer. The conditions of the analysis were capillary 3.0 kV and set collision cell RF 250.0 Vpp. Collision energy induced dissociation (CID) for the detection of biosurfactant was determined within the range of 10-17 eV.

CMC determination

A series concentration of extracted biosurfactant was prepared by dissolving biosurfactant in distilled water within a range of 5 to 100 mg/L. For a positive control, sodium dodecyl sulphate (SDS) (500-10 000 mg/L) was prepared. Distilled water was used as a negative control. The surface tension was measured using a tensiometer (Surface Tensiomat Model 21, Fisher Scientific, USA) [16].

Results and Discussion

Production of biosurfactant

The growth of *P. aeruginosa* UKMP14T began after 2 hours incubation and achieved exponential phase after 12-hours incubation with a specific growth rate (μ) of 0.27 h^{-1}. The stationary phase occurred after 18 hours incubation (~10^9 CFU/mL) and the number of bacteria remained constant until 9 days (Figure 1a). The surface tension (ST) of the culture medium was reduced to 52.8 dynes/cm (after 12 hours) compared to 61.8 dynes/cm at 0 hour incubation. The maximum decrease in the ST of the culture medium was 30 dynes/cm which occurred at 48 hours and it was constant until 9 days (Figure 1a). The presence of glycolipid biosurfactant of 0.017 g/L was detected within 12 hours incubation using anthrone assay. The maximum biosurfactant production was at day-7 with 0.802 g/L and reduced to 0.516 g/L after 9 days (Figure 1b). The pH of the medium decreased from pH 9.0 slowly to pH 5.0 at day-6 of incubation (Figure 1b). Protein was not detected in this biosurfactant.

The SEM-EDX analysis indicated the presence of carbon and oxygen elements in the structure of the biosurfactant based on the electron images taken from SEM after 96 and 168 hours of incubation. According to the EDX spectrum, the amount of carbon was estimated at 78% (atomic %) which is 5 times higher than the oxygen content, 22% (atomic %) (Figure 2b & c).

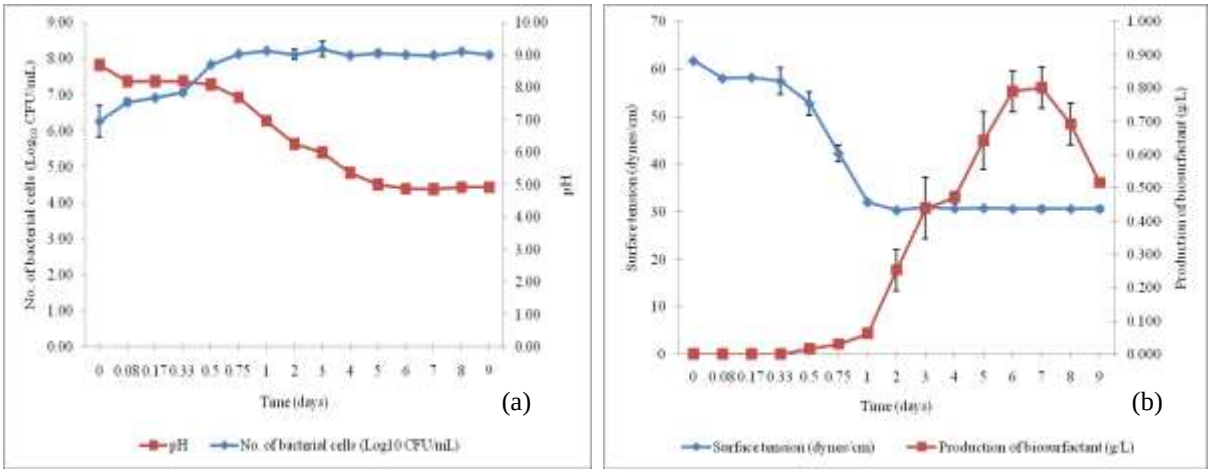

Figure 1. Production of glycolipid biosurfactant produced by *P. aeruginosa* UKMP14T when grown in MSM pH 9.0 with 1% (v/v) glycerol, 1.3 g/L of $(NH_4)_2SO_4$ with C/N ratio 14:1, temperature at 37°C, agitation speed of 150 rpm for a 9-days incubation time: (a) no. of bacteria (log_{10} CFU/mL) and pH; (b) surface tension (dynes/cm) and production of biosurfactant (g/L).

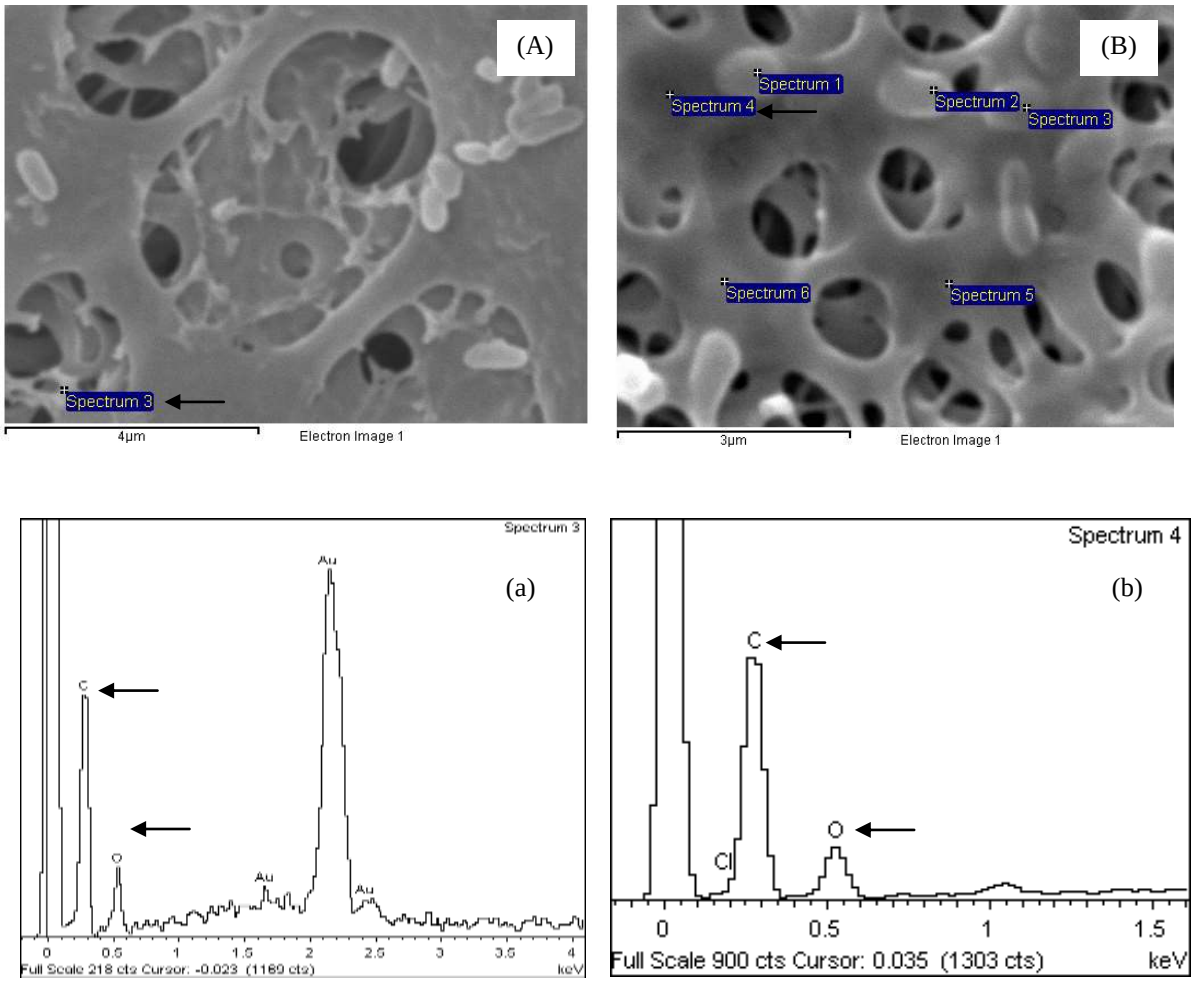

Figure 2. SEM-EDX analysis of biosurfactant produced by *P. aeruginosa* UKMP14T. Production of biosurfactant at different incubation time in optimum culture medium: A) 96 hours and B) 168 hours; EDX spectrum analysis: a) 96 hours and b) 168 hours.

The biosurfactant produced by *P. aeruginosa* UKMP14T was classified as glycolipid because of the presence of hexose sugar in the supernatant from the culture medium. In this study, anthrone assay was used for a purpose of detection. This glycolipid biosurfactant was categorized as secondary metabolite since it was produced during the stationary phase in acidic environment. The highest accumulated glycolipid biosurfactant occurred after 7 days incubation in culture medium. In this study, SEM can be utilized for high magnification imaging of the bacteria cells including the biosurfactant produced in the hydrated formed. SEM in combination with EDX, using electron images had successfully determined elements that were present in the real physical structure of biosurfactant. Moreover, through this analysis the group of biosurfactant can be distinguished by determining the atomic number of elements and their distribution. This study showed that only carbon and oxygen were present without the element of nitrogen in the biosurfactant produced. Therefore, this biosurfactant can be categorized in glycolipid group but not in lipopeptides or polymeric surfactants. The combination of these instruments (SEM-EDX) play a very important role in confirming the major elements and makes identification work easier as this will help in narrowing

the next step in the structural characterization study by providing solid preliminary data as reference. In addition, no previous work using SEM-EDX had been done before and this study was a pioneer in using these instruments for analysis.

The production of the biosurfactant by *P. aeruginosa* EM1 isolated from an oil-contaminated site was 4.9 g/L, when grown in MSM, pH 6.8 which contains 40 g/L of glycerol and 50 mM sodium nitrate ($NaNO_3$), grown at 37°C with an agitation speed of 200 rpm for 168 hours [18]. On the other hand, *P. aeruginosa* MR01 produced 2.1 g/L of biosurfactant, when grown in MSM, pH 8.0 with 1.2% (w/v) glucose and 0.1% (w/v) ($(NH_4)_2SO_4$), at 37°C with an agitation speed of 180 rpm for 48 hours [19]. Both studies showed a maximum decreased in the surface tension of the biosurfactant, about 30 mN/m, which is of the same value produced in this research. pH, agitation speed as well as C and N concentrations are major factors that effecting the microbial growth and inducing development component of protein for biosurfactant production. In addition, limitation of N nutrient (C:N ratio) is related to microbe lypogenesis. Limiting of certain nutrient in medium will accumulating intrasel lipid produced by microbe in medium. In rhamnolipid biosynthesis, the limiting step for this process is lipid formation, not carbohydrate [20, 21].

Chemical characterization of biosurfactant: TLC

Crude biosurfactant on TLC plate showing only yellow spots were detected and separated with different R_f values which 0.53, 0.36 and 0.26, respectively. Yellow spots with specific Rf values on TLC after sprayed with anthrone reagent showed the separation of the glycolipid biosurfactant from crude extract. The preliminary characterization method of TLC supported that biosurfactant produced by *P. aeruginosa* UKMP14T was a glycolipid.

HPLC

Five fractions of partially purified biosurfactant (F1, F2, F3, F4 and F5) were eluted and collected using HPLC at different elution times of 2.01, 2.27, 17.32, 21.56 and 23.01 minutes, respectively (Figure 3). The HPLC fractions were not mixed for further analysis and each fraction was analyzed individually. However, these fractions are partially purified using HPLC. Purposely to remove impurities and only mixtures of rhamnolipid congeners were collected. Each of these fractions were further analyzed individually with spectroscopic analyses such as FTIR, NMR and mass spectrometry for identification of the glycolipid biosurfactant.

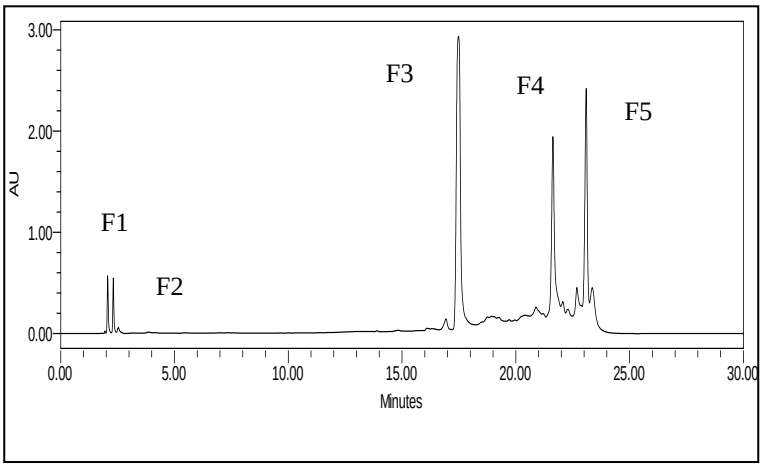

Figure 3. HPLC chromatogram of glycolipid biosurfactant produced by *P. aeruginosa* UKMP14T.

FT-IR spectrometry

Figure 4 represent FT-IR spectra from all HPLC fractions (F1, F2, F3, F4 and F5). The significance of these fractions is contained only mixtures of rhamnolipid congeners, since all the impurities were removed during separation using HPLC. FT-IR spectra of each HPLC fractions (F1-F5) indicated the functional groups of the glycolipid biosurfactant including rhamnolipid, where the important absorption spectra were located at 3308.46, 2922.91, 2857.09 and 1730.96 cm^{-1} (Figure 4). The spectra appearing at 3308.46 cm^{-1}, confirming for –OH stretching of hydroxyl group, 2922.91 and 2857.09 cm^{-1} showed the presence of –CH aliphatic stretching and $–CH_2$ methylene stretching and –C=O stretching vibrations of ester carbonyl group at 1730.96 cm^{-1}.

The FT-IR spectra revealed –OH stretching vibration for hydroxyl group, –CH aliphatic stretching, $–CH_2$ methylene stretching and ester carbonyl group (–C=O) elucidated the lipid moiety in glycolipid biosurfactant such as rhamnolipid.

This finding supported by FT-IR spectra from biosurfactant produced by *P. aeruginosa* DS10-129 (EBI accession no. AM419153) [22]. The broad spectrum appearing at 3368 cm^{-1} should be assigned to the –OH stretching vibration of hydroxyl group in the chemical structure. The strong absorption spectrum present at 2926 and 2856 cm^{-1} are expected to be the –CH stretching vibration of the hydrocarbon chain positions. Finally, the characteristic spectrum displayed at 1737 cm^{-1} confirmed the –C=O stretching vibrations of the carbonyl groups.

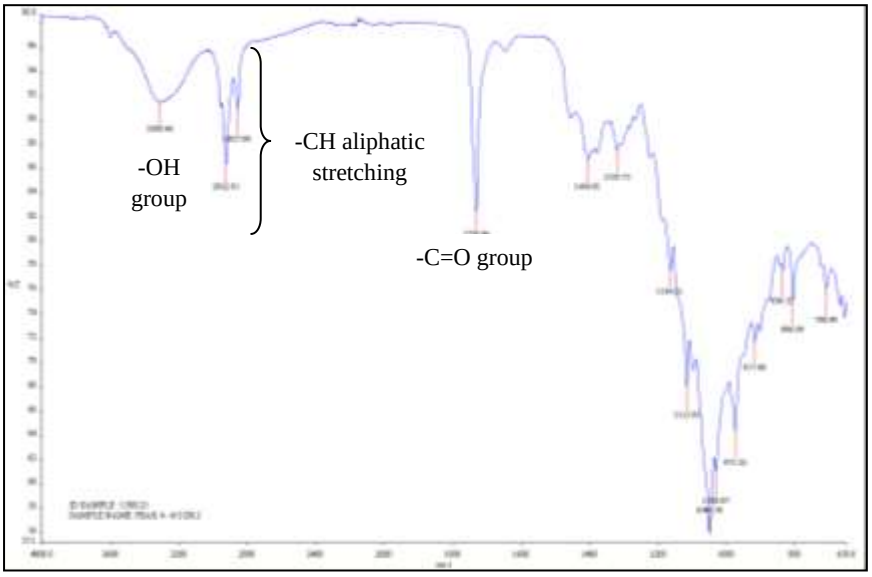

Figure 4. FT-IR spectra of HPLC fractions (F1-F5) from glycolipid biosurfactant produced by *P. aeruginosa* UKMP14T.

NMR spectrometry

The presence of di-rhamnolipid in fractions was detected by 1D ^{1}H and ^{13}C NMR analysis. The characteristics of rhamnose rings and lipid group were indicated by the appearance of the chemical shifts (δ) in the region of 0.90-4.93 ppm (Table 1) while the 2D NMR experiment, especially HMBC spectra, determined the satellites at chemical shift, δ 4.93/97.7 and 4.89/102.7 (Figure 5). Moreover, 1D and 2D NMR analyses exhibited the anomeric moiety at C1' and C1" as two rhamnose structures of di-rhamnolipid in fractions F1-F5, which is consistent with β-L-

rhamnopiranose(1'↔1)-hydroxyfatty acid and β-L-rhamnopiranose(1"→2')-β-L-rhamnopiranose linkages, respectively [23]. But in the lipid structure of rhamnolipid, long aliphatic hydrocarbon chain, as well as ester and carbonyl group, forming β-hydroxyfatty acid chain was confirmed. Since all of these fractions were partially purified, same results were obtained which is di-rhamnolipid after analysis and summarized in one table. Fraction F_2 is a set of data from other previous study as a comparison to this study.

Table 1. The ^{1}H and ^{13}C NMR data of fractions (F1-F5) and comparison with di-rhamnolipid, F_2

Moiety	Carbon	F1-F5 (δ_H, ppm[a])	F_2 (δ_H, ppm[b])	F1-F5 (δ_C, ppm[a])	F_2 (δ_C, ppm[b])

[a]600 & 150 MHz (^{1}H & ^{13}C respectively), in MeOD
[b]400 & 100 MHz (^{1}H & ^{13}C respectively), in $CDCl_3$: MeOD: D_2O (1:1:1) [23]

Mass spectrometry

The characteristic of the lipid moiety in rhamnolipid congeners was identified using ESI-MS data from the HPLC fractions (F1-F5) (Table 2). The major rhamnolipid identified was L-rhamnosyl-L-ramnosyl-β-hydroxydecanoyl-β-hydroxydecanoate (Rha-Rha-C_{10}-C_{10}) (Figure 6) based on the pseudo-molecular ion peaks at *m/z* 649. In addition, eight other congeners based on the ESI-MS/MS analyses were detected. The congeners were Rha-C_{10}-C_{10} (*m/z* 503), Rha-C_8-C_{10} (*m/z* 475), Rha-C_{10}-C_8 (*m/z* 475), Rha-Rha-C_8-C_{10} (*m/z* 621), Rha-Rha-C_{10}-C_8 (*m/z* 621), Rha-Rha-C_{10}-$C_{12:1}$ (*m/z* 675), Rha-Rha-C_{10}-C_{12} (*m/z* 677) and Rha-Rha-C_{12}-C_{10} (*m/z* 677). This study revealed three mono-rhamnolipid and six di-rhamnolipid with two β-hydroxyfatty acid chains but no rhamnolipid with single β-hydroxyfatty acid chain was found. The length β-hydroxyfatty acid chain varied among minor homologues, C_8, C_{10} and C_{12} with one unsaturated $C_{12:1}$. It was noted that di-rhamnolipid congeners were the predominant congener as compared with mono-rhamnolipid congeners. Moreover, three isomeric pairs of congeners could be distinguished in this study, namely Rha-C_8-C_{10}/Rha-C_{10}-C_8, Rha-Rha-C_8-C_{10}/Rha-Rha-C_{10}-C_8 and Rha-Rha-C_{10}-C_{12}/Rha-Rha-C_{12}-C_{10}. These isomeric congeners showed that the shorter chains of β-hydroxyfatty adjacent to the sugar were found to be dominant as compared with the congeners with longer chains.

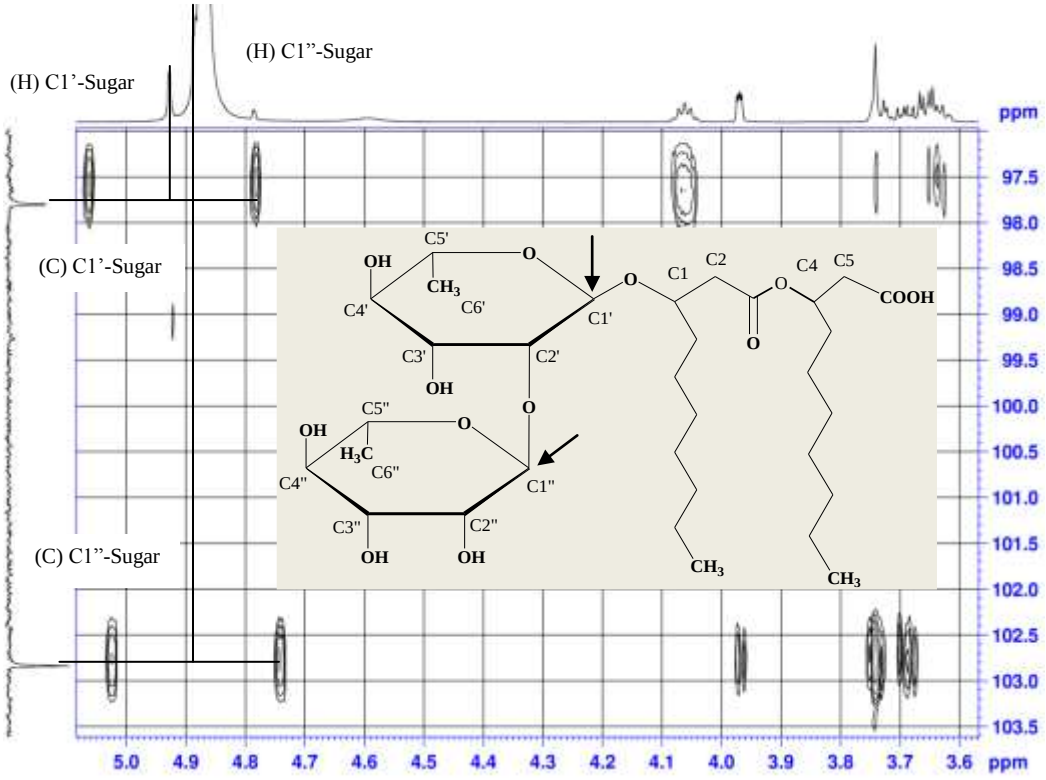

Figure 5. HMBC spectra of fractions F1-F5 (di-rhamnolipid), the glycolipid biosurfactant produced by *P. aeruginosa* UKMP14T showing the anomeric signals at δ 4.93/97.7 and 4.89/102.7 consistent with β-L-rhamnopiranose(1'↔1)-hydroxyfatty acid and β-L-rhamnopiranose(1"→2')-β-L-rhamnopiranose linkages, respectively.

Table 2. Chemical compositions with varies of fatty acids in rhamnolipid congeners produced by *P. aeruginosa* UKMP14T

Rhamnolipid congeners	**Fragmentations *m/z* (50-1000)**	**$[M-H]^-$ (*m/z*)**	**Difference between isomeric pairs $[M-H]^-$ (*m/z*)**
Rha-C_8-C_{10}	142, 163, 169, **305**, 311	475	**305** : Rha-C_8
Rha-C_{10}-C_8	141, 163, 170, **333**	475	**333** : Rha-C_{10}
Rha-C_{10}-C_{10}	163, 169, 170, 333, 339	503	
Rha-Rha- C_8-C_{10}	142, 169, 205, 311, **451**	621	**451** : Rha-Rha-C_8
Rha-Rha-C_{10}-C_8	141, 205, **479**	621	**479** : Rha-Rha-C_{10}
Rha-Rha-C_{10}-C_{10}	169, 205, 339, 479	649	
Rha-Rha-C_{10}-$C_{12:1}$	195, 205, 479, 365	675	
Rha-Rha-C_{10}-C_{12}	197, 205, **479**	677	**479** : Rha-Rha-C_{10}

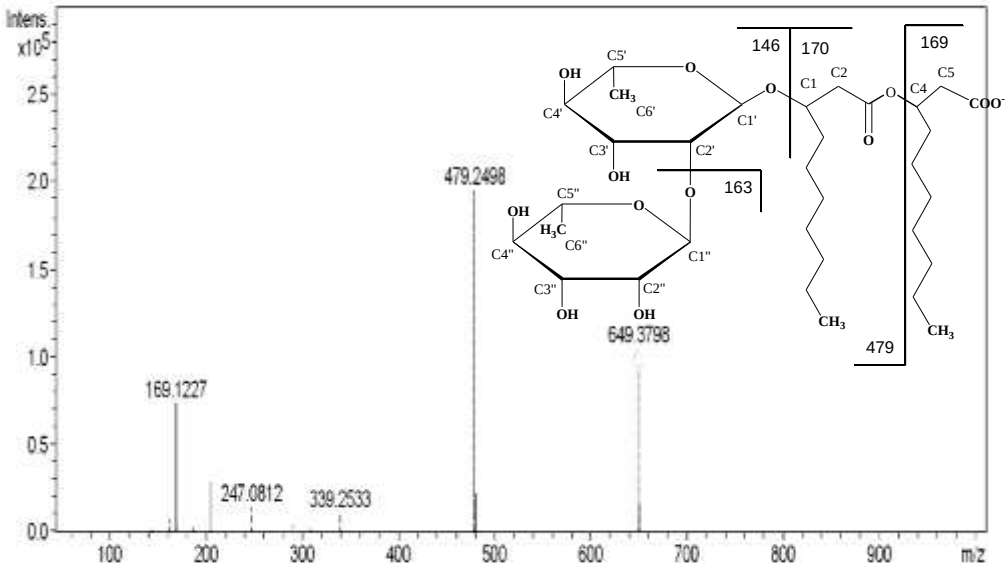

Figure 6. ESI-MS/MS spectra in negative ion mode of di-rhamnolipid (Rha-Rha-C_{10}-C_{10}) (*m/z* 649) produced by *P. aeruginosa* UKMP14T.

The length of the constituent fatty acids had been found to vary from C_8 to C_{14} and several single fatty acid-containing rhamnolipid compounds were also identified. Over 40 different rhamnolipid components had been described, all having molecular masses below 800 Da [4]. Five congeners where Rha-Rha-C_{10} act as main congener were produced by *P. aeruginosa* LBI when cultured with 3.2% (v/v) sunflower-oil refining waste as the main carbon source [24]. Whereas, *P. aeruginosa* strain MA01 produced 6 congeners, mixture of mono- dan di-rhamnolipid with ratio 1:1 when cultured with 10% (v/v) soybean oil [25].

In another study, it was reported that *P. putida* BD2, which was isolated from the Arctic soil, when grown in a medium containing 20 g/L glucose, produced only Rha-Rha-C_{10}-C_{10} [26]. The composition of the congeners is related to many parameters, the culture media composition, the culture condition as well as the age of the culture. The resulting mixture of the congeners determined the properties of the biosurfactant and even slight differences of the mixture can have great consequences on its physical-chemical properties. The presence of unsaturated bonds, the length of alkyl chain and the size of hydrophilic head group were correlated with surface-active properties of the biosurfactant. Furthermore, the presence of larger fatty acids chains plays a role in decreasing the CMC of rhamnolipid. For instance, mono-rhamnolipids are less soluble, adsorb onto surfaces more strongly and have a higher CMC value for hydrocarbon solubilization [27]. In this study, the two fatty acids-nine rhamnolipid congeners produced by *P. aeruginosa* UKMP14T were expected to have high surface active activity, thus increasing the efficacy of biosurfactant.

CMC determination

Rhamnolipid produced by *P. aeruginosa* UKMP14T was able to reduce surface tension of distilled water from 72 to 32 dynes/cm with the CMC value at 30 mg/L (Figure 7) as compared with the positive control SDS (40 dynes/cm) but at a much higher CMC value of 2000 mg/L (Figure 8).

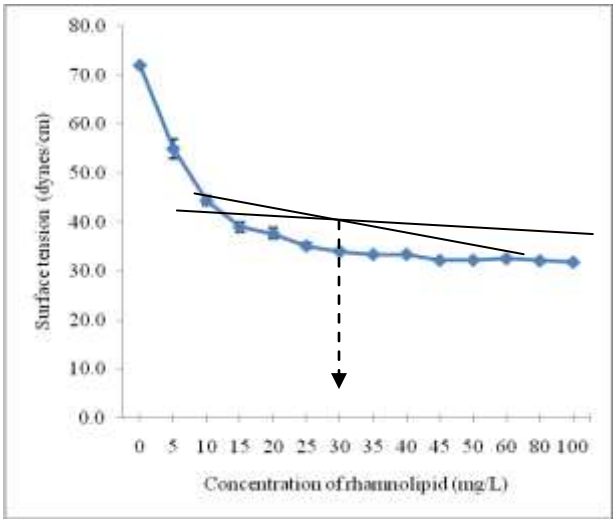

Figure 7. CMC value of rhamnolipid produced by *P. aeruginosa* UKMPT

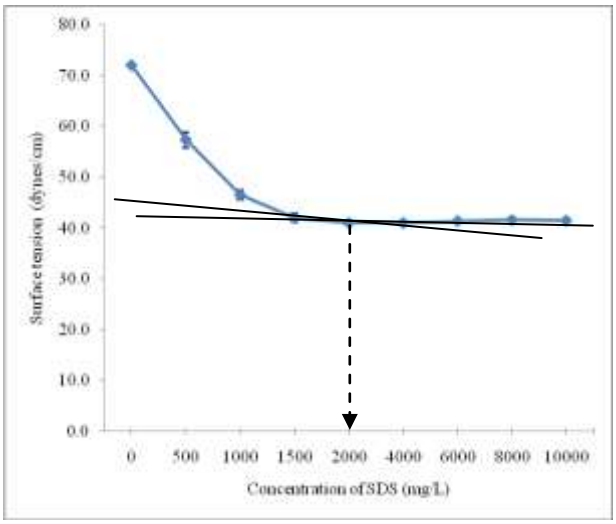

Figure 8. CMC value of sodium dodecyl sulphate (SDS)

Previous studies reported the CMC values of rhamnolipid varied based on *P. aeruginosa* strain and its culture conditions. Rhamnolipid with 13 congeners (main congener Rha-Rha-C_{10}-$C1_{2:1}$) produced by *P. aeruginosa* S6, was able to reduce ST of distilled water from 72 to 33.9 dynes/cm with CMC value 50 mg/L [28]. *P. aeruginosa* L2-1 also produced rhamnolipid with 16 congeners (Rha-Rha-C_{10}-C_{10}) with CMC value of 30 mg/L [29]. Interestingly, *P. aeruginosa* UKMP14T which produced ramnolipid with two fatty acids-nine congeners also has the same CMC value as *P. aeruginosa* L2-1, where all the congeners composed with two fatty acids. Therefore, this study put forth a suggestion that a higher amount of congeners in rhamnolipid does not necessarily lower the CMC value and that each congener present has important roles in determining the compounds surface active activities. Rhamnolipid with two fatty acids-nine congeners in this study acted as hydrophobic rhamnolipid. As a result, very low CMC value

was obtained that correlated to the higher surface activities. Moreover, determination of the CMC value is very important in the application of biosurfactant where aggregation structure of this compound will change based on this specific concentration. If it below the CMC value, the biosurfactant will exist in the form of monomers, but if it is above the CMC value, the concentration of monomers is constant and is balanced to form micelle. Micelle is a structure containing an arrangement of monomers molecule of biosurfactant by providing hydrophobic pseudo-phase inside the micelle and the hydrophilic phase outside the outer structure [30, 31]. Due to the unique characteristic of biosurfactant, it can replace the usage of synthetic surfactant in various industries including food, cosmetic, agricultural and pharmaceutical as emulsifier, stabilizer, thickener, lubricant agent, cleaner, biocontrol and anti microbial agent [32]. This study suggested the physicochemical characteristics of this rhamnolipid need to be further investigated with specific tests to determine its potential.

Conclusion

The new combination of rhamnolipid congeners produced by *P. aeruginosa* UKMP14T consist di-rhamnolipid (Rha-Rha-C_{10}-C_{10}) as main congener together with other two fatty acids-eight congeners. Spectroscopic analyses are very useful methods to elucidate structure, types of functional groups, weight and atomic percentage of different elements in the rhamnolipid. The low CMC value of this rhamnolipid indicated high surface active properties and for further study, the characteristics of physicochemical need to be determined for specification of its potential application.

PRODUCTION OF RARE EARTH ELEMENTS FROM MALAYSIAN MONAZITE BY SELECTIVE PRECIPITATION

(Penghasilan Unsur Nadir Bumi daripada Mineral Monazit Menggunakan Pemendakan Terpilih)

Abstract

Rare earth elements (REEs) are very valuable and have high demands for advanced technology nowadays. REEs can be classified to light rare earth elements (LREEs) and heavy rare earth elements (HREEs). Malaysian rare earth ore especially monazite, is rich with LREEs compared to HREEs. Therefore a study was carried out to extract the REE from Malaysian monazite. The objectives of this study are to determine the content of REEs in Malaysian monazite leach solution, as well as to produce high grade of REEs. Concentrated sulphuric acid was used in digestion process and the filtrate containing the REEs was determined using Inductively Coupled Plasma- Mass Spectrometry (ICP-MS). Ammonia solution was used for REEs precipitation from monazite leach solution. The result indicated that REEs was successfully separated from monazite leach solution through selective precipitation using ammonia at pH 2.34 and the percentage of REEs that successfully separated was 70.03 – 81.85%. The percentage of REEs which successfully separated from final solution was 96.05 – 99.10%. Therefore, to have high purification of individual REEs, solvent extraction process should be carried out.

Keywords: monazite, rare earth elements (REEs), separation, selective precipitation

Abstrak

Unsur nadir bumi sangat berharga dan mempunyai permintaan yang tinggi dalam teknologi termaju masa kini. Unsur nadir bumi dapat dikelaskan kepada unsur nadir bumi ringan (LREEs) dan unsur nadir bumi berat (HREEs). Bijih nadir bumi Malaysia terutamanya monazit kaya dengan unsur nadir bumi ringan berbanding unsur nadir bumi berat. Dengan itu, satu kajian telah dilakukan untuk mengekstrak unsur nadir bumi dari monazit Malaysia. Objektif kajian ini adalah untuk menentukan kandungan unsur nadir bumi dalam larutan larut lesap monazit Malaysia serta menghasilkan unsur nadir bumi bergred tinggi. Asid sulfurik pekat telah digunakan untuk menghadamkan monazit dan hasil turasan yang mengandungi unsur nadir bumi ditentukan menggunakan ICP-MS. Larutan ammonia telah digunakan untuk memendakan torium daripada unsur nadir bumi dari larutan larut lesap monazit. Keputusan kajian mendapati unsur nadir bumi berjaya diasingkan dari larutan larut lesap monazit melalui mendakan terpilih menggunakan ammonia pada pH 2.34 dan peratus unsur nadir bumi yang berjaya diasingkan adalah antara 70.03 – 81.85%. Peratus unsur nadir bumi yang berjaya diasingkan daripada larutan akhir pula adalah 96.05 – 99.10%. Oleh itu, bagi menghasilkan unsur nadir bumi yang berketulenan tinggi maka proses pengekstrakan pelarut perlu dilakukan.

Kata kunci: monazit, unsur nadir bumi, pengasingan, pemendakan terpilih

Introduction

Rare earths elements (REEs) are series of chemical elements found in the rare earth's crust that are vital to many modern technologies including consumer electronics, computers and networks, clean energy, communication, advanced transportation, health care and many others. There are 17 elements that are considered to be rare earth elements which are 15 elements in the lanthanide series and 2 additional elements that share similar chemical properties. 15 elements in lanthanide series are Lanthanum (La), Cerium (Ce), Praseodymium (Pd), Neodymium (Nd) and Samarium (Sm) that are classified as light rare earth elements (LREEs) meanwhile Europium (Eu), Gadolinium (Gd), Terbium (Tb), Dysprosium (Dy), Holmium (Ho), Erbiumthulium (Er) and Ytterbium (Yb) are classified as heavy rare earth elements (HREEs). Another two additional elements are Scandium (Sc) and Yttrium (Y) [1].

REEs are often found together in nature at low concentrations in various minerals. About 95% of the rare earths occur in only three minerals: bastnasite, monazite, and xenotime [2]. In Malaysian, monazite and xenotime are minerals phosphates that are present as by-product of tin mining processing. Many reports cite that Malaysia has reasonably substantial amounts of REEs. In facts, Malaysia has about 30,000 tonnes of rare earths based on the finding in the residual tin deposits [3]. Monazite contains more LREEs compared to HREEs that are associated together with NORM (Thorium and Uranium) in significant concentration. Monazite concentrate commonly contains 24.0 – 29.0% of phosphate (P_2O_5), 55.0 – 60.0% rare earth metal oxides, 5.0 – 10.0% thorium oxide (ThO_2) and 0.2 - 0.4% uranium oxide (U_3O_8) [4].

Various processing routes have been developed to recover rare earths elements from minerals. After mining, ore is beneficiated by flotation, magnetic or gravity methods to produce rare earth concentrates, which then undergo hydrometallurgical processing to recover rare earth metals or compounds [5]. The chemical treatment of monazite can be carried out via the alkaline through sodium hydroxide or via the acid by means of sulphuric acid digestion. Sulphuric acid digestion is the classical method which has been used for many years by the processing industry. The monazite leach solution produced through digestion with sulphuric acid contains REEs and others elements such as Th, U as well as phosphoric acid and excess sulphuric acid. The reaction of monazite and concentrated sulphuric acid is shown by equation 1 – 3 below [4]:

$$2RE(PO_4) + 3H_2SO_4 \longrightarrow RE_2(SO_4)_3 + 2H_2PO_4 \quad (1)$$

$$ThSiO_4 + 2H_2SO_4 \longrightarrow Th(SO_4)_2 + SiO_2 + 2H_2O \quad (2)$$

$$Th_3(PO_4)_4 + 6H_2SO_4 \longrightarrow 3Th(SO_4)_2 + 4H_2PO_4 \quad (3)$$

The high commercial value of the REEs depends on their purity and the quality of the compounds. In order to separate REEs from monazite leach solution, first selective precipitate was used to remove the thorium. The most common and promising precipitation methods are acidity control using precipitating agent. Selection of precipitating agent will depend on the specific composition of monazite leach solution. Traditionally, precipitation has been viewed from a chemical equilibrium and an inorganic cation or anion removal perspective [2]. Reducing the acidity of monazite leach solution at a pH of 1, 3, and 6 can precipitate Th, REEs and U respectively [6 7]. Meanwhile study by Gupta & Krisnamurty (2005) was showed the monazite leach solution is subsequently diluted with precipitating agent for neutralization to yield precipitates containing mainly thorium at pH 1.05, rare-earth at pH 2.3 and uranium at pH 6 [5]. Davis used sodium carbonate or sodium hydroxide to partially neutralize the monazite leach solution [8]. Meanwhile ammonia hydroxide [9] or magnesia [10] could be used to partially neutralize the monazite leach solution.

Monazite concentrate can contain up to 70% of REEs [11]. An ability to separate the REEs more than 70% can produce high grade REEs. Therefore, the objectives of this study are to determine the content of REEs in monazite leach solution as well as to produce high grade of REEs.

Materials and Methods

Preparation of monazite leach solution

Monazite sample used in this study were originally from *'amang'* factory in Perak. The monazite leach solution were prepared by digesting approximately 25 g of monazite in 50 ml of 98% sulphuric acid for 3- 4 hours at 200 –

230°C on the stirring hot plate, the mixture then was cooled to room temperature. Distilled water was added to dissolve the metal sulphates, and filtered to produce a clear solution. This clear solution was called as monazite leach solution. The monazite leach solution was diluted with distilled water to 250 mL. The content of REEs in monazite leach solution was determined using ICP-MS. The ICP-MS instrument used was an ELAN 9000 (PerkinElmer SCIEX). Prior to ICP-MS analyses, standard solution was prepared using PerkinElmer Pure Plus (multi-element calibration standard 2). It is noted that 100 mL of the 250 mL monazite leach solution was taken for the REEs and thorium analysis.

Selective precipitation of REE with ammonia solution

The acidity of monazite leach solution which contains REEs, thorium and uranium was reduced at differences pH by using ammonia solution. The measurements of pH were done using EUTECH instruments pH700. 100 mL of monazite leach solution was adjusted pH around 1.08 – 1.84 with ammonia (13.4 M) and was filtered to separate thorium. The content of REEs in filtrate solution was determined via ICP-MS. The filtrate solution again was adjusted the pH 2.34 – 3.43 with ammonia (13.4 M) to precipitate the REEs. After filtration, total REEs concentrations in the REEs precipitate was determined by dissolving it in hydrochloric acid and analysed via ICP-MS and final solution was also determined for total content of elements. Separation percentage of REEs from monazite leach solution was calculated. The flowchart REEs separation from monazite was summarized as shown in Figure 1.

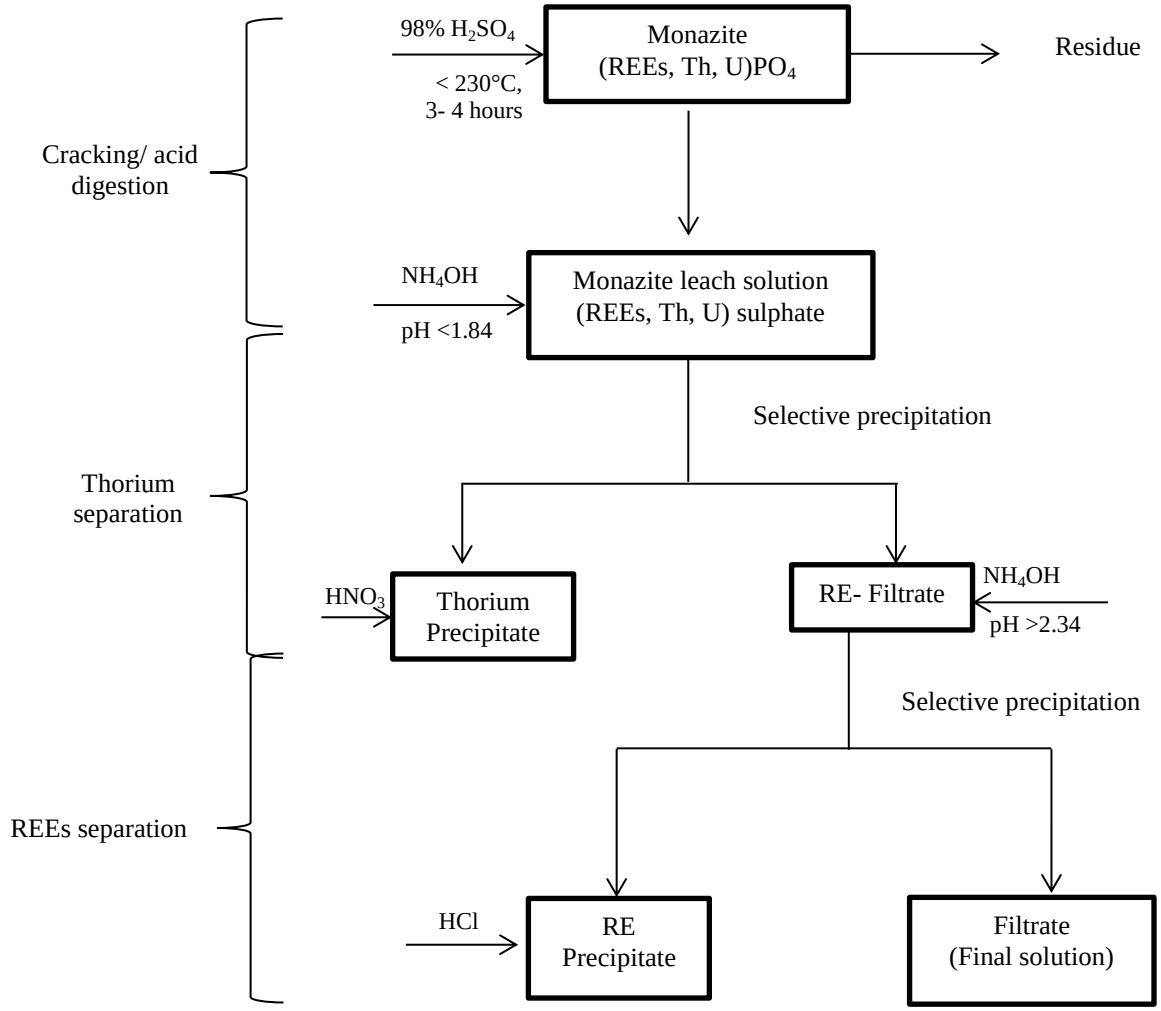

Figure 1. Simplified flowchart of REEs separation from monazite leach solution

Results and Discussion

The content of REEs in monazite leach solution

The result of REEs contained in 100 mL monazite leach solution was presented in Table 1. There are six LREEs and seven HREEs were determined by ICP-MS. The total concentration LREEs in 100 mL of monazite leach solution were Ce, La, Nd, Pr, Gd and Sm which contain 131.25, 75.87, 53.33, 14.77, 12.29 and 11.11 mg respectively. Meanwhile the HREEs determined were in range of 1.93–15.41 mg. The total content of LREEs were 298.62 mg and their amounts represent 69.17% of the total element in monazite leach solution. Monazite contains up to 70% REEs, primarily Ce and La as well as significant amount of Nd, Pr and Sm, from LREEs group [11]. The result shown clearly the content of LREEs was more abundant compared to HREEs in Malaysian monazite. Meanwhile, the monazite leach solution was prepared also contains significant amount of thorium. The presence of thorium in monazite leach solution was quite high, which is a concern in REEs separation processing. This study shown the percentage of thorium was contained in monazite leach solution more than HREEs. The percentage of thorium in 100 mL monazite leach solution determined was 19.40% compared to HREEs was 11.43%. This way was normal because the monazite mineral was considered as a source of world supply for both LREEs and thorium [12], whereas the higher content of HREEs could be found in xenotime and bastenite.

Table 1. The mean content of light rare earth elements, heavy rare earth elements and Thorium in 100mL monazite leach solution

Separation of REEs from monazite leaches solution

As mentioned above, monazite leach solution contains high concentration of thorium that should be removed first. Thorium is a radioactive element but it is valuable to use in nuclear reactor as nuclear fuel. Therefore, thorium was removed from monazite leach solution by gradually reducing the acidity until the insoluble thorium phosphate precipitated. The REEs phosphates were more soluble and remained in solution. Precipitation of thorium by ammonia solution at pH < 1.84 was done and the result was indicated in Table 2.

The result shown that an only small amount of REEs was precipitated and more than 96% of REEs left in the filtration. Kernal (1953) reported that at pH 1.6, 99% of thorium had precipitated together with only a few percent of REEs [13]. However, this study showed at pH 1.08 – 1.84 about 97.68% of thorium was precipitated with presence only 1.61- 3.08% of REEs. The total percentages of LREEs and HREEs in the filtrates are 97.33 and 97.93% respectively. It clearly showed that total percentage in rare earth filtrate for both LREEs and HREEs have no significant difference. The content of REEs in rare earth filtrate was in range 1.89 ± 0.06 - 127.58 ± 3.77 mg.

The higher content of REEs in rare earth filtrate was continued with second precipitation using ammonia solution at pH more than 2.34 and the result was shown in Table 3. The total content of LREEs and HREEs in rare earth precipitated were 230.95 and 36.21 mg respectively. From the result, the content of REEs determined in final solution very low was in range 0.04 – 2.59 mg. In comparison the total percentage of separation for LREEs and HREEs, the LREEs has shown the high total percentage separation was 98.18% whereas HREEs was 95.36%. The highest percentage separation was 99.10% of Sm while the separation of Ce which represents the major constituent of the LREEs was about 98.61%. On the other hand, for HREEs the Tb has shown high percentage of separation about 97.93%. Meanwhile, the content of thorium in final solution was 0.01 ± 0.00 mg and in percent of separation was 99.99%. Based on this result, it means almost all the thorium was successfully separated from the REEs.

Table 2. The mean content of REEs and Thorium in rich rare earth filtrate

Atomic number	**Elements**	**Total content of elements in 100 ml of leach solution (mg)**	**Total content of REEs in RE- filtrate (mg)**	**Percentage of separation (%)**

NORM				
90	Th	83.76± 1.17	1.94 ± 1.17	2.32

The percentage of individual precipitate at pH < 1.84 and pH > 2.34 was illustrated in Figure 2. It is clear that recovery of REEs at pH > 2.34 was above 70%. Meanwhile, less than 5% of REEs was precipitated at pH < 1.84. It can figure out that most of REEs was separated during ammonia precipitation and the optimum pH for REEs removal was in pH > 2.34. In addition to the effect of different pH, concentration of ammonia as a precipitant affect was affected of the separation percentage results. This study shown the percentage of REEs was successfully separated was in range 96.05 – 99.10%. Monazite can contain up to 70% REEs [11] and in this experiment was shown more than 70% of REEs was separated. It implies the high grade REEs was successfully produced via selective precipitation at selected pH value.

Table 3. The separation percentage of REEs and Thorium from monazite leach solution

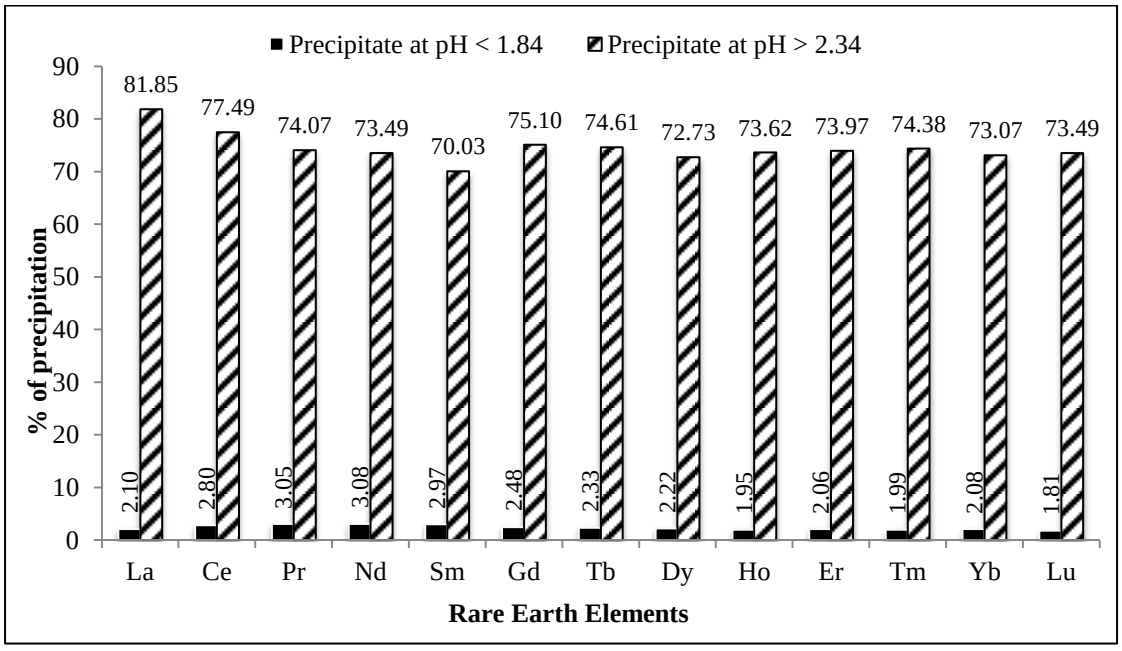

Figure 2. Percentage of individual REEs precipitated with ammonia solution at pH < 1.84 and pH > 2.34

This experiment will be continued by purification process to produce high-purity REEs. The resulting solution then will undergo further purification by solvent extraction with organic extractants in kerosene. Commercially, there are three organic extractant are chosen i.e di(2ethylhexyl)phosphoric acid (D_2EHPA), Tributylphosphate (TBP) and aliquat-336. The solvent extraction is usually used to separate individual REEs or produce mixed rare earth compounds.

Conclusion

Monazite leach solution was prepared by digesting the monazite with concentrated sulphuric acid. The content of REEs in the monazite leach solution is rich with LREEs with percentage 69.17% compared to HREEs only 11.43%. The presence of thorium in monazite leach solution was quit high. The REEs was separated from monazite leach solution through selective precipitation using ammonia at pH > 2.34 and the recovery percentage of REEs was 70.03 – 81.85%. The percentage of REEs was successfully separated from final solution was 96.05 – 99.10%. Therefore, high grade REEs can be obtained by selective precipitation from monazite leach solution. In order to have high purification of individual REEs, multistage solvent extraction should be carried out.

Abstract

Determination of volatile organic compounds (VOCs) in various matrices is often accomplished using solid phase microextraction (SPME) as a superior mode of extraction. Alternatively, another configuration of solid phase microextraction (SPME) namely hollow fiber-solid phase microextraction (HF-SPME) is a great approach to redress some limitations of the ordinary SPME fibers including fiber breakage, coating stripping and sample carry over. The HF-SPME technique highlights the use of hollow polypropylene (PP) membrane to hold and protect the adsorbent inside its lumen. Unlike the conventional SPME, the inexpensive HF device can be disposed after single use. Introducing extracting phase via sol-gel technology has gained great interest owing to its simple preparation method and promising way to obtain materials with good characteristics. In the present work, a new hybrid silica material based on methyltrimethoxysilane-(3-mercaptopropyl)trimethoxysilane (MTMOS-MPTMOS) was introduced as a new extractant of HF-SPME and the effectiveness of the proposed method was tested for analysis of hexanal and heptanal as the target VOC analytes. Preparation of the HF-SPME MTMOS-MPTMOS was simple in which the hybrid material was synthesized via sol-gel method and was self-polymerized in small segments of HF. Parameters affecting the efficiency of the HF-SPME MTMOS-MPTMOS in extracting both aldehydes were thoroughly investigated and analyzed by gas chromatography-flame ionization detection (GC-FID). It was found that the highest efficiency was achieved as the extraction was conducted in 30 min at a stirring rate of 1000 rpm in a 10 mL of sample solution whereby the back-extraction was performed via vortex for 3 min using 100 µL methanol as desorption solvent. Under the optimal conditions, linearity was observed over a range of 0.020-10.00 µg mL^{-1} with detection limits of 0.015 µg mL^{-1} and 0.010 µg mL^{-1} for hexanal and heptanal, respectively. The applicability of the HF-SPME MTMOS-MPTMOS for analysis of hexanal and heptanal in human urine sample was proven from the quantitative recoveries (> 90%) achieved. The HF-SPME MTMOS-MPTMOS offers an attractive alternative for rapid and convenient extraction tool and showed good potential for analysis of hexanal and heptanal from aqueous samples.

Abstrak

Penentuan sebatian organik meruap (VOC) dalam pelbagai matriks sering dicapai dengan pengekstrakan mikro fasa pepejal (SPME) sebagai mod unggul pengekstrakan. Sebagai alternatif, pengekstrakan mikro fasa pepejal-gentian berongga (HF-SPME) adalah pendekatan yang baik untuk mengatasi kekangan gentian SPME biasa termasuk kerapuhan gentian, salutan tertanggal dan

baki sampel suntikan tertinggal. Teknik HF-SPME mengetengahkan penggunaan membran polipropilena (PP) berongga untuk memegang dan melindungi fasa pengekstrak dalam lumen HF. Tidak seperti konvensional SPME, alat HF yang murah boleh dibuang selepas sekali penggunaan. Menghasilkan fasa pengekstrak melalui teknologi sol-gel telah mendapat perhatian luas kerana kaedah penyediaan yang mudah dan cara yang memberangsangkan untuk menghasilkan bahan dengan ciri-ciri yang baik. Dalam kajian semasa, bahan silika hibrid baharu berdasarkan metiltrimetoksisilana-(3-merkaptopropil)trimetoksisilana (MTMOS-MPTMOS) telah diperkenalkan sebagai bahan penjerap baharu HF-SPME dan keberkesanan kaedah yang dicadangkan telah diuji terhadap analisis heksanal dan heptanal sebagai analit VOC sasaran. Penyediaan HF-SPME MTMOS-MPTMOS adalah mudah yang mana bahan hibrid ini telah disintesis menggunakan kaedah sol-gel dan telah diswapolimer di dalam segmen kecil HF. Parameter yang mempengaruhi kecekapan HF-SPME MTMOS-MPTMOS dalam mengekstrak kedua-dua aldehid telah dikaji dengan teliti dan dianalisis menggunakan kromatografi gas-pengesan pengionan nyala (GC-FID). Kecekapan tertinggi telah dicapai apabila pengekstrakan dijalankan selama 30 min pada kadar kacauan 1000 rpm di dalam 10 mL larutan sampel yang mana pengekstrakan-kembali dilakukan melalui vorteks selama 3 min menggunakan 100 µL metanol sebagai pelarut penyahjerapan. Pada keadaan optimum, julat linear ialah 0.020-10.00 µg mL^{-1} dengan had pengesanan bagi heksanal dan heptanal masing-masing ialah 0.015 µg mL^{-1} and 0.010 µg mL^{-1}. Kesesuaian HF-SPME MTMOS-MPTMOS untuk analisis heksanal dan heptanal dalam sampel air kencing manusia terbukti dengan perolehan kuantitatif yang dicapai (> 90%). HF-SPME MTMOS-MPTMOS menawarkan alternatif menarik sebagai alat pengekstrakan yang cepat dan mudah serta menunjukkan potensi yang baik untuk analisis heksanal dan heptanal daripada sampel akueus.

Introduction

Aldehydes are common carbonyl compounds that take part in the pathology of certain diseases and their presence have been suggested as degradation products of lipid peroxidation [1, 2]. Besides, aldehydes were predominately VOCs biomarker found at elevated concentrations level in lung cancer subjects. In particular, hexanal and heptanal have been extensively studied as potential lung cancer biomarkers that can be measured in different biological samples [3 – 6]. The accurate determination of volatile compounds in biological samples is a major constraint due to the presence of overwhelming matrix effects and the analyte concentration might be too low to be analysed directly. Thus, searching for a reliable extraction technique is of vital importance. The prevalent extraction method employed to analyze aldehydes is solid phase microextraction (SPME) [2 – 6]. Specifically, carboxen/ polydimethylsiloxane (CAR/PDMS) [3] and polydimethylsiloxane/divinylbenzene (PDMS/DVB) [4 – 6] are two well-known SPME fibers that were used for the determination of aldehydes. SPME is a rapid and simple technique. Extraction, preconcentration and sampling can be carried out as a single step. However, SPME has certain limitations such as commercially available fibers are not chemically stable due to mere physical deposition or partial cross linking of the polymer coating. In addition, the ordinary SPME fibers suffer from low recommended operating temperature, fragile, limited lifetime and is expensive [7, 8]. Other than ordinary SPME fiber, several methods were developed for analysis of hexanal and heptanal in biofluids [9 – 11]. However, the proposed techniques involved complicated preparation material or extraction procedure. This is time consuming as it adds extra step in the sample preparation steps.

Sol-gel technology offers the simplest way to obtain adsorbent with good characteristic for extraction purpose. Various adsorbents were synthesized by sol-gel method including the combination of sol-gel precursors with other different coating materials to enhance the properties of extracting phase [12 – 16]. Some inherent advantages of sol-gel process that can redress the limitations of commercial SPME are; porous structure material with high surface areas for better analytes adsorption, coating is stable towards high temperature, good adhesion towards fiber as support owing to chemical bonding [17 – 19]. However, there are still several factors impeding the use of SPME fiber including troublesome in pre- and post-gelation treatment, long conditioning time needed before first use, and sample carryover during analysis. Emerging of different configurations of solid-based extraction is a promising solution and alternative to the above-mentioned problem.

Recently, Es'haghi et al. [20, 21] has come out with a new SPME approach namely hollow fiber-solid phase microextraction (HF-SPME). Instead of using a fiber, small segments of polypropylene HF were used for coating purpose. The possible memory effect can be avoided by discarding the HF tool after single use. Besides, the use of porous polypropylene enables to eliminate matrix interferences by prohibiting the larger molecules enter/adsorb

onto the coated material, thus, promotes clean extraction. HF-SPME technique was successfully applied for the determination of different types of compounds including phenobarbital [21] organophosphorus pesticides [22, 23] selected aflatoxins [20], diclofenac and piroxicam [24], diethylstilbestrol [25], metronidazole [26] and heavy metals [27]. Introducing HF-SPME extracting phase via sol-gel method is a good approach since the HF can act as a medium to hold the sol-gel material and in the same time, simple preparation of sol-gel material can be accomplished by in-situ gelation process of sol solution in the lumen of HF. To the best of our knowledge, no development of sol-gel hybrid materials for use as adsorbent material has been reported for the determination of hexanal and heptanal, particularly for HF-SPME. Therefore, in the present work, the sol-gel material based on methyltrimethoxysilane-(3-mercaptopropyl)trimethoxysilane (MTMOS-MPTMOS) is proposed to be employed as the main extractant of HF-SPME for the determination of hexanal and heptanal in aqueous samples.

Materials and Methods

Standards and Chemicals

Methyltrimethoxysilane (MTMOS), (3-mercaptopropyl)trimethoxysilane (MPTMOS), trifluoroacetic acid (95%) and polymethylhydroxysiloxane (PMHS) were obtained from Aldrich (St. Louis, MO, USA). HPLC grade methanol was purchased from Fisher Scientific (Leicestershire, UK) and deionized water was produced from a Millipore water purification system (Molsheim, France). Accurel Q3/2 polypropylene tubular membranes from Membrana (Wuppertal, Germany) with a wall thickness of 200 µm, pore size of 0.2 µm, and an ID of 600 µm were used for the HF-SPME device. Hexanal and heptanal were purchased from Merck Schuchardt (Hohenbrunn, Germany). Individual stock solution (1000 µg/mL) of hexanal and heptanal was prepared by dissolving the calculated amounts in HPLC grade methanol and fresh working solutions were prepared in methanol daily by further dilution of the stock solution.

Instrumentation

A 7820A Agilent GC from Agilent Technologies (Waldbronn, Germany) equipped with a HP-5 (5% phenyl methyl siloxane) column (30 m × 0.32 mm ID and 0.23 µm film thickness), a split/splitless injector and flame ionization detector (FID) was used for analysis of extracted hexanal and heptanal. Helium was used as the carrier gas at a flow rate of 1 mL/min. The flow rate of air as oxidant was set at 400 mL/min while the flow rate of hydrogen was set at 30 mL/min. All gaseous sources were supplied from Linde Malaysia (Kuala Lumpur, Malaysia). The oven temperature program was as follows: initial temperature of 50 °C, ramp to 80 °C at a rate of 10 °C/min, then to 180 °C at a rate of 40 °C/min to obtain a run time of 5.5 min. The inlet temperature used was 250 °C and the FID temperature was set at 280 °C.

The sol-gel MTMOS-MPTMOS was characterized using a Perkin Elmer FT-IR Spectrometer (Shelton, USA) in the region 650-4000 cm^{-1} via attenuated total reflectance (ATR) method. The images of the HF-SPME MTMOS-MPTMOS was captured with a Hitachi S3400N scanning electron microscopy (SEM) (Tokyo, Japan) using back-scattered electrons (BSE) mode at an accelerating voltage of 15 kV and low vacuum of 30 Pa.

HF membrane preparation

The polypropylene (PP) HF membrane was cut into ~ 2.5 cm segments and cleaned with acetone. It was then air dried before being injected with 6 µL of the prepared sol solution [22]. Both sides of the HF devices were heat-sealed before used. The sol solution was prepared by mixing appropriate volumes (µL) of precursors (MTMOS and MPTMOS), water, TFA (95%) as acid-catalyst, methanol (MeOH) as solvent and polymethylhydroxysiloxane (PMHS) in a 2 mL centrifuge tube to produce the desired mol ratios. The mixtures were vortexed for 2 min followed by centrifugation at 15 965 × *g* for 5 min. Then the homogenous solutions were directly injected into the lumen of the HF to allow for in-situ gelation. To ensure that the sol solidified in the HF, it was left at ambient temperature for overnight. The HF-SPME devices were then kept in an oven at 100°C for further drying before use.

HF-SPME Procedure

Typical HF-SPME extraction was performed using direct immersion mode in a sample vial containing 10 mL of deionised water spiked with an appropriate volume of a working standard hexanal and heptanal solution to obtain a final concentration of 10.0 µg/mL. To achieve the highest extraction efficiency, systematic studies were performed in triplicate for the optimization of several parameters including extraction time (15 - 70 min), sample volume (3 -

20 mL), sample stirring rate (450 – 1000 rpm) and salt addition (0 – 2.0%, w/v). After extraction, the PP HF membrane tool was transferred into a 2 mL vial containing an appropriate volume of suitable organic solvent (methanol, MeOH) prior to desorption process. For back-extraction, vortex-assisted method was selected to desorb the extracted analytes for 3 min. Parameters affecting desorption process including desorption solvent volume (80 – 500 µL) and vortex speed (15.8 – 86.4 × *g*) were also studied.

Preparation of real samples

The urine samples were obtained from healthy volunteers and stored at -2°C. An aliquot of the human urine samples was spiked with an appropriate amount of hexanal and heptanal. The urine samples were then diluted two times with deionised water and filtration through a 0.20 µm membrane filter prior to extraction. The same extraction procedure was applied for the spiked human urine and blank human urine sample (without spiking), similar to above-mentioned HF-SPME procedure.

Method Validation

The analytical performance of HF-SPME MTMOS-MPTMOS was validated in terms of repeatability, linearity, limit of detection (LOD) and limit of quantification (LOQ) using the optimized extraction conditions. The within batch and inter-batch precision were evaluated based on relative standard deviation in which the repeatability of extraction was calculated using 4 replicates. Linearity was obtained from the construction of calibration curve from 0.020 - 10.0 µg mL^{-1}. The LOD was determined at signal-to-noise ratio (S/N = 3) whilst the LOQ was determined at signal-to-noise ratio (S/N = 10). Accuracy (recovery) of the proposed HF-SPME MTMOS-MPTMOS method was assessed by spiking 1.0 and 0.25 µg mL^{-1} of hexanal and heptanal in human urine sample.

Results and Discussion

Preliminary Study

In order to assess the potential and effectiveness of the proposed sol-gel silica-based hybrid material in extracting hexanal and heptanal, effect of sol-gel process such as precursor, water, solvent and acid catalyst were optimized. Selection of optimal sol-gel synthesis was based on extraction efficiencies (measured by peak area response) obtained from GC-FID.

Effect of precursor

Precursors are the backbones of sol-gel polymer and synthesis of extracting phase using only precursors is much easier, faster, cheaper and more controllable as compared to addition of coating polymer [28]. In this study, the extracting phase was synthesized based on two precursors; MTMOS and MPTMOS. MTMOS is a good selection of precursor as the sol-gel network originating from an alkyl derivative of a tetraalkoxysilane precursor possesses a more open structure which can minimize cracking and shrinkage problems during drying step [29]. Meanwhile, the addition of MPTMOS that possess thiol (-SH) moiety can alter the polarity of the sol-gel hybrid formed thus enhance the possibility to extract the two mid-polar hexanal and heptanal more effectively.

Initially, the MTMOS amount was kept constant at 1 mmol whereas the addition of MPTMOS was evaluated at different mol ratios (1 – 7 mmol). Trifluoroacetic acid (TFA) as acid catalyst and methanol (MeOH) as solvent were fixed at a 2.5 and 6.0 mmol, respectively. PMHS as a deactivation agent (25 µL) was added to each sol solutions. As the mol ratios of MTMOS: MPTMOS was increased gradually from 1:1 to 1:4, better peak area response of hexanal and heptanal was obtained. However, further increase of MPTMOS from 5 mmol to 7 mmol resulted in a decrease of extraction performance for the two aldehydes. At higher mol of MPTMOS, the increase number of thiol moieties possibly led to covalent formation of disulphide (-S-S) [30]. This behavior decreased the number density of the bridging oxygen -Si-O-Si- as the network backbone thus alter the features of the sol-gel material in which the coated HF-SPME was easily ruptured. Therefore, the mol ratio 1:4 MTMOS: MPTMOS was selected as the optimum sol-gel composition and was used for further study.

Effect of water

Water is needed in sol-gel process to hydrolyze the precursors to form the reactive species for condensation reaction that leading to the formation of 3-D network [31]. In the present work, the sol-gel based on 1:4 mol ratio MTMOS: MPTMOS materials were prepared using different mol ratios of water from 3 mmol to 9 mmol, keeping the other

amount constant (6 mmol MeOH, 2.5 mmol TFA). Addition of 3 mmol water in sol solution resulted in the lowest extraction efficiency of hexanal and heptanal. It is possible that in the presence of small amount of water content in sol system, both precursors (MTMOS and MPTMOS) compete with each other to be hydrolyzed and only partial of the precursors enable to form reactive species for further reaction process. As the water content was increased from 3 mmol to 6 mmol, increasing in peak areas response were observed for hexanal and heptanal. Based on stoichiometric calculation, both MTMOS and MPTMOS have three methoxy groups each that can be hydrolyzed. This is parallel with the results obtained as the addition of 6 mmol of water in the sol system gave the highest peak area response. Further increase of water content from 7 to 9 mmol resulted in a reduction of extraction performance of the sol-gel hybrid material. It seems that the addition of higher volume of water content may not be necessary as water is also eliminated during the condensation process to produce the 3-D networks. In short, 6 mmol was selected as the optimum amount of water and was used for further investigation on sol-gel synthesis optimization.

Effect of acid catalyst

Catalyst plays a role in hydrolysis part of sol-gel process in which under acidic condition, the sol solution will undergo polymerization to form long, linear and poorly cross-linking material which is suitable for coating purpose or thin film end-product [32]. TFA, commonly used as acid catalyst, was adopted in this study. TFA is favourable since the organic acid could disperse in the organic matrix more evenly as compared to inorganic acid and enable to minimize crack formation as reported by Chen and co-workers [33]. The different mol of TFA varied from 1 mmol to 3.5 mmol were mixed in the sol solution consisting of 1 mmol MTMOS, 4 mmol MPTMOS, 6 mmol water and 6 mmol MeOH. According to the peak areas obtained (data not shown), using 2.5 mmol TFA (95%) gave the highest extraction efficiency, hence, was selected as the optimum acid mol in sol-gel MTMOS-MPTMOS.

Effect of solvent

Solvent is added in sol system to facilitate mixing of sol-gel precursors, water and deactivating reagents into a homogenous system [34]. In the current work, MeOH was used as the sol-gel solvent system and the effect of the solvent was investigated from 4-9 mmol. Higher peak areas of hexanal and heptanal were observed as MeOH was increased from 4 mmol to 7 mmol in sol solution. The apparent increase in signals is due to the increase amount of solvent which will favor more precursors to be solvated, hence increase the reaction rates of polymerization. However, addition of higher volumes of solvent (8 mmol and 9 mmol) caused a reduction in peak area performance for both hexanal and heptanal. This behavior is probably due to the excess amount of solvent which will dilute the sol solution and thus reduce the precursor concentration [31]. Thus, 7 mmol MeOH was selected as the optimum solvent to be added in the sol solution.

In brief, the optimum sol-gel MTMOS-MPTMOS in extracting the two aldehydes was 1 mmol MTMOS, 4 mmol MPTMOS, 6 mmol H_2O, 7 mmol MeOH, 2.5 mmol TFA (95%) and PMHS was added at a constant volume (25 µL) in the sol solutions. The optimization of sol-gel synthesis become more convenient and faster as the preparation of sol solution involved merely one-pot reaction at mild condition including vortex and centrifugation procedure before directly injected into the lumen of HF (the whole process takes ~10 min). Likewise, sol-gel hybrid is simply self-polymerized after left overnight and no troublesome post-gelation procedure is needed. SEM image of HF-SPME MTMOS-MPTMOS device is shown in Figure 1. It can be seen a thin layer coating surrounded the inner wall of hollow fiber with estimated thickness of 30 µm. Meanwhile, the small insert image indicates the sol-gel coating possesses a porous surface in which the pores are evenly distributed with average pore size of ~0.7 µm.

FTIR Characterization

To prove the existence of inorganic-organic networks in the synthesized material, the material was characterized using FTIR. The absorption bands of sol-gel hybrid MTMOS-MPTMOS spectrum are nearly identical to both spectra of MTMOS and MPTMOS precursors (Figure 2). The broad absorption band at wave number 3397.14 cm^{-1} corresponds to -OH stretching mode. This is possibly due to the presence of water or methanol in the sol-gel material. CH-stretching mode can be observed at wave number 2930.41 cm^{-1} but at lower intensity as compared to precursor's spectra. A very weak absorption band at 2556.02 cm^{-1} is due to the existence of thiol (-SH) functional group in the sol-gel hybrid. Even though the intensity is very low, it is similar to the absorption of pure MPTMOS precursor. Two wave numbers at 1000.15 cm^{-1} and 1091.13 cm^{-1} correspond to Si-O-Si absorption. The presence of the two bands with broader absorption at 1000.15 cm^{-1} and 1091.13 cm^{-1} as compared to spectra of MTMOS and

MPTMOS precursor indicates that siloxane chains become longer or branched, hence proved the successful polymerization of alkoxides to form Si-O-Si network.

Optimization of HF-SPME Performance

To obtain the highest extraction efficiency in extracting the two target aldehydes in aqueous samples, several parameters affecting the HF-SPME MTMOS-MPTMOS extraction performance were evaluated and optimized.

Selection of desorption method

Two desorption methods namely ultrasonication and vortex were used to back-extract the two analytes of interest. It was found that 20 min was the optimum desorption time using ultrasonication technique. In contrast, comparable peak efficiency for both aldehydes was obtained when desorption was performed via vortex for 3 min. As shorter analysis time is more practical, desorption via vortex for 3 min was selected for subsequent study.

Effect of extraction time

HF-SPME technique is based on an equilibrium process in which mass transfer is time-dependent. Thus, extraction time is a crucial factor to be optimized as the solute molecules need sufficient time to transfer from sample solution to HF interface and adsorbed onto the sol-gel material [21, 22]. In this work, different extraction times ranging from 15 min to 70 min were evaluated at ambient temperature and other extraction parameters were kept constant at a stirring rate of 600 rpm and sample volume of 10 mL while back-extraction was performed via vortex-assisted for 3 min using 100 µL MeOH (Figure 3). The selectivity of the fibre was found to be significantly higher for heptanal compared to hexanal. The extraction efficiency of hexanal and heptanal increased up to 30 min and no apparent signal differences was observed when extraction was increased from 40-70 min. Thus, 30 min was chosen as the optimum extraction time and was used for further study.

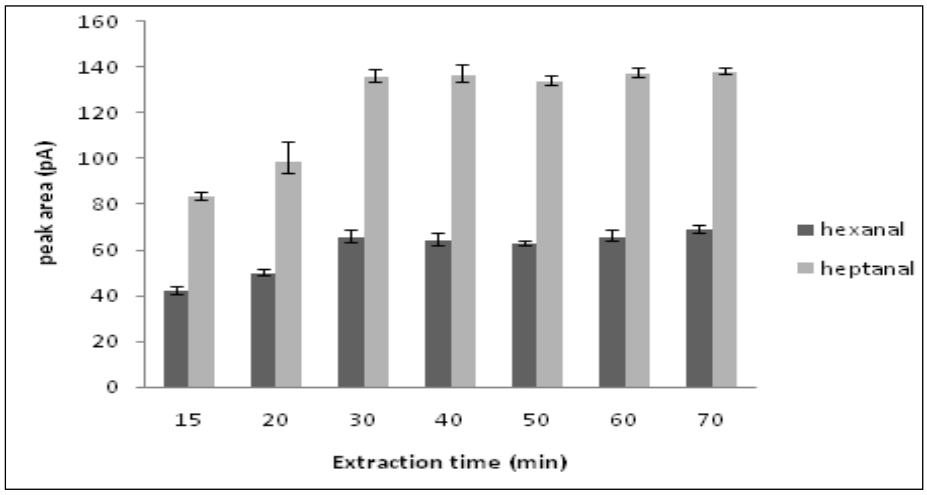

Figure 3. Effect of extraction time on the HF-SPME extraction efficiency (based on peak area). Extraction conditions: sample volume, 10 mL; stirring rate, 600 rpm. Desorption conditions: desorption solvent, MeOH; vortex assistance desorption for 3 min; vortex speed, 44.1 × *g*; desorption volume, 100 µL.

Effect of sample stirring rate and sample volume

Agitation of sample solution is favourable in extraction as it will shorten the required time needed for the analyte/s to reach equilibrium thus reduce the extraction time [21]. Effect of different stirring rate (450-1000 rpm) was tested for the HF-SPME MTMOS-MPTMOS extraction (Figure 4a). Higher stirring rate (beyond 1000 rpm) was avoided as it led to formation of excessive bubble during extraction and in the same time vigorous collision occurred between the HF and the vial wall. It was observed that higher stirring rate resulted in higher extraction efficiency as it can enhance the mass transfer of the analyte/s towards the extractant. Agitation at 1000 rpm showed the best extraction efficiency for hexanal and heptanal, thus, it was chosen as the optimum sample stirring rate.

During the HF-SPME process, the interaction between the analytes in the sample solution and the extractant is based on equilibrium, hence the ideal sample volume is also play a role to achieve the optimum extraction efficiency. Sample volume as a donor phase was varied from 3 – 20 mL (Figure 4b) for 30 min extraction time with an agitation rate of 1000 rpm while back-extraction was performed via vortex-assisted method for 3 min in 100 µL MeOH. Increasing the sample volume stepwise from 3 mL to 10 mL enhanced the peak areas of hexanal and heptanal. On the contrary, further volume increase to 15 mL and 20 mL gave poorer extraction efficiency for both aldehydes. This is probably due to poorer mass transfer kinetics in larger sample volume that resulted in the poor extraction efficiency observed. Therefore, 10 mL was chosen as the best sample volume for HF-SPME MTMOS-MPTMOS extraction.

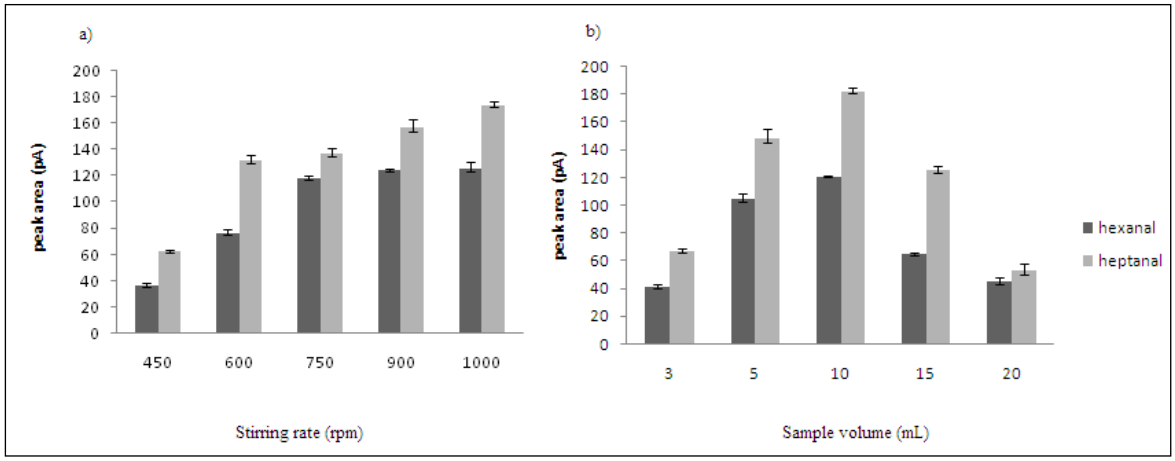

Figure 4. Effect of (a) sample stirring rate and (b) sample volume on the HF-SPME extraction efficiency (based on peak area). Other conditions are as in Figure 3.

Effect of salt addition

In most cases, salt is added to increase the ionic strength and to decrease the solubility of analyte/s in sample solution. In the present work, addition of sodium chloride was investigated at different concentrations from 0.5 - 2.0%, *w/v* (Figure 5) and the results were compared with the sample solution without the addition of sodium chloride. It was found that the higher the addition of salt concentration in sample solution, lower extraction efficiency of hexanal and heptanal was obtained. This is probably due to the presence of salt that can alter the properties of material coated in the tube of HF, change the diffusion rates hence, less analyte/s transfer to the extractant. Similar behavior was reported by Ebrahimi et al. [22]. Therefore, salt addition was not significant to be utilized for HF-SPME MTMOS-MPTMOS extraction of hexanal and heptanal.

Effect of desorption volume

Selection of appropriate volume of solvent is essential for the desorption capacity and to strip the analytes of interests from the sorbent phase. In this study, methanol was used as desorption solvent and the solvent volume was varied from 80 µL to 500 µL (Figure 6). Increase in extraction efficiency was observed for hexanal and heptanal when amount of the desorption volume was reduced. This is expected as the lower the desorption volume, the higher the preconcentration factor obtained. However, using a 80 µL desorption solvent resulted in peak decrease. The reason is, the volume level did not completely immerse the HF segments thus resulted in improper back-extraction of analyte/s. As the highest extraction efficiency was achieved using 100 µL of methanol, this volume was selected as the best desorption volume.

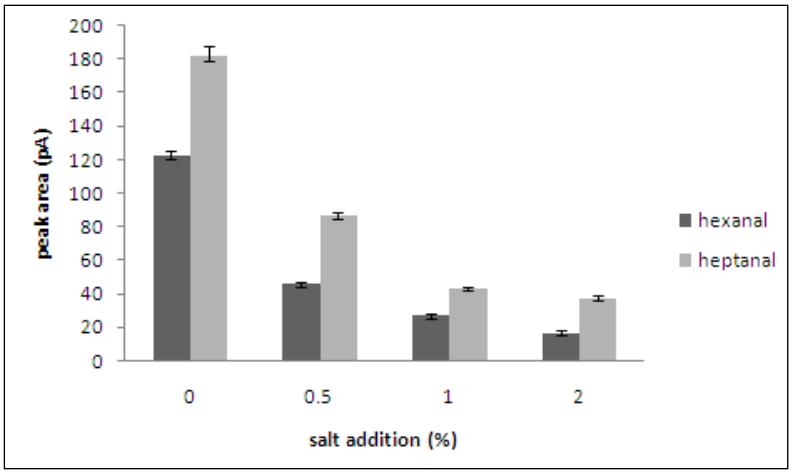

Figure 5. Effect of salt addition on the HF-SPME extraction efficiency (based on peak area). Other conditions are as in Figure 3.

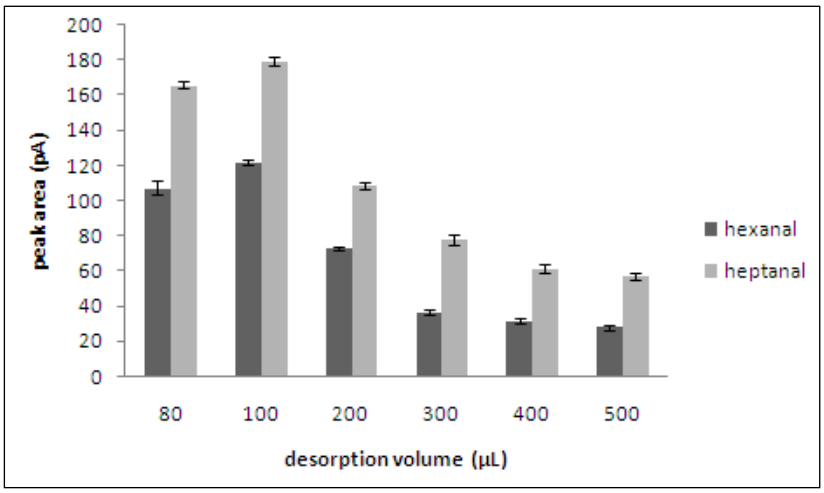

Figure 6**.** Effect of desorption volume on the HF-SPME extraction efficiency (based on peak area). Other conditions are as in Figure 3.

Effect of vortex speed

In this study, desorption was performed by vortex-assisted method. To select the ideal vortex speed, different vortex speed was explored within the range of 15.8 - 86.4 × *g* (Figure 7). As expected, increasing the speed of vortex provided higher extraction efficiency and the highest peak areas response of both aldehydes were obtained when the applied speed rate was 63.5 × *g*. Increasing the vortex speed to 86.4× *g* led to massive bubble formation and this is a fast speed to use to back-extract the analyte/s in 100 µL of desorption solvent, resulting in the reduction of extraction efficiency for both hexanal and heptanal. As vortex assistance desorption at 63.5 × *g* gave the highest extraction efficiency in determining hexanal and heptanal, it was chosen as the best vortex speed.

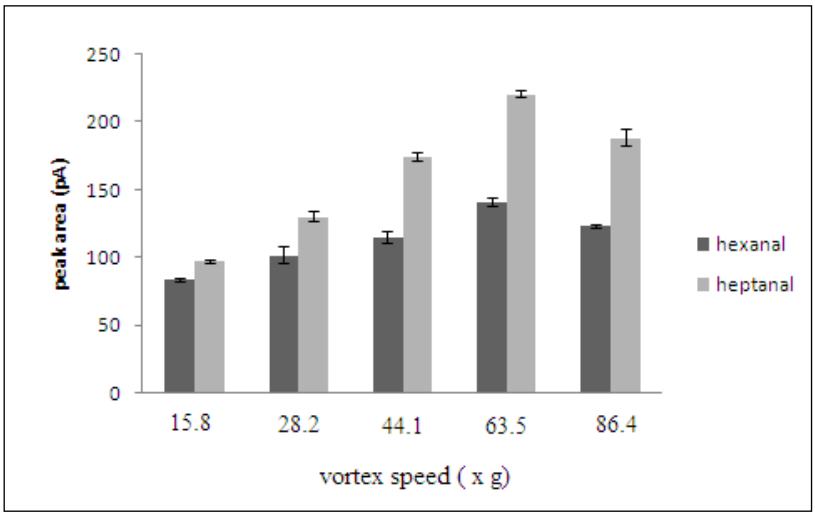

Figure 7. Effect of vortex speed on the HF-SPME extraction efficiency (based on peak area). Other conditions as in Figure 3.

Method Validation

Optimum extraction performance of hexanal and heptanal based on peak area response measured by GC-FID was achieved using 30 min extraction time, 1000 rpm agitation rate using 10 mL of aqueous sample, back-extraction of extracted analytes performed via vortex for 3 min at a speed of 63.5 × *g* using 100 µL methanol as the desorption solvent. Table 1 summarizes the calibration curve equation, limit of detection (LOD = 3 S/N), limit of quantification (LOQ = 10 S/N)) together with their coefficient of determination (R^2) and precision (intra batch and inter-batch) of HF-SPME MTMOS MPTMOS under the optimum extraction conditions. Linearity order observed was 500 with good coefficient of determination (> 0.996).

Table 1. Calibration curve equation, coefficient of determination, LOD, LOQ and precision values (within batch and inter-batch) HF-SPME at optimum conditions

Compound	Calibration curve Equation	Coefficient of determination (R^2)	LOD (µg/mL)	LOQ (µg/mL)	Within batch RSD (%, *n* = 4)	Inter batch RSD (%, *n* = 4)
Hexanal	y = 0.013x + 4.568	0.9985	0.015	0.040	3.82	7.86
Heptanal	y = 0.021x + 6.378	0.9969	0.010	0.030	3.25	9.36

Linear range: 0.020 –10.0 µg mL^{-1}

The applicability of the proposed HF-SPME MTMOS-MPTMOS method was tested on human urine from a healthy volunteer. Urine samples were spiked with hexanal and heptanal standard at certain concentrations after confirming the non-presence of the two aldehydes. Two levels of spiking were used in order to compare the recovery and precision values. Quantitative percentage recoveries were obtained for hexanal and heptanal (91.21 – 97.51 %, RSD < 5.5%, *n* = 3) (Table 2). Figure 8 shows the chromatograms of extract of blank and spiked urine samples (at 0.25 µg/mL of hexanal and heptanal) using HF-SPME MTMOS-MPTMOS. Based on the chromatograms, it is noticed that there was no significant interference from the sample matrix thus proved that HF-SPME method provided clean extraction.

Table 2. Average recovery of hexanal and heptanal in spiked urine sample

Analyte	Spiked concentration (µg/mL)	Average recovery (%)	RSD (%, *n* = 3)
Hexanal	1.0	97.51	3.28
	0.25	95.34	5.58
Heptanal	1.0	93.16	4.00
	0.25	91.21	2.78

**All extractions were carried out at optimum conditions*
**n = 3 (three different extractions)*

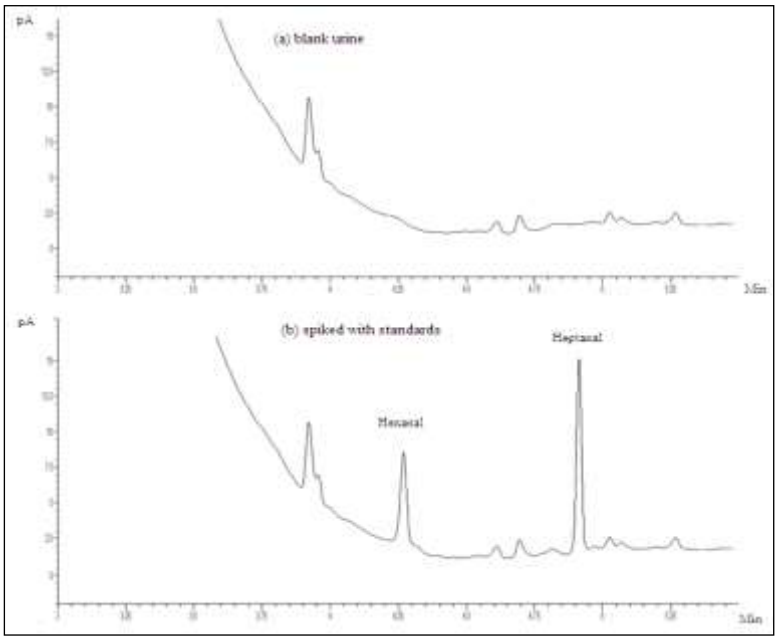

Figure 8. Chromatograms of a) blank urine sample b) extract of urine sample spiked with 0.25 µg/mL mixture of hexanal and heptanal using the proposed HF-SPME MTMOS-MPTMOS. Unknown peaks are most likely small molecular weight interferences from urine sample.

Conclusion

The sol-gel hybrid material, MTMOS-MPTMOS was successfully synthesized using mild conditions and used as a new adsorbent of HF-SPME for quantitative analysis of hexanal and heptanal from human urine samples with minimum sample preparation process. Several parameters affecting the extraction performance were successfully optimized and used in method validation. The proposed HF-SPME MTMOS-MPTMOS method is an easy and convenient microextraction technique that provides easy material preparation step and can be potentially applied for determination of hexanal and heptanal in human urine sample analysis.

Abstract

A series of silver-activated phosphate glass was prepared by melt quenching method. The effect of silver nanoparticle addition on the phosphate glass microstructure, composition and chemical characteristics was investigated using x-ray diffraction, fourier transform infrared and photoluminescence spectroscopy. Other physical property such as density was also evaluated. The density increased when the amount of silver ions were increased, due to the enhanced formation of non-bridging oxygen. In this study, we discuss the emission mechanism of two radio-photoluminescence peaks at 460 nm and 620 nm, where the electrons and holes produced by γ-irradiation a re-trapped by Ag^{+} ions to produce Ag^{0} and Ag^{2+} ions respectively, when the Ag^{+}-doped phosphate glass is exposed to γ-ray. We proposed that an emission mechanism of 460 and 620 nm radio-photoluminescence peaks with these Ag^{2+} and Ag^{0} ions. Furthermore, a correlation between the investigated properties and glass composition is discussed.

Keywords: silver nanoparticle, optical and physical properties, radio-photoluminescence glass dosimeter

Abstrak

Satu siri gelas argentum-aktif fosfat telah dihasilkan menerusi kaedah peleburan. Kesan penambahan nanobahan argentum ke dalam mikrostruktur gelas fosfat, komposisi dan sifat-sifat kimia dikaji dengan menggunakan pembelauan sinar-X, penjelmaan inframerah Fourier dan spektroskopi pendarcahaya. Sifat fizikal yang lain seperti ketumpatan kacaturut dikaji. Ketumpatan kaca bertambah apabila jumlah ion-ion argentum ditingkatkan, disebabkan oleh peningkatan pembentukan oksigen tanpa-hubung. Dalam kajian ini, kami membincangkan mekanisme pemancaran oleh dua puncak radio-pendarcahaya pada jalur 460 nm dan 620 nm, di mana elektron dan lohong yang terhasil daripada sinar-γ diperangkap oleh ion – ion Ag^{+} seterusnya menghasilkan ion – ion Ag^{0} dan Ag^{2+}, apabila kaca Ag^{+}-aktif fosfat didedahkan kepada sinar-γ. Kami turut membincangkan mekanisme pemancaran bagi setiap puncak radio-pendarcahaya pada jalur 460 dan 620 nm berdasarkan ion – ion Ag^{2+} dan Ag^{0} berkenaan. Tambahan lagi, hubung kait antara komposisi kaca dan sifat-sifat kaca yang terhasil turut dibincangkan.

Kata kunci: nanobahan argentum, sifat fizikal and optik, dosimeter kaca radio-pendarcahaya

Introduction

Recent technological applications have generated more interest in the study of glasses especially oxide glasses [1 – 6]. Among oxide glasses, phosphate based glasses are particularly attractive due to their ability to accommodate large concentrations of active ions without losing their useful properties of the material [1]. Phosphate glasses are relatively easy to prepare and offers a large range of compositional possibilities, which facilitates in tailoring the physical, chemical and optical properties of interest for specific technological applications [7]. In particular, embedding materials such as metal nanoparticles in glasses are expected to produce promising materials for functional optical devices due to a large third-order nonlinear susceptibility and an ultra-fast non-linear response [8]. The doping process plays an important role in the development of many optoelectronic devices especially dosimeters. Some dopants such as noble metal ions capture negatively charged electrons or positively charged holes, creating defects in the form of a change in their valence state through photo chemical reaction during exposure to successive gamma irradiation [6]. Radio-photoluminescence (RPL) in various glasses containing silver impurities has long been examined [9 – 11] for applications in personal solid-state dosimetry and radiation measurements. Yokota et al. [11] reported how to produce a glass element having low energy dependence, high sensitivity and good chemical stability. Moreover, the centers of luminescence will never disappear unless the glasses are annealed with high temperatures of about 400 $^{\circ}$C. This produces some excellent features such as repeatable measurement and small dispersions among samples [12].

In this study, phosphate glass dosimeters were prepared from reagent powders of P_2O_5, Li_2CO_3, $Al(OH)_3$, $NaNO_3$, $H_3BO_3$and silver nanoparticles. The optical and physical properties were determined with different silver ion contents within the phosphate base glass. The photoluminescence properties of silver-phosphate glass were studied. In addition, the density of the phosphate glass system was determined. The excitation and emission properties of radio-photoluminescence glass dosimeter in the form of Ag^+-doped phosphate glass and discussed the mechanism of RPL which is based on the excitation and emission properties also were evaluated.

Materials and Methods

Before synthesizing the Ag-doped phosphate glass, silver nanoparticles was firstly prepared. To obtain the Ag nanoparticles, 0.2 M of $AgNO_3$ (Aldrich; ≥ 99%) and 0.2 M of NaOH (Fluka; ≥ 97%) were dissolved in 100 ml of deionised water (resistivity = 18.2MΩ, TOC ≤ 5 ppb) under magnetic stirring at room temperature for 10 minutes. Triethanolamine (TEA) was poured into each solution at a molar ratio of 1:3 with excess TEA and continued stirring for 20 minutes. NaOH solution was added to the $AgNO_3$ solution during the ultrasound irradiation process (misonix-400, 60 Hz, 70 amplitude) for 60 minutes under nitrogen gas flow. The sample was then centrifuged and washed with excess deionised water to remove impurities and the excessive TEA used to cap the surface of the Agproducts, then dried overnight at 60 °C in the oven. The crystallinity and morphology of the products were later characterized by XRD (Bruker X-ray diffractometer) and TEM (Hitachi H-7100) instruments.

Secondly, phosphate glass for the solid state dosimetry was prepared from reagent grade powders of anhydrous P_2O_5, Li_2CO_3, $Al(OH)_3$, $NaNO_3$ and H_3BO_3. Silver nanoparticles were used as the main component for the radio-photoluminescence glass dosimeter. Silver-doped phosphate glasses were prepared by the melt-quenching method. The weight composition of the glass dosimeters were 9.26% $Al(OH)_3$, 7.34% Li_2CO_3, 2.0% $NaNO_3$, 2.72% H_3BO_3 and P_2O_5:Ag (73.58:5.1, 74.38:4.3& 75.18:3.5 respectively) in mol %, weighted using a digital weighing machine with an accuracy of ± 0.01 g, then mixed together using a mortar and pestle. Appropriate amount of each powder was melted in an alumina crucible which was placed in an electrical heated furnace in atmosphere. At a heating rate of about 10^0C/min, the temperature was gradually increased up to 600 $^{\circ}$C and kept at this temperature for 5 hours. Once the mixture was liquidised, the temperature was then increased again to 1250 $^{\circ}$C and left for one hour to obtain the appropriate viscosity. After the stirring and refining process, the glass liquid was then poured into a preheated stainless steel plate. At this point it then takes 24 hours to complete the annealing process at 350 $^{\circ}$C. The density of the glass samples were measured using the Archimedes principle, and distilled water was used as the immersion liquid. All samples were irradiated withγ-radiation, performed using a Co-60 source delivered at 1.8 kGy/h. In this work, the samples were irradiated such that the absorbed dose was 1 kGy. Excitation and emission measurements were performed at room temperature and RPL intensity was measured using FLS-920 spectrophotometer (excitation wavelength: 265 and 320 nm). The RPL emitted from the crystal was observed in a direction perpendicular to that

of the excitation beam and analysed using suitable filters with central wavelengths of 460and 620nm, respectively. The structure of the silver-phosphate glass was investigated using X-ray diffraction (Bruker X-ray diffractometer) and Fourier transform infrared spectroscopy (Perkin Elmer/Lamda 950).

Results and Discussion

The glass density values are lightly shifted in the range 2.48 to 2.67 g/cm^3, increasing with the silver content. With a high amount of Ag in the vitreous network the density increases up to 2.67 g/cm^3, possessing higher density values.

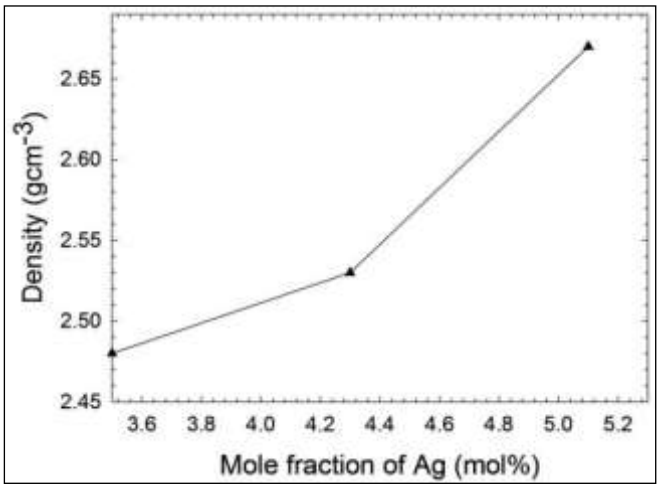

Figure 1. Density with different mole fraction (mol %) of silver-activated phosphate glass system

The micrograph of the Ag nanoparticles was obtained via TEM analysis is shown in Fig. 2(a). It shows structures consisting of irregular spherical metallic Ag with the average particle size estimated to be in range of 5 to 17 nm, determined by using the Sigma scan method as shown in Fig. 2(b).

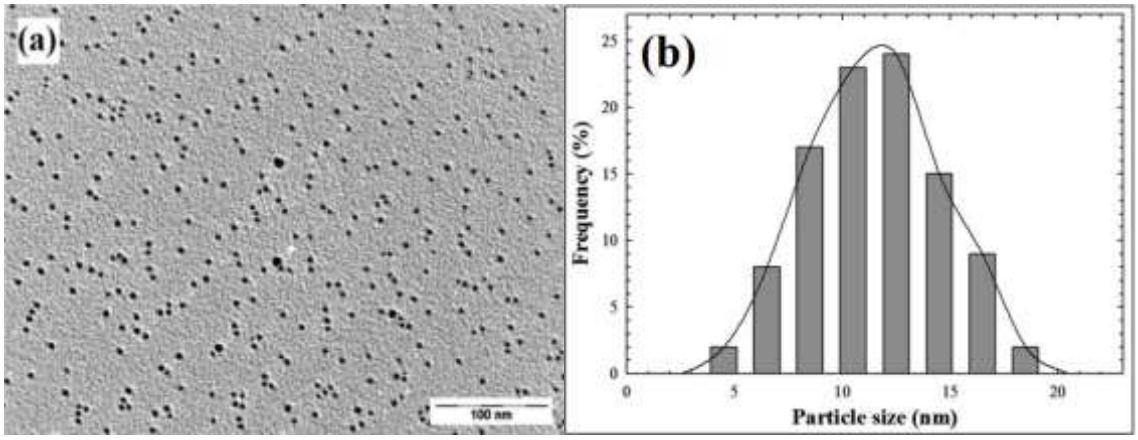

Figure 2. TEM micrograph of Ag nanoparticles prepared by sonication method

Aggregations occur due to large specific surface area and high surface energy, occurring during the process of sonication [13]. Due to the advantageous properties of silver nanoparticles, addition of these nanoparticles to phosphate glass increases the luminescence properties of the glass. Thus, it is interesting to study the effects of the addition of silver nanoparticles to phosphate glassesand the influence of its ions on the glass forming network.

The XRD pattern of Ag nanoparticles is shown in Fig. 3(a). The series of characteristic peaks have been indexed to metallic Ag indicating a face-centered cubic structure, according to JCPDS Card No. 1-87-717, with the lattice parameters; a = 4.0857 nm and space group fm-3m. No diffraction peaks of impurities have been observed, implying that all the $AgNO_3$was fully decomposed into Ag nanoparticles.

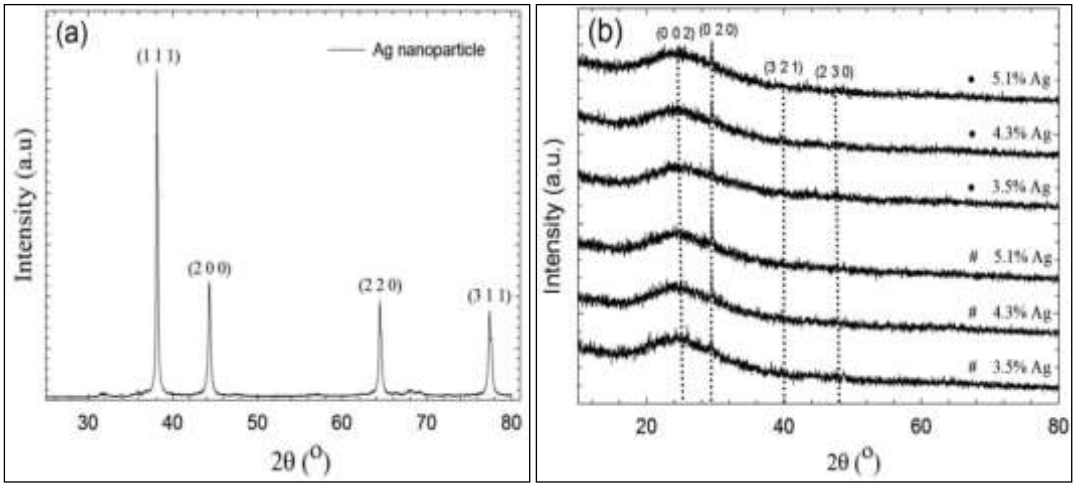

Figure 3. X-ray diffraction patterns of the (a) silver nanoparticles and (b) 3.5, 4.3 and 5.1mol % of Ag nanoparticles doped phosphate glasses before (#) and after (•) 1.0 kGy of γ-irradiation.

Figure 3(b) shows the pattern of the silver-activated phosphate glasses. The silver content was increase, no remarkablechange was exhibited in the XRD profiles of the six samples with differing silver contents (3.5, 4.3 and 5.1 mol %) before and after γ-irradiation. The overall features of these XRD curves confirm the amorphous nature of the glasses doped with silver nanoparticles. The pattern displays no sharp peaks, indicating the absence of any crystalline nature observed broad humps in the glass samples, characteristic of the phase at diffraction angles (2θ) to be fully amorphous, indicates that these glass samples are composed of a glassy phase. The series of characteristic peaks were indexed to monoclinic structure of silver phosphate with the lattice parameters; a = 11.86 nm, b = 6.06 nm, c = 7.31 nm and space group P21/n. From the XRD patterns, two strong peaks are present in the region at 24.38^o (0 02) and 29.51^o (0 2 0), which indicates that the material was silver doped in phosphate glass related in JCPDS Card No. 1-72-122. Therefore silver diffraction peaks were not well identified, since they were only present in the after mentioned bands. A great deal of interest has been shown in glasseswith implanted metallic clusters. As expected, the signal intensity of silver increased in the 5.1% sample, due to a higher amount of Ag nanoparticle.

In order to obtain more information about the prepared glasses, FTIR measurements were performed. Figure 4 shows the FTIR spectrum of each sample before and after gamma irradiation (1 kGy) for the silver doped phosphate glasses. The positions of the bands for the Ag-doped phosphate glass system are summarized in Table 1. A comparison of spectra in Figure 4 shows that the samples before and after γ-irradiation shows nearly similar IR transmission (absorption) spectra, which may be due to similar composition of the glass matrix, except for a change in the intensities of some peaks in same region for different amount of Ag, which seems to be having less or negligible effect on IR absorption spectra. Main observation after 1 kGy γ-irradiation is the generation of some new

peaks in the 800 – 1017 cm^{-1} range dominated by P-O-P linkages. This clearly indicates the breaking of these P-O-P linkages, which produces more non-bridging oxygen. This is associated with an increase in the intensity of band due to P=O bond at 1187 cm^{-1} (non-bridging oxygen), which confirms the idea of breaking P-O-P linkages in the glass. The bands in the region of 1400-500 cm^{-1} show a number of strong characteristic bands of phosphate glass. There is no significant difference in the line shapes of the spectra, because all of the samples contain > 50 mol% P_2O_5, which is as expected. These spectra consist of two main sets of IR absorption bands in the low and high frequency regions due to phosphate group and O-H molecule (bending mode), respectively. The three bands located in the range of 2346 – 2926 cm^{-1}were relatively weak and can be assigned to the stretching vibrations of P-O-H group in different structural sites, which was consistent in all samples. The shoulder observed at 1425 cm^{-1} is due to the characteristic stretching mode of the P=O bond.

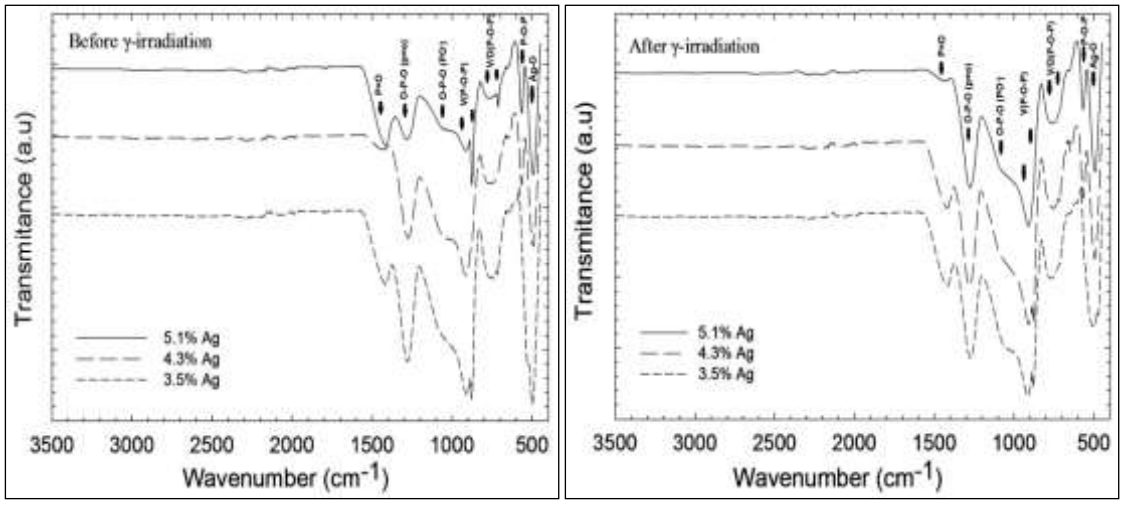

Figure 4. FTIR spectra for the phosphate glasses doped with 3.5, 4.3 and 5.1 mol % of silver nanoparticles.

Several authors have reported that the band corresponding to the stretching vibration of doubly bonded oxygen could be found in the frequency range of 1230 – 1390 cm^{-1}. The band at about 1281 cm^{-1} is assigned to the asymmetrical stretching vibration of O-P-O and P=O groups, ν_{as}(O-P-O)/ ν_{as} (P=O), while the medium broad band at 1100 cm^{-1} is related to the symmetric stretching vibration of that group, ν_s(O-P-O). The 1100 cm^{-1} band is the dominant feature of the spectra and has been assigned to P-O- groups. Moreover, increasing the quantity of the silver component, results in alteration of each band in the region of 1200 –1500 cm^{-1}, confirming the modifying behaviour of silver. The phosphorous non-bridging oxygen portion of PO_4 tetrahedra in a chain structure has been referred to as a $P\text{-}O^-$ unit. The asymmetric stretching vibration of the metaphosphate group, $\nu_{as}(PO_3)$ was observed in the range of 1012 –1153 cm^{-1}. This indicates that the bands due to $\nu_{as}(PO_3)$ can interfere with the band at 1100 cm^{-1}. The broadening observed in the region of 900 – 1105 may be due to the interference of $\nu_s(PO_3)$ with the spectral range 1000 – 1060 cm^{-1}. The shoulder around 878 cm^{-1} is assigned to the asymmetric stretching vibration of P-O-P linkages, ν_{as}(P-O-P), while the relatively weak band around 764 cm^{-1} is due to the symmetric stretching vibration of that linkage, ν_s(P-O-P). The region below 600 cm^{-1} is usually assigned to the vibration of metals [14]. The broad band at about 525 – 539 cm-1 may be assigned to the harmonics of P-O-P bending vibration as well as to the deformation mode of PO^- group. The wavenumbers of 480 and 510 cm^{-1} corresponds to the stretching and Ag-O symmetrical vibrations in PO_4. Piao et. al [15] describes that production of electron hole pairs during irradiation provides another path for bond rearrangement, reducing the constraints on structural relaxation. The relaxation process releases some of the excess energy stored in the structure, resulting in change in the bond angle.

Table 1. Vibrational assignment of the FTIR spectra of Ag-doped phosphate glass samples

No.	Vibrational mode	Wavenumber (cm^{-1})
1.	V_s(P-O-H)	2346-2926
2.	Stretching mode of P=O	1425
3.	Asymmetric stretching O-P-O V_{as}(O-P-O)/(P=O)	1281
7.	Symmetric stretching V_s(O-P-O)/PO^-	1100
8.	$V_{as}(PO_3)$	1012-1153
9.	$V_s(PO_3)$	1000-1060
10.	Asymmetric stretching P-O-P V_{as}(P-O-P)	878
11.	V_s(P-O-P)	764
12.	Harmonics of P-O-P bending vibration/deformation mode of PO^-	525-539
13.	V_s(Ag-O)	480 & 510

Figure 5 shows the radio-photoluminescence spectra of the silver-activated phosphate glass excited at 265 and 320 nm after gamma irradiation with an absorbed dose of 1 kGy.

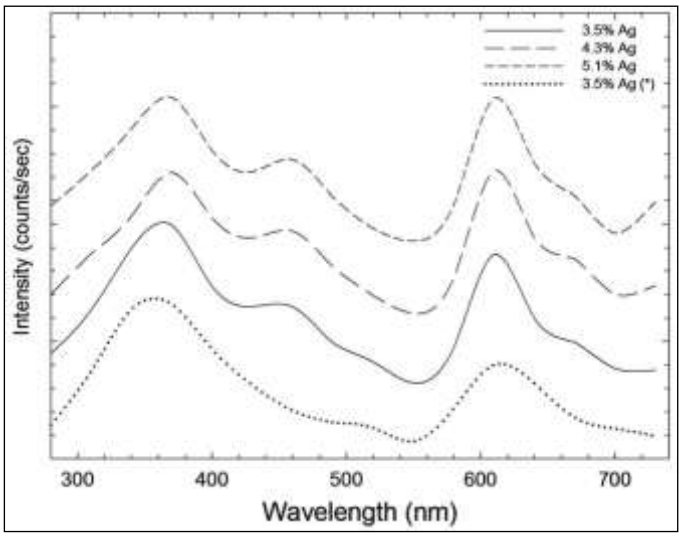

Figure 5. Radio-photoluminescence spectra of the silver-activated phosphate glass excited at 265 and 320 nm before (*) and after gamma irradiation with an absorbed dose of 1 kGy.

The PL spectra were measured to investigate the emission of silver ions corresponding to the dipolar electric transition $4d^{10} \rightarrow 4d^9 5s^1$. The main feature is composed of an excitation band at 265 nm, which consequently released an emission at 380 nm. Another excitation band can be seen at around 320 nm leading to emission between

450 up to 700 nm, with a band located around 460 nm and second band around 620 nm. This last intrinsic fluorescence is due to Ag^{+}–Ag^{+} pairs. One has to mention that for the lowest amount of Ag nanoparticles doped (3.5 %), the relative intensity of the band at 500 nm appears, to indicate that different nature of luminescent centers are most likely occurring. The existence of this emission band can be related to the formation of significant amount of Ag^{0} centers within the glass network. Even if the formation mechanisms of hole and electron traps are different, in all the irradiated cases, the 460 and 620 nm peak observed in the emission spectrum is believed to be due to aggregation of Ag^{0} and Ag^{+} ions which have possibly generated additional chemically stable clusters Ag_m^{x+} such as Ag_2^{+}, Ag_3^{2+} [9]. All these observations are consistent with a decrease of the emission of isolated silver ions showing that silver is definitely acting as the electron trap [16]. There is no emission peak observed for 3.5% of Ag-doped phosphate glass sample before γ-irradiation at 460 nm, which means there is no mechanism of hole and electron traps occurs and no Ag^{0} centreswere producedwithin the glass network.

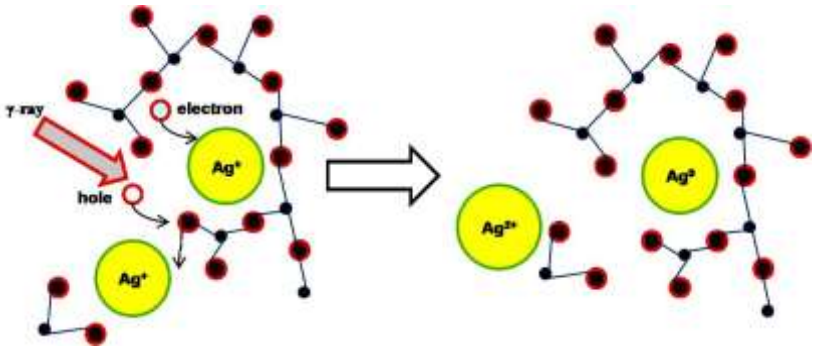

Figure 6. The colour centers formation mechanism of Ag-activated phosphate glass dosimeter

Radio-photoluminescence glass dosimeteris a mixture of inorganic amorphous solid and does not have lattice structure and lattice luminescence centers (molecular-level structures). Therefore, we can only establish the RPL model based on the energy of the excitation source and the energy of the released visible light. The networks of phosphate glass can be classified by the oxygen-to-phosphorus ratio, as set by the glass composition.The colour or luminescence centers are structured at the silver activated phosphate glass, as shown in Figure 6. The number of ionic silver is proportional to the numbers of electron traps. However, excessive numbers of ionic silver decreases the penetration efficiency of the pulse ultra-violet laser and increases energy dependence [17]. Therefore, a proper ratio of ionic silver is required for the best luminescence and excitation efficiency [18].

After γ-irradiation, the $AgPO_4$ in silver activated phosphate glass can be viewed as Ag^{+}/PO_4^{-}-related colour centres, produced inside the samples of Ag-doped phosphate glass (Equation 1). The glass changed colours from colourless to slightly yellow after γ-irradiation. When the tetrahedron of PO_4^{-} is exposed to radiation, it loses one electron and forms a positron hole, hPO_4 as shown in Equation 2. Equation 3 shows that the electron released from the PO_4^{-} will combine with Ag^{+} to form an Ag^{0}. In gamma irradiated silver-doped phosphate glasses, all electrons are trapped by Ag^{+} ions immediately after irradiation because Ag^{+} has a strong ability to trap electron. Similarly, hPO_4 will combine with Ag^{+} to become an Ag^{2+}as shown in Equation 4. The process where Ag^{+} ions trap holes is the main reason of the stabilization phenomenon of RPL centers. Both Ag^{0} and Ag^{2+} form the colour centers. The colour centers formation mechanisms are shown below.

$$AgPO_4 \rightarrow Ag^{+} + PO_4^{-} \quad (1)$$

$$PO_4^{-} \rightarrow hPO_4 + e^{-} \quad (2)$$

$$Ag^{+} + e^{-} \rightarrow Ag^{o} \text{ (electron trap)} \quad (3)$$

$$Ag^{+} + hPO_4 \rightarrow PO_4 + Ag^{2+} \text{ (hole trap)} \quad (4)$$

When these colour centers were excited with ~335 nm pulse ultra-violet lamp, the electrons in Ag^0 and $Ag^{2+}$are excited to higher energy levels and emit 600 – 700 nm visible orange light, then return to the original colour centers. These electrons will not return to the valence band of the glass material directly because the energy gained by electrons from the pulse ultra-violet laser is not high enough to let electron escape from colour centers. For electrons to gain enough energy to return to the valence band, the glass needed to be annealed at ~400 ^{0}C for one hour. The colour centers won't disappear after readout; hence, this glass can be read repeatedly.

Conclusion

In summary, optical, physical and chemical measurements on radio-photoluminescent silver-activated phosphate glass to clarify the origin and characteristics of the γ-induced colour centres was performed in this sudy. It was established that the phosphate glasses suitable for dosimeter control possess density values ranging from 2.48 to 2.67 g/cm^3. The glass density values are composition dependent, which the density increases with increasing Ag nanoparticles content in the vitreous network. FT-IR spectra of Ag-doped phosphate glasses have been studied before and after γ-irradiation. The FT-IR absorption spectra of Ag-doped phosphate glasses provide information about the main characteristics frequencies for phosphate bonds present in the glass network such as P=O, P-O-P, O-P-O and P-O-H. The presence of P-O-H bond indicates the hygroscopic nature of these phosphate glasses. The decrease in oxygen content of glass sample after γ-irradiation was indicating by bond breaking in the glass sample. This creates oxygen vacancy in the glass sample, which has been noticed as generation of defects in the optical observations. The optical properties such as RPL emission and excitation spectra of the Ag^+-doped phosphate glass were also investigated in this study. RPL emission spectrum consists of two emission bands peaked at about 460 nm and 620 nm. Blue RPL at 460 nm was closely connected to the 265 nm bands of the excitation spectrum. These bands were attributed to the Ag_2^+ and Ag^0 centres, respectively. On the other hand, orange RPL at 620 nm was associated with the 320 nm band in the excitation spectrum and this optical activity was due to the Ag^{2+} centres. Finally, the effect of gamma irradiation was observed in the form of change in the structural units of phosphate glass due to breaking and rearrangement of bonds in the glass network. All these changes were found to be dependent on the composition of the glasses system.

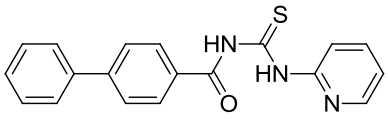
Abstract

Copper (II) ion chemical sensors based on pyridine-thiourea derivatives; *N*-pyridyl-*N'*-(biphenyl-4-carbonyl)thiourea (**L1**), and *N*-pyridyl-*N'*-(3,5-dimethyoxybenzoyl)thiourea (**L2**) were synthesised, characterised, and studied as ionophores in the form of thin-films PVC membranes. The ionophores exhibited good responses towards copper (II) ion over the concentration range of 2 x 10^{-4} to 10 x 10^{-4} M with a limit of detection 1.34 x 10^{-5} to 1.48 x 10^{-5} M. The proposed sensors **L1** and **L2** revealed good performance in term of reproducibility and regeneration of the ionophores with low relative standard deviation (RSD) values 4.17 % and 2.74 % respectively. Besides, quantum chemical calculation performed using Gaussian 09 program indicated the oxygen (O) atom from carbonyl moiety (C=O) was the most favourite reactive site and mainly responsible for ionophore– Cu(II) interaction. The obtained data revealed pyridine-thiourea derivatives offered great potential as ionophore for the detection of Cu (II) ion.

Keywords: pyridine, thiourea, metal sensor, density functional theory, spectroscopic

Abstrak



Pengesan kimia bagi ion kuprum (II) berasaskan terbitan piridil-tiourea; *N*-piridil-*N'*-(bifenil-4-karbonil)tiourea (**L1**), and *N*-piridil-*N'*-(3,5-dimetoksibenzoil)tiourea (**L2**) telah disintesis, dicirikan, dan dikaji sebagai ionofor dalam bentuk membran-membran PVC filem nipis. Ionofor – ionofor tersebut menunjukkan tindak balas yang baik terhadap ion kuprum (II) dalam julat kepekatan 2 x 10^{-4} to 10 x 10^{-4} M dengan had pengesanan 1.34 x 10^{-5} sehingga 1.48 x 10^{-5} M. Pengesan **L1** dan **L2** yang dicadangkan ini menunjukkan prestasi yang baik dari segi kebolehkeluaran semula dan penjanaan semula bagi ionofor – ionofor tersebut dengan nilai sisihan relatif piawaian yang rendah iaitu masing – masing 4.17% dan 2.74%. Selain itu, pengiraan kuantum kimia dilakukan dengan menggunakan program Gaussian 09 yang menyatakan bahawa atom oksigen (O) daripada moiti karbonil (C=O) adalah kawasan paling reaktif dan selalunya terlibat dalam interaksi ionofor-Cu (II). Data yang diperolehi menyatakan terbitan piridil-tiourea menawarkan potensi yang bagus sebagai ionofor bagi pengesanan ion Cu (II).

Introduction

In this developing era, industrial sector has rapidly become one of the most important sectors throughout the world. Production and manufacturing sectors gradually increase the rate of pollution as a result of the industrialisation process. Undoubtedly, metal as pollutant is known to be one of the common water pollution and has emerged as a harmful pollutant due to its toxicity at low concentration. Excessive amount of heavy metals will produce various toxicological effects and danger to most living organisms including to human [1, 2]. Among these, copper (Cu) which is classified as one of the metal pollutants which known to be toxic substance at certain concentration [3, 4]. Furthermore, Aziz et al. [5] reported the maximum limit under Standard B of Malaysian-Environmental Quality Act 1974 (Sewage and Industrial Effluents) 1979 is 1.0 mg/L which eventually make the detection process of this species to be such a challenge. Generally, metal detection in water samples depends on the utilization of expensive instrumentation techniques which at certain extend, can be rather complicated and time consuming [6 – 8]. Nowadays, there is a growing interest on research directed to the precaution of environmental control and industrial processes. Therefore, chemical sensor has arisen as an ideal option due to its rapid and simple approach towards detection. Thus, we proposed to synthesise and characterise a new class of ionophores featuring multi-chelating agent of pyridyl-thiourea derivatives which were fabricated into thin-film as molecular sensor towards copper (II) ion as an analyte of choice. A series of pyridine substituted thiourea compounds with different aromatic substituents namely biphenyl and 3,5-dimethoxybenzene were synthesised as proposed metal dication sensors prior treated as chemosensor for the detection of Cu (II) ion in the form of thin films. Figure 1 depicts all molecular structures of ionophores synthesised in this study.

Due to electronic conjugation system, multiple donor atoms (S, O and N) for complexation and ease of synthesis, thiourea moiety was chosen as material for development of potential chemical sensor. In order to enhance electronic conjugation of this system, several electron donor groups (R) were selected which expected to generate ideal flow of electrons via the progress of fair electronic conjugation in thiourea molecular framework. Besides, pyridine was introduced as substituent in this system to increase number of possible binding sites for interaction of metal ion. In order to specifically find the accurate interacting site of this molecule towards copper (II), density functional theory (DFT) calculation using Gaussian 09 was also carried out. The study on limit of detection, reproducibility and efficiency of these molecules in the form of thin films were carried out via UV-visible analysis. Result revealed that the efficiency and suitability of this system can be applied as chemical sensor for Cu^{2+} ion detection.

Materials and Methods

Reagents

The chemicals used, namely ammonium thiocyanate, 2-benzylaminopyridine, biphenyl-4-carbonyl chloride, and 3,5-dimethoxy benzoyl chloride, were purchased from Sigma-Aldrich, Merck, Acrós Organics, and R & M Chemical. All solvents used in this study such as acetone, chloroform, dichloromethane, diethyl ether, ethyl acetate, hexane, methanol, and acetonitrile were purchased from Merck, Fisher Scientific, and R & M Chemical. For film membrane preparation, high molecular weight poly(vinyl chloride)(PVC), sodium tetraphenyl borate, tributyl phosphate, and tetrahydrofuran (THF) were used as received from Merck.

Characterisation

Infrared (IR) spectra were recorded using FT-IR Perkin-Elmer 100 spectrophotometer within spectral range 4000-400 cm^{-1}. CHNS microanalysis was carried out using a FLASHEA 1112 CHNS analyser for determination of

percentage of CHNS elements presence in the synthesised compounds. NMR spectra were recorded on Bruker Avance III 400 (^{1}H 400.11 MHz, ^{13}C 100.61 MHz) using deuterated chloroform ($CDCl_3$) at room temperature. The interaction between ionophores and Cu^{2+} were investigated using UV-visible spectrophotometer Shidmazu 1601 series in 1 cm path length quartz cell. Thin films membranes were fabricated via SCS 6808 spin-coater at angular speed of spinning at 2500 rpm. Theoretical evaluation was carried out to predict and investigate potential interaction between the synthesised compounds and Cu^{2+} ion via Gaussian 09 program package. The basic set used in the theoretical simulation was based on density functional theory (DFT) calculation at B3LYP/LANL2DZ to obtain several significant structural parameters.

Theoretical Evaluation on Interaction of the Pyridyl-Thiourea Compounds Towards Cu(II)

The theoretical analysis was carried out to observe several important parameters such as interaction behaviour, binding strength and binding mode of the pyridyl-thiourea derivatives (**L1** and **L2**) towards the tested analyte which undoubtedly contributed in sensing capability of each compound towards the studied metal ion using Gaussian 09 software. This theoretical analysis was based on DFT calculation at B3LYP/ 6-31G (d,p) for the thiourea compound and B3LYP/LANL2DZ for interaction of the synthesised compounds towards Cu (II) ion.

Synthesis of ionophores: Synthesis of *N*-pyridyl-*N'*-(biphenyl-4-carbonyl)thiourea (L1)

Ammonium thiocyanate (0.46 g, 6.00 mmol) in acetone was charged into a solution of biphenyl-4-carbonyl chloride (1.30 g, 6.00 mmol) to yield a suspension of pale yellow solution and white precipitate after *ca*. 4 hours of refluxed condition with constant stirring. The white precipitate was filtered. Then, a solution of 2-aminopyridine (0.56 g, 6.00 mmol) in acetone was added dropwise into the pale yellow filtrate. The reaction mixture was stirred at refluxed condition for *ca.* 6 hours. After adjudged completion by TLC (ethyl acetate: hexane; 1:4), the reaction was cooled to room temperature. Subsequent to addition of three ice cubes into the yellow filtrate, pale yellow precipitate was formed and filtered. The precipitate was recrystallized from methanol to produce yellow solid of **L1** (1.45 g, 73%).^{1}H NMR (400.11 MHz, $CDCl_3$): δ_H 7.13 (t, J_{HH} = 6 Hz, 1H, Ar-CH); 7.35 (d, J_{HH} = 7 Hz, 1H, Ar-CH); 7.39 (pseudo-d, J_{HH} = 6 Hz, 2H, Ar-CH); 7.55 (pseudo-d, J_{HH} = 6 Hz, 2H, Ar-CH); 7.66 (d, J_{HH} = 8 Hz, 2H, Ar-CH); 7.75 (t, J_{HH} = 8 Hz, 2H, Ar-CH); 7.92(d, J_{HH} = 8 Hz, 1H, Ar-CH); 8.36 (d, JHH = 8 Hz, 1H, Ar-CH); 8.72 (d, J_{HH} = 8 Hz, 1H, Ar-CH); 9.24, 13.24 (2 x s, 1H, NH); ^{13}C NMR (100.61 MHz, $CDCl_3$): δ_C 116.5, 121.4, 127.3, 127.8, 128.3, 128.6, 129.1, 130.1, 138.4, 139.3, 146.6, 147.5, 151.1 (13 x s, Ar); 166.1 (s, C=O); 177.3 (s, C=S); Elemental analysis for $C_{19}H_{15}N_3OS$: [Found (Calculated.)]: C = 69.12 (68.45); H = 4.73 (4.53); N = 12.55 (12.60); S = 9.96 (9.62).

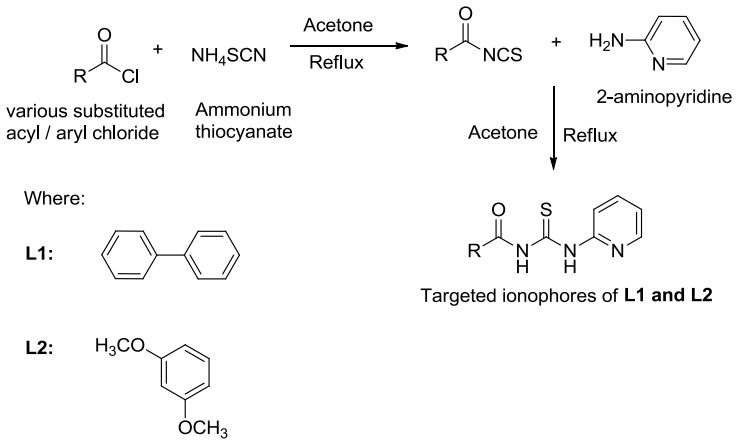
Synthesis of *N*-pyridyl-*N'*-(3,5-dimethyoxybenzoyl)thiourea (L2)

Yielding pale yellow crystalline solid (64% yield), **L2** was prepared from 3,5-dimethoxybenzoyl chloride (1.51 g, 7.51 mmol), ammonium thiocyanate (0.57 g, 7.51 mmol), and 2-aminopyridine (0.71 g, 7.51 mmol) in the same manner as described in **L1**. ^{1}H NMR (400.11 MHz, $CDCl_3$): δ_H 3.80 (s, 6H, OCH_3); 6.62 (t, J_{HH} = 4 Hz, 1H, Ar-CH); 6.10 (d, J_{HH} = 2 Hz, 1H, Ar-CH); 7.84 (t, J_{HH} = 8 Hz, 1H, Ar-CH); 8.34 (d, J_{HH} = 6 Hz, 1H, Ar-CH); 8.67 (d, J_{HH} = 8 Hz, 1H, Ar-CH); 9.48, 13.47 (2 x s, 1H, NH); ^{13}C NMR (100.61 MHz, $CDCl_3$): δ_C 55.8 (s, OCH_3); 105.6, 106.0, 116.9, 121.4, 139.7, 150.6, 161.3 (8 x s, Ar-CH); 166.1 (s, C=O); 177.5 (s, C=S); Elemental analysis for $C_{15}H_{15}N_3OS$: [Found (Calculated.)]: C = 56.98 (56.77); H = 4.94 (4.76); N = 13.21 (13.24); S = 10.68 (10.10).

Preparation of film membranes

A solution of polyvinyl chloride (PVC) powder (120 mg), sodium tetraphenylborate (1.5 mg), tributylphosphate (240 mg), and of the compound (**L1** and **L2**) (80 mg) were dissolved in tetrahydrofuran (THF) with vigorous stirring for *ca.* 6 hours until the solution became a homogenous viscous solution [9]. The resulting solution was then transferred onto a glass slide of 5 cm x 0.5 cm which was placed in a SCS 6808 Spin Coater. The substrate was spun at high speed (2500 rpm) to obtain smooth and homogenous thin film.

Preparation for pH studies



The study was carried out in pH buffered solution to minimise any change in pH due to the effects of temperature, light and the presence of carbon dioxide gas in air which can produce errors in the results. In this study, 1 mL of 5 x 10^{-4} M of Cu(II) ion solution was added to 5 ml of 5 x 10^{-5} M solutions of **L1** and **L2** prepared in different pH buffers (pH range from 3 to 10). A sample of the mixture was transferred into 1 cm^3 cuvette and the spectral

properties of these samples were recorded via UV-vis spectroscopy. Collected data was plotted to study effect of pH on response of **L1** and **L2** to sense the presence of Cu (II) ion.

Results and Discussion

Synthesis and characterisation of pyridine-thiourea

The pyridine-thiourea derivatives are proposed as ionophores (Figure 1) have their own advantages such as exhibit quick and ease of synthesis and purification. Scheme 1 shows the general synthetic work-up of the pyridine-thiourea derivatives synthesis. The molecular system featuring electron donating molecular framework has ability to increase their electron density throughout the molecular system, a desired feature to promote the binding ability of the ionophores with Cu (II) ion. Besides, **L1** and **L2** theoretically have known as multidentate ligand due to the existence of different coordination sites (N, O, and S) in particular geometry. Good yield of synthesised compounds were obtained of 73 %, and 89 % for **L1** and **L2** respectively.

Scheme 1. The general synthetic work-up of ionophores synthesis

The main IR bands of interest for **L1** and **L2** have been identified to show five absorption bands, namely, ν(N-H), ν(C-H), ν(C=O), ν(C-N), and ν(C=S). The first absorption band was assigned as the secondary amine N-H which could be observed at 3259 to 3267 cm^{-1} as medium intensity absorption band which was in a good agreement with previous works carried out by [10, 11] who reported the N-H stretching band was located in similar region. In most thiourea derivatives, N-H stretching band appeared at above 3200 cm^{-1} due to the influence of strong intramolecular hydrogen bond between N-H…O=C [12, 13] which led to the formation of broad and weak absorption band of N-H stretching [14,15]. Meanwhile, C-H alkane stretching bands could be observed in the region of 2974 to 3064 cm^{-1} as aromatic and alkyl type of CH groups were present in their molecular structures. In addition, in a range of 1524 to 1536 cm^{-1}, high intensity of ν(C-N) absorption band clearly been observed. Strong absorption band observed at 1670 cm^{-1} in both spectra were assigned as C=O absorption band. The appearance of the strong band was in a good agreement with previous studies carried out by [16 – 18]. The C=O stretch in all synthesised compounds were found at lower wavenumber compared with expected carbonyl stretching at around 1700 cm^{-1} as most carbonyl thiourea derivatives were stabilised by formation intramolecular hydrogen bond of C=O…H-N which led to emergence of pseudo-six-membered ring [19]. Consequently, formation of the intramolecular hydrogen bond interaction led to an increase in its polarity making the double bond character to be weaker and shifting the band to a lower wavenumber region [20]. The absorption band of C=S stretch for all synthesised compounds appeared as medium bands within range of 739 to 741 cm^{-1}. The presence of intramolecular hydrogen bonding between C=O with N-H moiety led to stronger electronegativity property of the N-H group which simultaneously enhanced double bond character of the C=S group [21] in which was found by several researchers [12, 22, 23].

In the ^{1}H NMR spectrum of **L2** a singlet resonance at δ_H 3.80 ppm was attributed to methoxy moiety in the compound. The O-CH_3 resonance was located at higher chemical as it was bonded to electronegative oxygen atom which pulled the electrons from proton methyl and deshielded the resonance to higher chemical shift region [24, 25]. High intensity singlet resonance with 6H integration shows that this resonance represents two symmetrical methoxy groups as reported by [26, 27]. The aromatic protons of both **L1** and **L2** can be observed at δ_H 7.13 – 8.74 ppm appeared as distinctive multiplet resonances due to the presence of unresolved aromatic protons [28]. The most common observation in ^{1}H NMR analysis of typical acyl thiourea molecular system is the presence of two singlet N-H resonances at the most downfield position [10, 11]. Both of these resonances were observed as distinctive broad singlets at the most deshielded region in the spectra. This is due to the presence of several electron-withdrawing moieties namely carbonyl and thiocarbonyl in the molecule which decreased electron density around the resonances and shifted the protons of N-H to downfield position [17, 29]. However, carbonyl-substituted N-H proton (NHCO) was found to be at lower chemical shift (δ_H 9.24 - 9.48 ppm) in comparison to thione-substituted N-H proton (NHCS) which is located at δ_H 13.24 - 13.47 ppm as the formation of intramolecular hydrogen bond between carbonyl moiety and thione-substituted N-H resonance produced stronger deshielding effect [12,15]. Carbon resonances in ^{13}C NMR spectra of **L2** could be observed at upfield position (δ_C 55.8 ppm) due to the presence of methyl moiety in molecular structure. However, CH_3 resonance of **L2** is observed at higher chemical shift (δ_C 55.8 ppm) as it was bonded to electronegative atom, oxygen, shifted the resonance to a higher chemical shift [30]. Resonances of aromatic carbon were observed at δ_C 105.5-161.2 ppm. Two distinctive resonances at the most downfield region (δ_C 166.0 and 177.3 ppm) can be observed which corresponded to carbonyl (C=O) and thione (C=S) respectively in both spectra of **L1** and **L2** [16, 31, 32]. This is due to formation of intramolecular hydrogen bonding and electronegativity effect of oxygen and sulphur atoms which pulled certain amount of electrons from both moieties and deshielded the resonances to higher chemical shift [13, 33]. The existence of several important resonances at expected regions in ^{1}H and ^{13}C NMR spectra of all synthesised compounds proved that pyridine-thiourea derivatives of both **L1** and **L2** were successfully synthesised.

Evaluation of sensing performances towards Cu (II) ion: Reaction responses

The reaction of the films towards different concentration of Cu (II) ion was investigated. Figure 2 and Figure 3 show the reaction response of **L1** and **L2** in the presence of Cu (II) ion within concentration range of Cu (II) ion was 2 x 10^{-4} M to 10 x 10^{-4} M. Upon exposure of Cu (II) ion to the film, the formation of absorption band of **L1** towards Cu (II) ion observed at wavelength of 385 nm. The higher the concentration of Cu (II) ion, higher the intensity of the absorption bands was observed. Similar observation was discovered in **L2** film with formation of medium absorption shoulder bands when Cu (II) ion was introduced to the film.

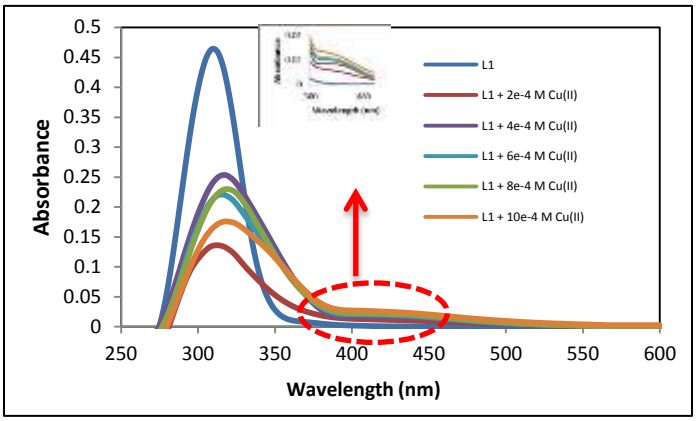


Figure 2. Reaction response of **L1** towards Cu (II) ion

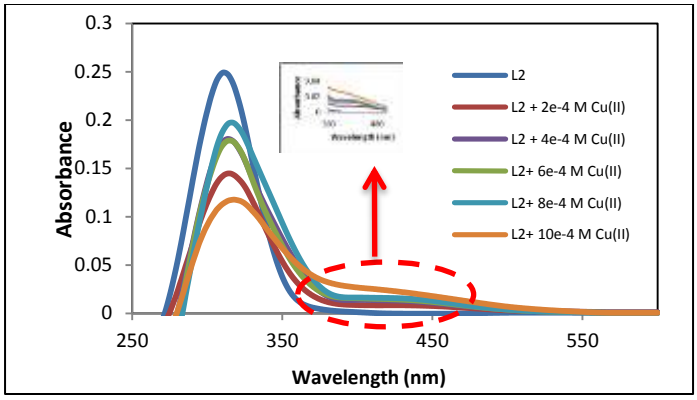

Figure 3. Reaction response of **L2** towards Cu (II) ion

Reproducibility of L1 and L2

A reproducible film will produce a stable and consistent data which is very crucial aspect in the sensing application. A number of 8 strips of samples were fabricated and used to complete the reproducibility test. Figure 4 shows reproducibility data behaviour of **L1** and **L2**.

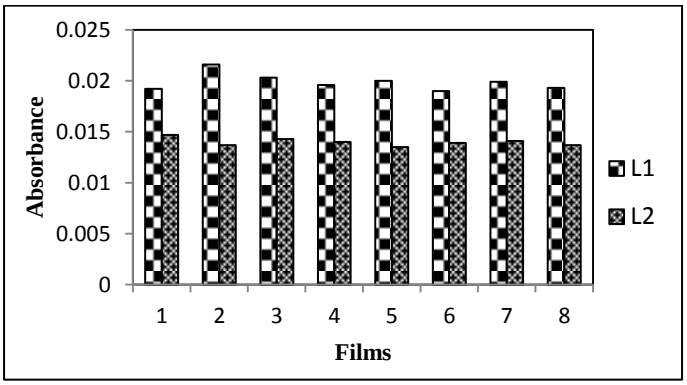

Figure 4. Graph of reproducibility studies for **L1** and **L2**

Figure 4 indicates stable and consistent reading for all films. Thus, the consistency in reading of the film showed that all films exhibited high reproducibility ability. Relative standard deviation (RSD) was calculated to prove and compare which film system possessed the best reproducibility. Table 1 shows the RSD value of **L1** and **L2** for their reproducibility property.

Table 1. RSD value of reproducibility for **L1** and **L2**

Film	Average, x	Standard Deviation	Relative Standard Deviation (%)
L1	0.019863	0.000828	4.17
L2	0.013988	0.000383	2.74

Table 1 revealed both **L1** and **L2** exhibited low value of RSD which were 4.17% and 2.74% respectively in which indicates higher ability of reproducibility [34, 35]. Therefore, it can be concluded that both L1 and L2 films exhibited reproducible results for detection of Cu(II) ion which is critical in order to produce uniform and accurate reading in its sensing performance. L2 exhibits the most effective reproducibility compared to L1. Higher RSD value might be caused by several technical errors during preparation of thin film such as uncontrollable thickness as well as uniformity of the films and amount of compound trapped in the films.

Regeneration of L1 and L2

Regeneration of chemosensor represents the ability of the sensors to be used repeatedly. An ideal sensor is a sensor with high regeneration property in which it can be used repeatedly and effectively for several measurements. Figure 5 shows regeneration data of all designated chemosensor (**L1** and **L2**).

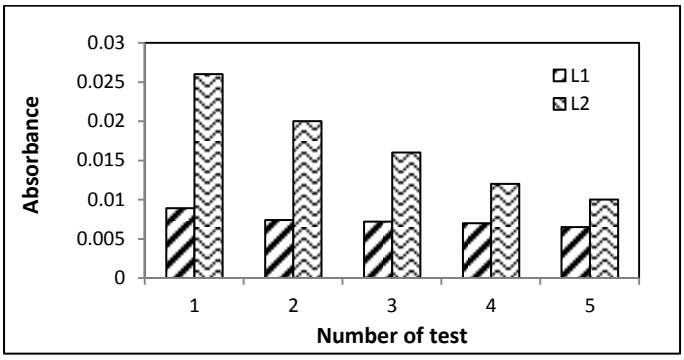

Figure 5. Graph of regeneration for **L1** and **L2**

L1 found to have ideal regeneration pattern up to 5 cycles which indicated multi-testing films. However, the sensing performance of **L2** decreased dramatically from the first to the fifth cycles compared to **L1** which showed gradual decreasing of its sensing performance. Based on Figure 5, **L1** offered ideal regeneration ability compared to **L2**. Table 2 shows the value of RSD in term of regeneration property of **L1** and **L2**.

Table 2. RSD value of regeneration for **L1** and **L2**

Film Cycle	**L1**		**L2**	
	Absorbance	**Percentage of regeneration (%)**	**Absorbance**	**Percentage of regeneration (%)**
1	0.0089	100	0.026	100
2	0.0074	83.15	0.020	76.92

Mean, x	0.007400		0.016800	
Standard deviation (σ)	0.000903		0.006419	
RSD (%)	12.20		38.21	

The huge decrease of absorbance for both **L1** and **L2** films was contributed by the second cycle. This is due to the film which was used directly after fabrication process without any cleaning process to remove untrapped residue of the compound which led to involvement of the untrapped residue in the sensing mechanism. **L1** exhibits the lowest RSD value with 12.20% compared to **L2** with 38.21%. Large value of RSD for **L2** contributed from the leaching of compound from the film during the metal ion leaching process in EDTA solution which reduced the amount of compound to detect Cu (II) ion leading to lower sensing response in the following cycles. This is due to the strength of EDTA to bind to Cu (II) ion and unsurprisingly, it is also able to attract the compound-Cu(II) complex from the film. Besides, due to the unbounded compounds in the film on the glass substrate, the compounds were easily detached and leached off when the film became swollen during the sensing studies.

Limit of Detection (LOD)

In this respect, LOD of **L1** and **L2** films towards Cu (II) ion was carried out to investigate the efficiency and sensitivity of the sensors for Cu (II) detection which was calculated using Equation 1. Figure 6 shows the LOD graph of **L1** and **L2**.

$$LOD = \frac{3s}{\sigma} \quad (1)$$

where *s* is the standard deviation for the blank and σ is the slope of the LOD graph.

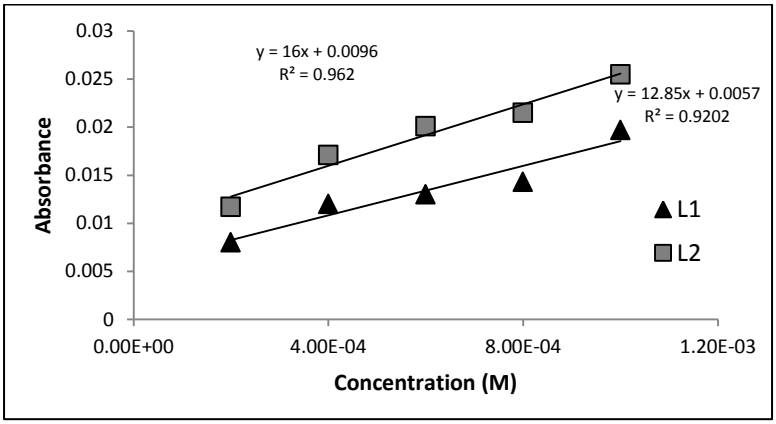

Figure 6. Calibration curves for LOD of **L1** and **L2**

LOD results revealed that, **L1** shows higher sensitivity towards detection of Cu (II) ion compared to **L2**. These experimental results were in good agreement with the theoretical investigation which **L1** exhibits higher response towards Cu (II) ion. In contrast, **L2** shows lowest sensitivity towards Cu (II) ion which was initially proven in the theoretical study on its binding mechanism and low interaction energy of **L2** towards Cu (II). Table 3 shows the data of LOD analysis of **L1** and **L2**.

Table 3. The data of LOD for **L1** and **L2**

Film	**L1**	**L2**
σ	12.85	16.00
s	5.76×10^{-5}	7.87×10^{-5}
LOD (M)	1.34×10^{-5}	1.48×10^{-5}

σ = slope of LOD graph; s = standard deviation

pH Effect

The reaction of metals with ligands is pH dependence. Therefore, pH study was carried out to find optimum pH condition for the reaction of Cu (II) ion with the selected compounds (**L1** and **L2**) which was carried out in the range pH 2 to pH 9. Figure 7 illustrates the effect of pH in the metal-ligand sensing performance.

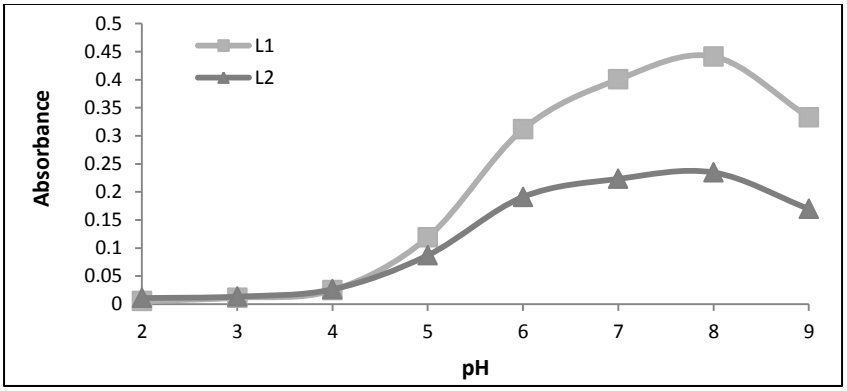

Figure 7. pH effect for metal-ligand sensing performance of **L1** and **L2**

Result obtained revealed that **L1** and **L2** showed quite similar patterns in the pH dependent graph which the curve started to increase at pH 4 then declined at pH 9. The most optimum pH for **L1** and **L2** compounds to sense Cu (II) ion was found at pH 8. This is due to the existence of intensive competition between H^+ and Cu (II) which decreased the ability of the compounds to form interaction with the metal ion resulting in lower response of absorbance at highly acidic condition [36]. Consequently, the absorbance of the compound-Cu (II) complex increased with increasing pH value.

Density functional theory (DFT) analysis

The ability of **L1** and **L2** to interact with Cu (II) was proven via density functional theory (DFT) analysis. Based on the analysis, **L1** and **L2** possessed ability to interact with the metal ion via C=O and C=S which acting as chelating ligand [37, 38]. Chelating behaviour of a ligand is known to have better and stronger interaction to enhance sensing performance of chemosensor. Similar binding behaviour observed in both **L1** and **L2** due to the presence of thiourea moiety in their molecular frameworks which is much dominant than other possible binding sites in the molecules. Based on the theoretical study, nitrogen atom of pyridine found to be twisted away from the interaction area which proved the pyridine portion was not involved in the interaction. There were several parameters which were taken into consideration in this analysis to compare capability of the compounds to interact towards Cu (II) such as interaction distance and binding energy. In term of interaction distance, **L1** indicated the lowest distance compared to **L2**. The interaction distance of **L1** via C=O and C=S towards Cu (II) are 2.027 Å and 2.520 Å respectively. The obtained distances were in the same region as reported by [31, 39]. This showed that **L1** has the highest strength to bind with Cu^{2+} followed by **L2**. Furthermore, in term of binding energy, the most negative value indicates optimum stability and strength of the interaction [40]. **L1** exhibits the most negative value of interaction energy (-230.34 kJ/mol) compared to **L2** -227.34 kJ/mol. The stronger binding energy and the shorter interaction distance of **L1** was caused by the stronger electron donating effect of biphenyl than 3,5-dimethoxybenzene groups in **L2**. Table 4 shows details on the theoretical evaluation data of these compounds via Gaussian 09 analysis.

Table 4. Theoretical interaction study between **L1** and **L2** towards Cu^{2+}

Compound	C=O···Cu (Å)	C=S···Cu (Å)	Binding Energy (kJ/mol)
L1	2.027	2.520	-230.34
L2	2.030	2.523	-227.34

Conclusion

On the basis of the results discussed in this paper, two new pyridine-thiourea derivatives **L1** and **L2** have been successfully synthesised and characterised prior to form active ionophores film entrapped in a PVC matrix for detection of Cu (II) ion. The reaction response of the ionophores towards different Cu (II) ion concentration was observed via difference in spectral features upon interaction with Cu(II). Apparently, **L1** exhibited good response with high sensitivity towards Cu(II) ion with limit of detection $1.34x10^{-5}$ M which was in good agreement with theoretical calculations. In fact, the theoretical analysis proved the oxygen (O) atom mainly defines its reactive site compared to sulphur (S) atom. Whilst, nitrogen (N) atom on pyridine moiety found to be twisted away from the interaction area; therefore, pyridine portion does not involved in the interaction mechanism with Cu (II). In addition, **L1** offered ideal interaction and binding energy for Cu (II) sensing (2.027 and -230.34 kJ/mol). In conclusion, a novel approach involving single molecular system of pyridine-thiourea (**L1** and **L2**) exhibited promising ability and potential for Cu (II) detection.

Abstract

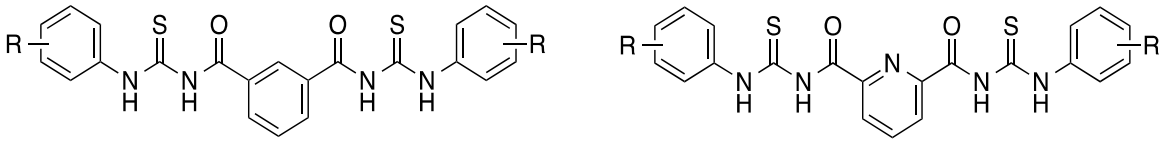
Thioureas play an important role in medicinal chemistry and agricultures due to their biological activity such as antibacterial, antifungal, antiviral, herbicides, rodenticides, phenoloxidase enzymatic inhibitors, anti-HIV and anti-tumor agents. In this study, five substituted bis-thioureas have been synthesized. The isophataloyl chloride and 2,6- pyridinedicarbonyl dichloride were easily converted to bis-isothiocyanate compound *via* the reaction with ammonium thiocyanate by solid–liquid phase transfer catalysis of polyethylene glycol-400 (PEG-400). Bis-isothiocyanate compound was reacted with aniline derivatives to produce substituted bis-thioureas in good yield at room temperature. All the novel compounds were obtained as yellow solid after recrystallization using DMF/EtOH/H_2O. Their chemical structures were confirmed by Infrared spectrosopy (IR), Nuclear Magnetic Resonance (NMR) ^{1}H and ^{13}C and mass spectrometry. The five synthesized compounds were screened for antimicrobial activities using disc diffusion method for antimicrobial activity against Gram-positive bacteria (*Bacillus Subtilis* and *Staphylococcus Aureus*), Gram-negative bacteria (*Escherichia Coli* and *Salmonella Typhi*) and a mold (*Aspergillus Niger*). All tested compounds showed low antimicrobial activity since the diameter of inhibition zone (IZ) measure was less than positive control inhibition zone.

Keywords: bis-thiourea, antimicrobial activities, PEG-400

Abstrak

Sebatian tiourea memainkan peranan penting dalam kimia perubatan dan pertanian kerana sebatian ini mempunyai aktiviti biologi seperti antibakteria, antivirus, herbisid, rodentisid, perencat enzim fenoloksidase, anti-HIV dan agen anti-tumor. Lima sebatian bis-tiourea telah disintesis dalam kajian ini. Sebatian bis-isotiosianat disintesis dengan mudah melalui tindak balas di antara sebatian isofataloil klorida atau 2,6-piridinadikarbonil diklorida dengan ammonium tiosianat melalui pemindahan mangkin fasa pepejal-cecair polietilena glikol-400 (PEG-400). Seterusnya, sebatian bis-isotiosianat ditindak balas dengan sebatian amina bagi menghasilkan sebatian bis-tiourea dengan hasil yang baik pada suhu bilik. Semua sebatian diperolehi dalam bentuk pepejal bewarna kuning selepas penghabluran semula menggunakan pelarut DMF/EtOH/H_2O. Pencirian struktur sebatian dibuat melalui kaedah spektroskopi Infra Merah (IR), Resonans Magnet Nukleus (NMR) ^{1}H dan ^{13}C dan spektrometer jisim (MS). Kajian aktiviti antimikrob bagi lima sebatian yang telah disintesis dibuat melalui kaedah resapan cakera melawan bakteria Gram positif (*Bacillus Subtilis* and *Staphylococcus Aureus*),bakteria Gram negatif (*Escherichia Coli* and *Salmonella Typhi*) dan kulat (*Aspergillus Niger*). Semua sebatian menunjukkan aktiviti antimikrob yang diperolehi rendah kerana diameter zon perencatannya (IZ) lebih kecil daripada zon perencatan kawalan positif.

Kata kunci: bis-tiourea, aktiviti antimikrob, PEG-400



Introduction

Antimicrobial agents has received much attention in recent years due to the dramatically increased of bacterial and fungi infectious diseases. Since penicillin was introduced as antibiotics in 1940's and were among the first medications to be effective against many bacterial infections, antibiotics have been used widely in fight against infectious diseases caused by bacteria and fungi. However, the usage and misuse of antibiotics has led to the emergence of antibiotic-resistant pathogens including multidrug-resistant strains [1 – 3]. As consequence, it has caused failure in the treatment of infectious diseases. In that respect, there is growing interest in the discovery of new antibacterial agents.

Thioureas were first synthesized by Neuki in 1873 [4]. Thiourea derivatives exhibit various biological activities such as antiviral [5, 6], antibacterial [7], fungicidal [8, 9], herbicidal [10] and anti-HIV [11]. In 2011, Peng et al. have reported some 1,3-benzenedicarbonyl bisthiourea showed inhibition activities against cancer cells, such as human nasopharyngeal cancer cell line, CNE_2 and human oral cavity cancer cell line, KB with IC_{50} value 10.72 and 9.91 µm respectively [12].

Some example of bis-thiourea derivatives are N^3, $N^{3'}$-bis (disubstituted)isophatalyl-bis(thiourea), bis(thiourea)hydrazide [13], 2,2'-diaminobinapthalene-bis(thiourea) [14] and (bis)thiourea polyamine [15]. The derivatives of bis(disubstituted)isophtalayly-bis(thiourea) were also reported by Wang et al., Peng et al. and Jamil et al. research groups in 2005, 2011 and 2013, respectively [16, 17, 18]. In 2011, 1,2-Bis(*N*'-benzoylthioureidothioureido)-4-cholorobenzene was reported by Yamin research group [19]. The former compound is similar to 1,2-bis(*N*'-benzoylthioureido)benzene reported by Thiam and co-workers [20] during 2008 except for the presence of 4-chlorobenzene bridge at 1,2 position that connected the two benzoyl thioureido group.

In view of these observations, we have designed 1,3-benzenedicarbonyl and 2,6-pyridinedicarbonyl bisthiourea derivatives in order to investigate their antimicrobial activities. Herein, we report the syntheses of five bisthioureas compound **NA1-5** as shown in Figure 1 with the aid of solid-liquid phase transfer catalyst, PEG-400 [12]. Their structures of all the compounds were confirmed by IR spectroscopy and ^1H and ^{13}C Nuclear Magnetic Resonance (NMR). All compounds were screened for antimicrobial activities against Gram-positive bacteria, Gram- negative bacteria and a mold.

Materials and Methods

Chemicals (isophataloyl chloride, 2,6-pyridinedicarbonyl dichloride, aniline, 4-fluoroaniline, 3,5-bis(trifluoromethyl)aniline, ammonium thiocyanate, and PEG-400) and solvents (dichloromethane, dimethylformamide and ethanol) were purchased from Sigma Aldrich and MERCK and used directly without further purification. Melting points were determined by using BÜCHI Melting Point Model B-545. Infrared spectra were obtained using FTIR Perkin Elmer-1310 Spectrum GX Spectrophotometer in the spectral range of 4000

– 400 cm^{-1}. ^{1}H and ^{13}C were analysed by using Bruker Avance III 600 MHz and Jeol JNM-ECP 400MHz NMR spectrometer.

Synthesis of compounds

The general procedure for synthesizing compounds **NA1-5** (Scheme 1) was as follows. Isophataloyl chloride (2.46 mmol) or 2,6-pyridinedicarbonyl dichloride (2.45 mmol) was dissolved in 30 mL dichloromethane.
Subsequently, ammonium thiocyanate (7.38 mmol) and PEG-400 (0.22 mmol) were added to the solution and was stirred at room temperature for 2 hours. The resulting mixture was filtered to give isothiocyanate compound which was directly used without further purification. Aniline derivatives (5.15 mmol) was added and stirred for another hour. The yellow precipitate formed was filtered and washed with distilled water and purified by recrystallization using Dimethylformamide/Ethanol/Water.

Scheme 1. Synthesis of bis(thiourea) derivatives

Antibacterial screening

All synthesized compounds were screened for their antimicrobial activity by using disc diffusion method against five microbs (*Bacillus Subtilis, Staphylococcus Aureus, Escherichia Coli, Salmonella Typhi, and Aspergillus Niger*). Streptomycin (10µg) and Kinamycin (30µg) were used as positive control and Dimethyl sulfoxide as negative control. All bacteria were cultured in nutrient broth and incubated at 37 °C for 24 hours. After that, the agar media was prepared by pouring the nutrient agar solution into the sterilized petri dishes. Then, the cultures were spread on the surface of Nutrient Agar (NA). The discs (6 mm diameter) were impregnated with (10µL/disc) and (30µL/disc) test samples and then placed on the surface of the agar media. Experimental plates were incubated at 37 °C for 24 hours. Antimicrobial activity was determined by measuring the diameter of inhibition zone (IZ) and compared with positive control.

Results and Discussion

In this study, bis-isothiocyanate compound was not isolated and directly treated with respective aniline derivatives to give the corresponding bis-thiourea (**NA1-5**) in moderate to good yield *via* nucleophilic substitution mechanism. IR studies showed that, strong absorption in region 3250 – 3383 cm^{-1}, which corresponds to υ (N-H) stretching. The υ (C=O) absorption bands were observed in region 1650-1687 cm^{-1}. The medium intensity bands around 1152 – 1127 cm^{-1} attribute to the stretching of υ (C=S). All absorptions band value was in agreement with standard absorption value for thiourea compounds.

In the ^{1}H NMR spectra, the CONH protons appear as singlet in the range of δ 12.3 – 12.4 ppm whereas CONH protons appeared at δ 11.1 – 11.5 ppm. The appearance of N-H signals at higher frequency was due to the presence of carbonyl and thiocarbonyl groups which exert strong deshielding effect. The aromatic protons of parent 1,3-benzenedicarboxamide appeared around δ 8.5 –7.8 ppm. The aromatic protons of amine in compound NA1 and NA2 showed peaks in the range of δ 7.5 – 7.2 ppm and δ 8.8 – 7.9 ppm respectively. The protons signals of amine in NA2 were observed at higher frequency because the protons were deshielded by CF_3 groups. Compounds with parent 2,6-pyridinedicarboxamide protons signals were found at δ 8.0 –7.5 ppm while aromatic protons of amine in compound NA3, NA4 and NA5 appeared at δ 8.5 – 6.8 ppm. The aromatic protons signals of amine in compound NA3, NA4 and NA5 were slightly different from each other may be influenced by the nature of substituent group attached to the compound. Electronegative

atom reduced the electron density around those protons and hence the protons were deshielded. The ^{13}C NMR assignments showed that, the carbon signals for (C=S) and (C=O) appeared at δ 180.0 – 178.0 ppm and 167.2 – 162.0 ppm respectively. While aromatic carbon signals were observed at δ 154.1 – 116.9 ppm. All compounds were obtained as yellow solid after recrystallization using DMF/EtOH/H_2O. Their chemical structures were validated by FTIR, ^1H and ^{13}C NMR. The physical and spectroscopic data of the new compounds are shown below.

1,3-Benzenedicarboxamide, N^1,N^3-bis[[(4-methylphenyl)amino]thioxomethyl] **NA1:** Yield 78%, Yellow solid, m.p 222.0 °C, IR (KBr pellet, cm^{-1}) : υ (N-H) 3250.1, υ (C=O) 1655.9, υ (C-N) 1253.1, υ (C=S) 1151.0, ^1H (DMSO-d_6) $^{\delta}H$ (ppm): 12.4 (s, 2H, CSNH), 11.5 (s, 2H, CONH), 8.5 (s, 1H, Ar-H), 8.18 (d, J = 5.6 Hz, 2H, Ar-H), 7.8 (t, J = 8 Hz, 1H, Ar-H), 7.56 (d, J = 8.4 Hz, 4H, Ar-H), 7.24 (d, J = 8.0 Hz, 4H, Ar-H), 2.3 (s, 6H, CH_3), ^{13}C (DMSO-d_6) $^{\delta}C$ (ppm): 179.3 (C=S), 167.7 (C=O), 136.3 (Ar-C), 135.8 (Ar-C), 133.7 (Ar-C), 132.4 (Ar-C), 129.7 (Ar-C), 129.3 (Ar-C), 124.8 (Ar-C), 21.1 (CH_3).

1,3-Benzenedicarboxamide, N^1,N^3-bis[[(3,5-bis(trifluoromethyl(phenyl))amino]thioxomethyl] **NA2:** Yield 72%, Yellow solid, m.p 195.6 °C, IR (KBr pellet, cm^{-1}) : υ (N-H) 3232.8, υ (C=O) 1656.1, υ (C-N) 1245.8, υ (Ar-CF_3) 1280.0, υ (C=S) 1127.0, ^1H (DMSO-d_6) $^{\delta}H$ (ppm): 8.8 (s, 1H, Ar-H), 8.5 (s, 4H, Ar-H), 8.4 (d, J = 6.6 Hz, 2H, Ar-H), 7.9 (s, 2H, Ar-H), 7.8 (t, J = 7.2 Hz, 7.8Hz, 1H, Ar-H), ^{13}C (DMSO-d_6) $^{\delta}C$ (ppm): 180.0 (C=S), 167.1 (C=O), 140.1 (Ar-C), 133.4 (Ar-C), 132.5 (Ar-C), 131.7-131.0 (q, $^3J_{CE}$ = 33.9 Hz, C-CF_3), 129.6 (Ar-C), 127.9 (Ar-C), 126.0-120.6 (q, $^1J_{CF}$ = 270.1 Hz, CF_3), 119.5 (Ar-C).

2,6-pyridinedicarboxamide, N^1,N^3-bis[[(4-fluorophenyl)amino]thioxomethyl] **NA3:** Yield 53%, Yellow solid, m.p 210.4 °C, IR (KBr pellet, cm^{-1}) : υ (N-H) 3383.6, υ (C=O) 1679.7, υ (C-N) 1227.8, υ (C-F) 1352.8 υ (C=S) 1151.0, ^1H (DMSO-d_6) $^{\delta}H$ (ppm): 8.0 (d, J = 7.8 Hz, 2H, Ar-H), 7.94 (t, J = 8.4 Hz, 7.2Hz, 1H, Ar-H), 7.27-7.25 (m, 4H, Ar-H), 6.88-6.83 (m, 4H, Ar-H), ^{13}C (DMSO-d_6) $^{\delta}C$ (ppm): 178.9 (C=S), 163.7 (C=O), 160.9–159.3 (d, $^1J_{EC}$ = 242.8 Hz, C-F), 149.3 (Ar-C), 140.4 (Ar-C), 134.4 (Ar-C), 127.1-127.0 (d, $^3J_{EC}$ = 8.8 Hz, Ar-C), 126.9 (Ar-C), 115.4-115.5 (d, $^2J_{EC}$ = 21.9 Hz, Ar-C).

2,6-pyridinedicarboxamide, N^1,N^3-bis[[(4-methylphenyl)amino]thioxomethyl] **NA4**: Yield 65%, Yellow solid, m.p 177.0 °C, IR (KBr pellet, cm^{-1}) : υ (N-H) 3280.7, υ (C=O) 1656.0, υ (C-N) 1241.8, υ (C=S) 1144.2, ^1H (DMSO-d^6) $^{\delta}H$ (ppm): 12.3 (s, 1H, CSNH), 11.7 (s, 1H, CSNH), 11.1 (s, 1H, CONH), 10.9 (s, 1H, CONH), 8.2 (t, J = 8.4 Hz, 7.2 Hz, 1H, Ar-H), 7.7 (d, J = 8.0 Hz, 4H), 7.6 (d, J = 8.4 Hz, 1H, Ar-H), 7.5 (d, J = 1, 8.4 Hz, 1H, Ar-H), 7.2 (d, J = 8.0 Hz, 4H, Ar-H), 2.3 (s, 6H, CH_3), ^{13}C (DMSO-d_6) $^{\delta}C$ (ppm): 179.0 (C=S), 166.9 (C=O), 154.1 (Ar-C), 140.6 (Ar-C), 138.8 (Ar-C), 134.4 (Ar-C), 130.4 (Ar-C), 129.4 (Ar-C), 126.4 (Ar-C), 25.7 (CH_3).

2,6-pyridinedicarboxamide, N^1,N^3-bis[[(3,5-bis(trifluoromethyl(phenyl))amino]thioxomethyl] **NA5:** Yield 62%, Yellow solid, m.p 345.5 °C, IR (KBr pellet, cm^{-1}) : υ (N-H) 3296.0, υ (C=O) 1687.1, υ (Ar-CF_3) 1283.1, υ (C-N) 1246.6, υ (C=S) 1151.8, ^1H (Acetone-d_6) $^{\delta}H$ (ppm): 11.1 (s, 2H, CONH), 8.7 (s, 4H, Ar-H), 8.5 (d, J = 7.8 Hz, 2H, Ar-H), 8.4 (t, J = 7.2 Hz, 7.8 Hz, 1H, Ar-H), 7.8 (s, 2H, Ar-H), ^{13}C (Acetone-d_6) $^{\delta}C$ (ppm): 178.8 (C=S), 162.0 (C=O), 148.4 (Ar-C), 140.4 (Ar-C), 140.2 (Ar-C), 140.1 (Ar-C), 132.0-131.4 (q , $^3J_{EC}$ = 33.0 Hz, C-CF_3), 126.0 (Ar-C), 126.2-122.6 (q, $^1J_{EC}$ = 270.0 Hz, CF_3), 120.1 (Ar-C), 116.9 (Ar-C).

Antimicrobial activities

The antibacterial and antifungal activities of five new bisthioureas were tested against two Gram-positive bacterias (*Staphylococcus Aureus, Bacillus Subtilis),* two Gram-negative bacterias *(Escherichia Coli and Salmonella Typhi)* and single fungal strain - *Aspergillus Niger* using disc diffusion method. Streptomycin and Kinamycin were used as positive controls (Table 1).

Table 1. Antimicrobial result for five bis-thiourea compounds

Compound	Bacteria Inhibition Zone (mm)									
	Concentration (µg/disc)									
	A.Niger		***B.Subtilis***		***S.Aureus***		***E.Coli***		***S.Typhi***	
	10µg	**30µg**	**10µg**	**30µg**	**10µg**	**30µg**	**10µg**	**30µg**	**10µg**	**30µg**
NA1	-	-	6.5	6.5	7.0	7.0	6.5	6.5	-	-
NA2	-	-	6.5	6.5	7.0	7.0	6.5	6.5	-	-
NA3	-	-	7.5	7.5	7.0	7.0	6.5	6.5	-	-
NA4	-	-	6.5	6.5	6.5	6.5	6.5	6.5	6.5	6.5
NA5	-	-	7.0	7.0	6.5	6.5	6.5	6.5	8.0	9.0
Streptomycin 10µg	12.0		18.0		16.0		18.0		18.0	
Kinamycin 30µg	22.0		20.0		20.0		24.0		24.0	

Unfortunately, tested compounds did not display a remarkable activity against both type of bacteria and fungi. Nevertheless, compound NA5 showed valuable inhibitory activity. The activity of these compounds might be attributed to the presence of high electronegative substituent which enhanced the lipophilicity of the compounds. The lipophilicity of the compounds plays an important role in the penetration of solutes into the bacterial cell tissue [13]. The antibacterial activity of compound NA5 was higher than NA3 because NA5 contained multi fluoro group substituents which increase the lipophilicity of this compound. In contrary, all tested compounds had no activity against gram-negative bacteria. This observations showed that, the compounds were generally had better permeability towards gram-negative bacteria cell tissue.

Based on the test results, tested compounds had very low inhibition zone (IZ) values. It is known that thiourea compounds were generally exhibit good antimicrobial activities. However in this study, the results were contrary. This might be due to the solubility of the target compounds on the surface of the agar medium. Thus, the compounds were suspended on the agar surface and cannot reacted against those bacterias

Conclusion

In conclusion, five derivatives of 1,3-benzenedicarboxamide and 2,6-pyridinedicarboxamide bis-thiourea have been synthesized via solid-liquid phase transfer catalysis of PEG-400 and characterized by FTIR, ^{1}H and ^{13}C NMR. The preliminary studies on the antimicrobial activity via disc diffusion method showed that NA5 exhibit potential activity against *Staphylococcus Aureus*. For further research, we are planning to investigate the effect of transition metal complexation with these compounds toward their antimicrobial activity as some reports demonstrated that bis-thioureas antimicrobial activity were enhanced when complexed with transition metal. In addition, more sensitive antibacterial screening method such as dilution method should be used to evaluate the potential of synthesized compounds.

Abstract

Traditional liquid – liquid extraction of pesticides consumes large volumes of organic solvent which are hazardous to the operator and is not environment friendly. Solid phase microextraction (SPME) is a solvent less extraction method which is safer to the operator and is environmental friendly. A sol-gel hybrid fibre coating material, poly(dimethylsiloxane)-poly(vinyl alcohol) (PDMS-PVA) was synthesized and used in head space solid phase microextraction (HS-SPME) of chlorpyrifos. The thickness of the synthesised PDMS-PVA fiber coating was 13.5 µm and it is thermally stable up to 400 °C. The PDMS-PVA sol-gel hybrid fiber was also stable to two organic solvents tested; acetonitrile and dichloromethane (1 hour dipping) and showed no significant changes in extraction performance for chlorpyrifos. Extracted chlorpyrifos was analysed using gas chromatography electron capture detector (GC-ECD). Optimum SPME parameters affecting the PDMS-PVA HS-SPME performance namely extraction time (15 min), extraction temperature (50 °C), desorption time (5 min), desorption temperature (260 °C) and stirring rate (120 rpm) were used for extraction. It was found that HSSPME using PDMS-PVA sol-gel fiber gave significantly better extraction performance of chlorpyrifos compared to commercial 100 µm PDMS fiber. The PDMS-PVA fiber showed excellent operational performances such as temperature stability (up to 380 °C), coating lifetime (up to 170 times use) and organic solvent stability. The PDMS-PVA-HS-SPME method showed excellent recovery for chlorpyrifos from tomatoes (98.0 %, 5.9% RSD) at 0.01 µg/g spiked level (5 times lower than maximum residue limit set by European Union).

Keywords: sol-gel hybrid, solid phase microextraction, chlorpyrifos, gas chromatography-electron capture detector

Abstrak

Pengekstrakan cecair – cecair tradisional bagi pestisid menggunakan isipadu pelarut organik yang banyak yang merbahaya kepada operator dan tidak mesra alam. Pengekstrakan mikro fasa pepejal (SPME) adalah teknik pengekstrakan tanpa pelarut yang lebih selamat kepada operator dan mesra alam. Bahan gentian tersalut hibrid sol-gel poli(dimetilsiloksana)-poli(vinil alkohol) (PDMS-PVA) telah disintesis dan digunakan untuk pengekstrakan mikro fasa pepejal ruang kepala (HS-SPME) klorpirifos. Ketebalan PDMS-PVA gentian tersalut yang telah disintesis ialah 13.5 µm dan stabil terma sehingga 400 °C. Gentian hibrid sol-gel PDMS-PVA juga stabil terhadap dua pelarut organik yang diuji, asetonitril dan diklorometana (1 jam celupan) dan tidak menunjukkan perbezaan ketara dalam prestasi pengekstrakan klorpirifos. Klopirifos yang telah diekstrak dianalisis menggunakan kromatografi gas-pengesan penangkapan elektron (GC-ECD). Parameter optimum SPME yang mempengaruhi prestasi PDMS-PVA-HS-SPME iaitu masa pengekstrakan (15 min), suhu pengekstrakan (50 °C), masa penyaherapan (5 min). suhu penyaherapan (260 °C) dan kadar putaran (120 rpm) telah digunakan untuk pengekstrakan. HS-SPME menggunakan gentian sol-gel PDMS-PVA menunjukkan prestasi pengekstrakan yang jauh lebih signifikan untuk klorpirifos berbanding dengan gentian komersial 100 µm PDMS. Gentian PDMS-PVA telah menunjukkan prestasi operasi yang cemerlang seperti kestabilan

suhu (sehingga 380 °C), jangka hayat salutan (sehingga 170 kali penggunaan) dan kestabilan terhadap pelarut organik. Kaedah PDMS-PVA HS-SMPE menunjukkan perolehan semula yang cemerlang untuk klorpirifos daripada sampel tomato (98.0 %, 5.9% RSD) pada aras pakuan 0.01 µg/g (5 kali lebih rendah daripada had maksimum residu yang ditetapkan oleh Kesatuan Eropah).

Introduction

The social concern about the levels of pesticides in the environment and the constant trend observed in current legislations to reduce their maximum residue levels allowed in a variety of matrices is increasing the number of samples to be analyzed well as the need for their accurate determination at very low levels. The help from the advance and improving technology especially in extraction and detection makes the study on pesticides more significant.

In recent years, separation and extraction sciences faced important developments. Starting with solid-phase extraction (SPE) in the 1980s, other modern methods, such as supercritical fluid extraction (SFE), supercritical fluid chromatography (SFC), solid-phase microextraction (SPME) and capillary electro-chromatography (CEC) have been introduced. Among the extraction methods available, SPME is more favorable due to its simplicity, solvent free application, rapid and versatility. Therefore to expand the potential of SPME as an extraction method is a very interesting challenge in improving separation science.

Commercial SPME fibers have generally good extraction properties compared to other conventional extraction method. However there are some drawbacks and certain aspects of their performance that can be improved. For instance, incomplete desorption that causes carry-over problems and a reduction of the lifetime of the fibers due to direct extraction of higher salt content samples and complex matrices, have been reported in the literature [1]. Furthermore, the low thermal stability, generally bleeding at high temperature (> 250 °C) and solvent stability can lower the extraction and desorption process. Recently, some new types of fibers, such as non polar silica particles bonded with C_8, C_{18} [2], pencil lead [3], graphite [4], nafion perfluorinated resin [5], polypyrrole [6], anodized aluminum wire [7], and molecularly imprinted polymer-coated fiber [8] have been prepared. However, almost all of these fibers coated with polymer are generally prepared by mere physical deposition, high temperature epoxy immobilization or partial crosslink of the polymer coating on the surface of the fused-silica fibers. The lack of proper chemical bonding between the polymer coating and fused-silica fiber surface may be responsible for the low thermal and chemical stability. The fiber coating lifetime is also limited, usually from 40 to 100 extractions [1]. In addition, the price of commercially available fibers is high due to their preparation process requiring expensive equipment.

Apparently the introduction of sol-gel technology has a promising alternative to overcome those problems. Sol-gel coating technology offers important advantages compared with conventional coating technique; strong adhesion between the coating and the bare fused-silica surface, the porous silica surface structure of sol-gel coating which can provide high surface areas and allow for high extraction efficiency and relative ease to change the composition of the coating which therefore will have different selectivity. This technology has been widely used to prepare SPME fiber because it can effectively create chemically bonded, porous and highly crossed coating on the fused silica fiber surface [9 – 12]. The simplicity of the sol-gel coating procedure provides excellent batch-to-batch reproducibility of the home-made fibers. A work done by Cajlakovic et al. [13] using poly(vinyl alcohol) (PVA) copolymer as optical pH sensing material offers a promising option for PVA to become as coating material in SPME fiber. This work successfully demonstrated that PVA with cross-linked produced a homogenous and crack-free membrane, making it more suitable for SPME fiber coating by sol-gel technology process.

In the current study, a simple and economical methodology for the determination of chlorpyrifos using headspace solid phase microextraction (HS-SPME) with an in-house silica-based sol-gel hybrid, polydimethylsiloxane-poly(vinyl alcohol) (PDMS-PVA) fiber coupled to gas chromatography equipped with an electron capture detector is presented and its use assessed in terms of thermal stability, solvent stability, reusability and application to real sample analysis of chlorpyrifos from water and tomato samples.

Materials and Methods

Reagents

Methyltrimethoxysilane (MTMOS), hydroxyl-terminated polydimethylsiloxane (OH-TPDMS), poly(vinyl alcohol) (PVA), trimethylmethoxysilane (TMMS), poly(methylhydroxysilane) (PMHS), and trifluoroacetic acid (TFA) were purchased from Sigma-Aldrich (USA). Sulfuric acid was obtained from Merck (Darmstadt, Germany). Hydrochloric acid and sodium hydroxide were purchased from Fluka Chemika (Switzerland). Chlorpyrifos was purchased from Dr. Ehrenstorfer (Augsburg, Germany). HPLC grade methanol was obtained from Merck (Schuchardt, Germany). Double-distilled deionized water of at least 18 MΩ was purified by Nano ultra pure water system (Barnstead, USA). Stock solution of 1000 ppm of chlorpyrifos was prepared in methanol. Working standard solutions was prepared by diluting the stock solutions with HPLC grade methanol. The stock solution and working standard was stored at 4 °C when not in use.

Preparation of fused silica fiber and PDMS-PVA sol-gel hybrid coating

Pieces of fused silica fiber were soaked in concentrated sulfuric acid for 3 h to remove original polyimide layer and to expose the fused silica core for sol-gel coating process. The fused silica fibers were then rinsed with distilled water and dipped into 1 M NaOH solution. The basic solution was removed and the fibers were exposed to 0.1 M HCl solution for 30 min to neutralize the excess NaOH. The activated fused silica fibres were then rinsed with distilled water, dried at 120 °C and stored for 12 h in a desiccator before use.

The PDMS-PVA sol phase was prepared by mixing 600 µL MTMOS, 300 mg OH-TPDMS, 80 mg PVA, 50 µL PMHS, and 400 µL of 95 % aqueous TFA in a glass tube. The mixture was vortexed for 2 min before being centrifuged at 12 000 rpm for 5 min. The top sol solution was used for fiber coating (1 cm length). After the treated fiber was dipped vertically into the sol solution for 20 min, a sol-gel coating was formed on the bare outer surface of the fiber end. For each fiber, this coating process was repeated three times with a freshly prepared PDMS-PVA sol phase. The coated fibers were then end-capped in a 20 % (v/v) methanolic solution of TMMS for 1 min. The in-house coated fibers were then mounted on used, discarded commercial SPME assemblies, after careful removal of the original fiber. Prior to use, the new PDMS-PVA fibers were conditioned in the GC injection port at 100°C for 2 h and then for 6 h at 280°C under 1 mL min^{-1} of Helium flow. The remaining sol from the fiber coating process was allowed to gel at room temperature for 2 h, ground, washed with distilled water and methanol, and conditioned under the same conditions as the fibers. It was used to run field emission-scanning electron microscopy (FE-SEM).and Fourier transform infrared spectroscopy (FTIR).

Characterization of sol-gel hybrid PDMS-PVA

The sol-gel PDMS-PVA composite was characterized using a 1600 series PE spectrophotometer (MA, USA) FTIR using KBR method in the range of 400 – 400 cm^{-1}. Thermal gravimetric analysis (TGA) was conducted using a Mettler Toledo TG-50 thermal analyser (Greifensee, Switzerland) within a temperature range 50 –800 °C. The thickness and surface morphology of the sol-gel hybrid PDMS-PVA was determined using a JEOL JSM-6710F FE-SEM (Tokyo, Japan).

Head space-solid phase microextraction

The fiber was conditioned by inserting it into the GC injection port at 250°C for a period of 30 min to 1 h. Then the fiber was repeatedly injected into the GC-ECD system until interfering peaks disappeared from the chromatogram monitored and satisfying baseline was obtained. Injection was performed under the same temperature programming for analysis. For HS-SPME mode, 2 mL of sample solution was placed in a 5 mL sample vial containing a magnetic stir bar and the vial was sealed with a PTFE septum. The vial was placed on a magnetic hot plate. Then the fiber was carefully introduced directly into the head space above the aqueous phase and stirred at a rate of 120 rpm for 15 min (temperature set to 20 °C). After the preset extraction time, the fiber was retrieved and introduced for a period of 5 min into the GC injection port for chlorpyrifos analysis.

Gas chromatography-electron capture detector conditions

The OPPs extracted by the SPME fiber was analyzed using an XL Perkin Elmer gas chromatography-electron capture detection (GC-ECD) system (CA, USA). For desorption of the analytes inside the GC injection port was set

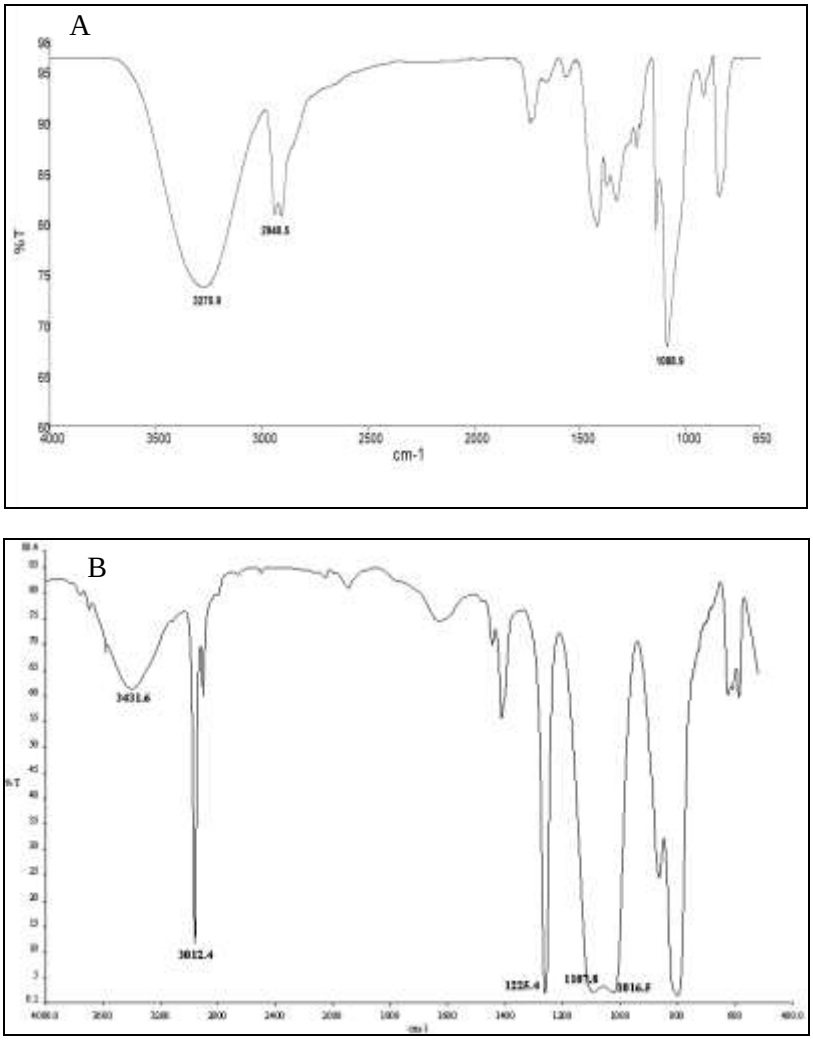
at 280 °C. The column was kept at 180 °C for 2 min, then ramped at 4 °C min^{-1} to 200 °C, hold for 1 min and finally ramped at 10°C min^{-1} to 290°C, and hold for 1 min. The detector temperature was set at 300 °C. Helium was used as the carrier gas at a flow rate of 1.0 mL min^{-1} and nitrogen as a make-up gas was used at a flow rate of 32.4 mL min^{-1}. The pressure of the carrier gas was 10.0 psi. Peak areas of the ECD chromatogram signals were used to demonstrate the effect of parameters on the extraction efficiency of chlorpyrifos.

Real sample analysis

For real sample analysis, tomato (*Solanum lycopersicum*) was chosen as the sample as the matrix contains high colorant pigment due to the presence of carotenoid to assess matrix effect in PDMS-PVA-HS-SPME. The tomato was purchased from one of the local markets in Skudai, and stored in refrigerator to keep them fresh before analysis. The tomato was cut into small pieces and finely homogenized by using a chopper. Analytical portions of the tomato samples (10.0 g) were weighed in a 50 mL centrifuge tube and 20 mL deionized water was added. Then the sample was left to be extracted for 30 min on an ultrasonic bath. After the ultrasonication process, it was filtered through a filter paper. For analysis purpose, an aliquot of the sample (2 mL) was taken by micro-pipette to a SPME vial and followed by PDMS-PVA-HS-SPME procedure. For the accuracy test (recovery), the samples were fortified with chlorpyrifos at three different concentrations (0.005, 0.008 and 0.01 µg/g) and stored in refrigerator for one night to allow interactions between the chlorpyrifos and sample matrix. The chlorpyrifos concentration used is well below the MRL (5 – 100 times lower than the MRL) set by European Union for chlorpyrifos in tomato (0.5 mg/kg).

Results and Discussion

Preparation of sol-gel hybrid PDMS-PVA coating



In this study, the sol-gel process was carried out using four principal ingredients which are, precursor, coating materials, deactivation reagent and acid catalyst. MTMOS was selected as precursor as it can avoid cracking and shrinkage of the coating during the gel-drying process. The sol-gel network originating from an alkyl derivative of precursor possesses a more open structure and can more effectively relieve stresses during drying, minimizing the cracking tendency [14]. PDMS is well known as a good non-polar stationary phase [15], but the addition of PVA is likely to improve the selectivity of fiber towards relatively polar or lower molecular weight compounds. As studied by Li et al. [16] who used terminated silicone oil as one of his coating material, it was not only to lengthen the silica network, leading to increase surface area of the fiber but also to spread the stationary phase of the fiber uniformly. In addition Cajlakovic et al. [13] proved PVA can be incorporated in sol-gel networks by the usual polycondensation processes and acts as a strong cross-linking agent. Another important ingredient used in the sol-gel coating process is PMHS, a well-known surface deactivation reagent in gas chromatography [10, 17]. Molecules of PMHS contain reactive hydrogen atoms capable of derivatizing silanol groups at elevated temperatures. Molecules of this ingredient get physically incorporated in the coating during the coating process. Post-coating thermal conditioning step leads to the deactivation of the fiber surface. The chemical structure of PMHS is very similar to that of PDMS, so it would not be a problem with PMHS as a deactivation reagent since its incorporation into the coating structure should have little effect on the sol-gel SPME fiber characteristic. Trifluoroacetic acid (TFA) was chosen as an acid catalyst to be added in the sol solution mixture. The reason for this is because during the sol-gel reaction, if the hydrolysis and polycondensation reaction rate is too fast, the coating stationary phase can hardly bond because of the space resistance of the three-dimensional network existed. Therefore, TFA is used to decrease the water reaction content in the sol, resulting in a slower hydrolysis reaction.

Characterization of sol-gel hybrid PDMS-PVA

Characterizations of the sol-gel hybrid PDMS-PVA were carried out on the in-house sol-gel PDMS-PVA fiber in order to verify whether the fiber was successfully synthesized. The physical characterizations included Fourier transform infrared (FTIR) spectroscopy, thermogravimetric analysis (TGA) and field emission-scanning electron microscopy (FE-SEM).

The FTIR spectra obtained from the sol-gel OH-TPDMS and PDMS-PVA composite were evaluated and subsequently compared. The spectrum of PDMS-PVA with the corresponding spectrum of the conventional PDMS from pure OH-TPDMS and PVA is also shown for comparison purposes (Figure 1). The position and characteristic of OH-TPDMS bands observed were in good agreement with those reported in the previous studies [18, 19]. The broad absorption band at 3436.7 cm^{-1} for sol-gel PDMS-PVA matches to the axial stretching of O-H bonds, and is

attributed to residual hydroxyl groups not eliminated after the end-capping treatment. However the intensity absorption present is small as the percentage transmittance is only 2 %. The decrease in hydroxy group peak in PDMS-PVA shows that it has been chemically bonded with other components. This band is also present in the OH-TPDMS with major intensity at 3431.6 cm^{-1}. Other absorption peaks match both those of sol gel PDMS-PVA and OH-TPDMS: 2965.0 cm^{-1} corresponds to the stretching of C-H bonds on methyl groups and 1022.3, 1096.1 and 1262.2 cm^{-1} corresponds to the stretching of Si-O bonds. However peaks at 2168.1 and 900.8 cm^{-1} present in sol-gel PDMS-PVA but not found in OH-TPDMS spectrum are attributed to Si-H bounds from PMHS, used as a surface deactivation reagent. The broad absorption peak around 1622.4 cm^{-1} found on PDMS-PVA can be attributed to the stretching of alkenic and vinylic C=C bonds, possibly formed by loss of water from poly(vinyl alcohol) (PVA) chains incorporated in the polymer framework. However, the presence of the hydroxyl absorption band suggests that the dehydration of the PVA chains have not been completed under the conditions used. This did not happen in PDMS-PVA fiber because the conditioning temperature for the fiber was up to 300°C compared to that the composite in example around 120°C for the maximum temperature.

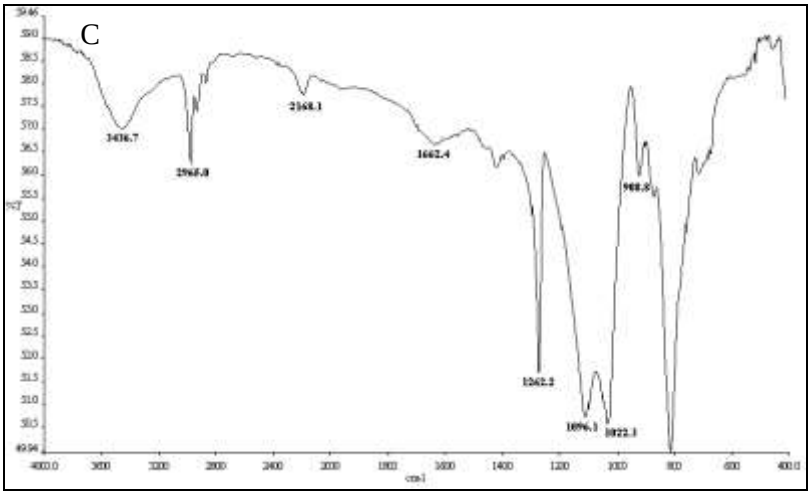


Figure 1. Infrared absorption spectra of: (A) PVA, (B) OH-TPDMS and (C) sol-gel PDMS-PVA

Thermal stability of the sol-gel PDMS-PVA fiber was studied using TGA in order to determine the limit of the operating temperature for the fiber and also helpful to enhance its coating lifetime. The TGA was performed under nitrogen gas and over the range temperature of 50-800°C at heating rate of 10°C min^{-1}. TGA curves (Figure 2) shows that the thermal degradation of the sol-gel PDMS-PVA composite occurs in three main stages. The first mass loss corresponds to slight degradation of PDMS-PVA which occurs at 240 °C. Between 240 °C and 330 °C, only 2 % of the total mass is lost for the sol-gel PDMS-PVA. The main mass loss step happens between 400 °C and 630 °C, corresponding to a loss 50 % of the initial mass with no other thermal series visible after this temperature. The last event was considered as characteristic of the thermal degradation of the sol-gel PDMS-PVA and can be assigned as its maximum practicable temperature. For the commercial PDMS SPME fiber, the maximum recommended operating temperature is only 280 °C; otherwise the fiber will deteriorate and affect analysis result negatively.

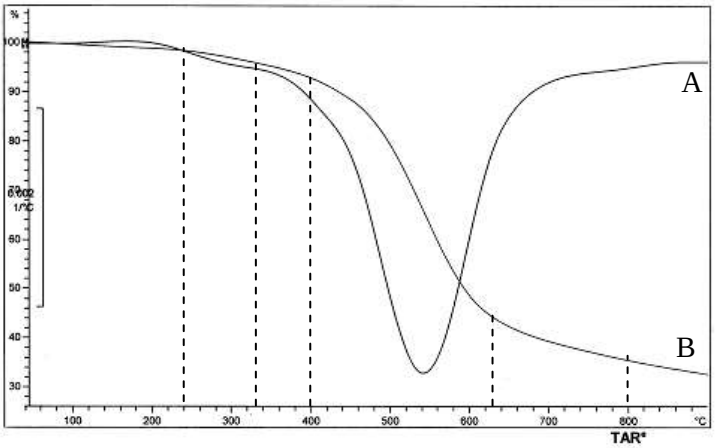

Figure 2. (A) TGA curve and (B) its first derivative of TGA curve for the sol-gel hybrid PDMS-PVA composite

The morphology of the sol-gel PDMS-PVA fiber surface was analyzed using FE-SEM. The average thickness of the sol-gel PDMS-PVA layer was estimated as being ~13 µm. This thickness is 6.5-8 times considerably thinner than most conventional coating thickness on commercial SPME fibers (100 µm for PDMS and 85 µm for polyacrylate). From this point of view, sol-gel coatings might seem inconvenient for SPME. However, the surface of the PDMS-PVA coating seems to be compact and smooth and also shows a high density of small particles with apparent rugged surface. Therefore increased in the availability of the surface area on the fiber thus enhanced the extraction performance.

Optimization of HS-SPME process

In order to optimize the HS-SPME technique, factors affecting the extraction efficiency such as extraction time, extraction temperature, stirring rate, desorption time, and desorption temperature were studied. Extraction time is determined by the length of time required for the analyte to reach equilibrium between the concentrations of analyte in the sample and the fiber stationary phase. Six different extraction times ranging from 5 to 40 min of HS-SPME with stirring rate fixed at 120 rpm have been studied. According to the literature [20 – 22], the extraction time can be shortened by working in the non-equilibrium area. Indeed, full equilibrium is not necessary as long as other parameters such as stirring rate and sampling time are kept constant and the result allowed a good and reproducible extraction response for chlorpyrifos. The optimum extraction time selected for the sol-gel PDMS-PVA fiber is 15 min (Figure 3). The rugged structure believed to be possessed by the PDMS-PVA fiber provided high surface area, allowing fast and effective extraction.

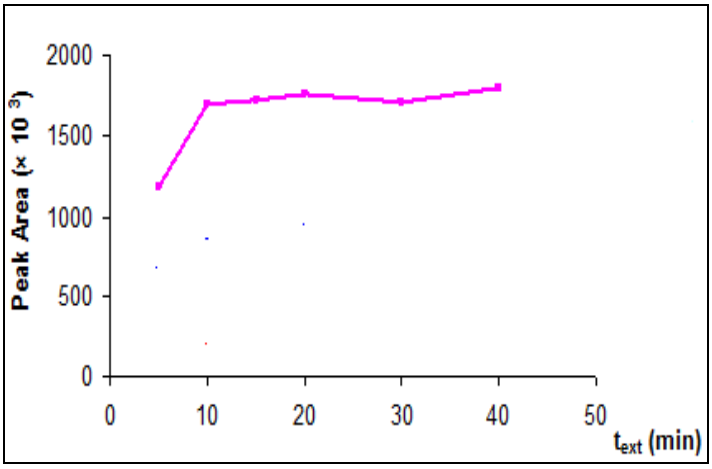

Figure 3. Extraction time profile for chlorpyrifos using PDMS-PVA fiber. HS-SPME conditions: t_{ext} 50 °C, t_{des} 5 min, T_{des} 250 °C, and stirring rate 120 rpm

The effects of extraction temperature ranging from 25 to 80 °C have been studied. In general with increasing temperature, the extraction ability of the fiber increased, this is because increasing temperature can significantly increase analyte evaporation rates (distribution constant) and mass transfer at the solution-gas interface (distribution velocity), which enhances the analytes to enter the gas phase and fiber coating. The extraction temperature profile for chlorpyrifos is shown in Figure 4. The figure shows that the equilibrium was established at extraction temperature of 50 °C. Consequently, 50 °C was selected as the optimum extraction temperature for PDMS-PVA fiber. The rate of diffusion of analytes through the static layer at the fiber solution interface increase with increasing temperature, so that more analytes are extracted at high temperature if equilibrium has not been reached [23].

Desorption time of the analyte from the fiber was studied to ensure complete desorption of the chlorpyrifos into the GC column. Six different desorption time varying from 1 to 10 min were studied. It was observed that desorption efficiency increase with an increase in desorption time from 1 to 5 min. After 5 min, there was no significant

increase in the peak area observed. Therefore 5 min of desorption time was selected as the optimum desorption time as it gave the highest amount of the analyte extracted (based on peak area).

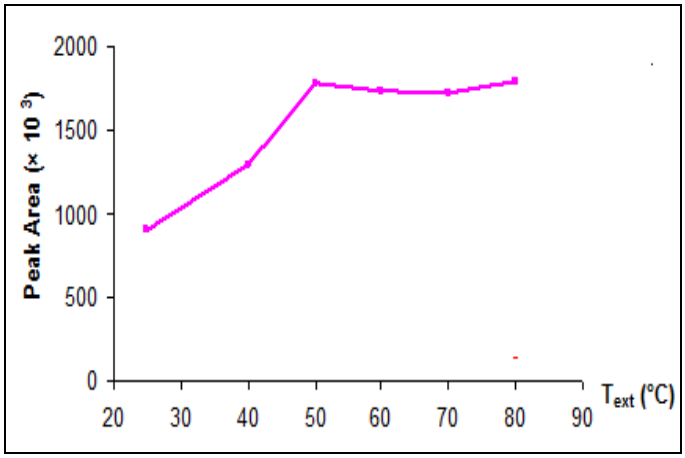

Figure 4. Extraction temperature profile for chlorpyrifos using PDMS-PVA fiber. HS- SPME conditions: t_{ext} 20 min, t_{des} 5 min, T_{des} 250 °C, and stirring rate 120 rpm

Desorption temperature of HS-SPME is measured from the GC injection port temperature indicator. In the current study, the effects of desorption temperatures ranging from 230 °C to 280 °C have been studied. Desorption temperature is important to guarantee complete desorption of the analyte studied to avoid carryover at the fiber. The result shows that there are no significant differences in peak area obtained at different temperature. Even though high temperature enhanced the desorption process but it can also degrade the analytes, worst it can damage the fiber and shorten its lifetime. Therefore, 260 °C was selected as the optimum desorption temperature since complete desorption the analyte studied were obtained from the coating. Furthermore, the PDMS-PVA fiber reveals that it can maintain the OPP peak area value obtained at different desorption temperature, which was almost the same.

Sample agitation or stirring was applied to enhance extraction and reduce extraction time, especially for higher molecular weight analytes with high diffusion coefficients. For practical purposes magnetic stirring bar was used in this study. It allows the control of the stirring rate and cyclic change in stirring direction. The effects of stirring rate ranging from 0 rpm to 600 rpm have been studied in the current work. The result obtained shows that the extraction efficiency increases as the stirring rate increased up to 120 rpm and decreases when the stirring rate further increased to 600 rpm. This agrees with the fact that SPME is a method based on equilibrium and that good diffusion through the phases is essential to reach equilibrium faster. Therefore a constant 120 rpm stirring rate was selected as the optimum stirring rate for HS-SPME of the chlorpyrifos.

Method validation

The optimized conditions for the HS-SPME extraction of chlorpyrifos using PDMS-PVA fiber are as follows; 15 min extraction time, 50 °C extraction temperature, 5 min desorption time, 260 °C desorption temperature and 120 rpm stirring rate. Under the optimum conditions, the PDMS-PVA-HS-SPME method was developed and validated for the extraction of spiked chlorpyrifos from water samples in terms of linearity, precision, limits of detection (LOD) and limits of quantification (LOQ). Good coefficient of determination was obtained (r^2 = 0.9972) within linearity range 0.001-0.1 ppm. The LOD at S/N = 3 obtained was 0.0076 ppm which is 5 –10 times lower than the maximum residue limit (MRL) set by the European Union (EU) [24].

Real sample analysis

The method developed for HS-SPME-PDMS-PVA for water samples was extended to tomato samples. Since no chlorpyrifos was detected in the tomato samples analysed, it was spiked with three different concentrations of

chlorpyrifos in order to determine the accuracy and precision of the PDMS-PVA HS-SPME method developed. It was found that at 0.01 and 0.008 µg/g spiking level, the accuracy of the PDMS-PVA-HS-SPME method developed was comparable with the commercial 100 µm PDMS-SPME. Sample matrix from the tomato samples was found not to significantly affect the accuracy of the PDMS-PVA-HS-SPME method. The precision of the PDMS-PVA-HS-SPME was better than the commercial 100 µm PDMS SPME. However, the accuracy of the commercial 100 µm PDMS SPME was better for samples spiked at the lowest level, 0.005 µg/g. The lower recovery obtained using the PDMS-PVA HS-SPME is probably due to the sample matrix effect which is more pronounced in the in-house SPME fibre. Comparable precision was obtained for samples spiked at 0.005 µg/g for both the SPME fibres (Table 1). Figure 5 shows the chromatogram of a spiked tomato sample analysis using the HS-SPME-PDMS-PVA.

Table 1. Percentage recovery and RSD of different concentrations of spiked chlorpyrifos from tomato sample using optimum HS-SPME conditions

Spiked concentration (µg/g)	**% Recovery (% RSD, *n* = 3)**	
	13 µm PDMS-PVA	**Commercial 100 µm PDMS**
0.005	62.64 (5.35)	76.86 (5.68)
0.008	85.65 (8.24)	85.62 (6.81)
0.01	98.01 (5.91)	91.70 (7.02)

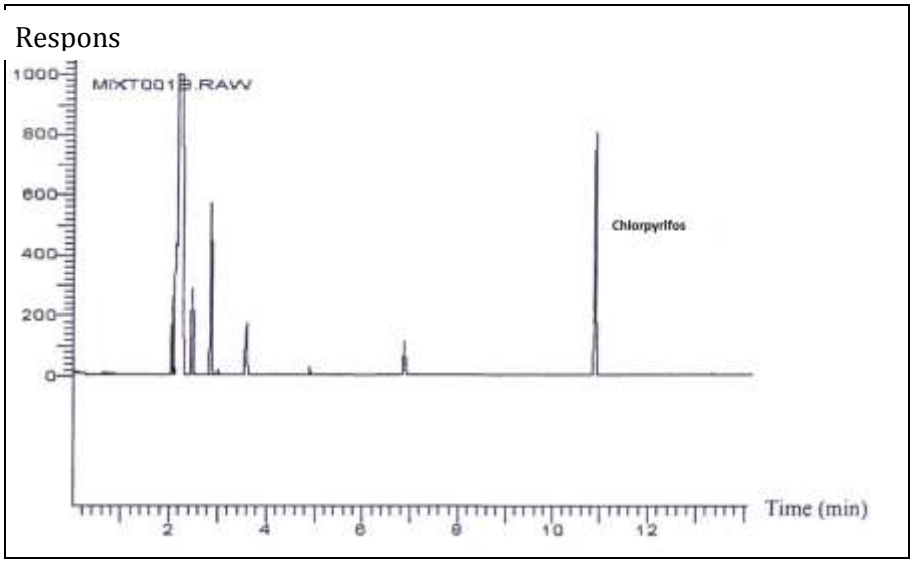

Figure 5. Chromatogram of spiked chlorpyrifos from tomato samples using the in house PDMS-PVA fibre. GC conditions:HP-5 column (30 m × 0.32 mm ID and 0.25 µm film thickness). Carrier gas: He at 1.0 mL min^{-1}. Detector: ECD. Injection port temperature: 280°C, Detector temperature: 300°C. Temperature programming: 180 – 290 ^{o}C at 4°C min^{-1} to 200°C (hold 1 min) and 10°C min^{-1} to 290°C (hold 2 min).

Conclusion

Sol-gel hybrid PDMS-PVA coating was successfully synthesized and applied as a SPME fiber coating for analysis of chlorpyrifos. The new sol-gel hybrid PDMS-PVA coating has high temperature stability up to 380 ^{o}C and showed comparable extraction performances to commercial 100 µm PDMS fiber in the extraction of chlorpyrifos

from tomato samples spiked at 0.01 and 0.008 µg/g. Matrix effect from the tomato samples did not significantly affect the extraction of chlorpyrifos spiked at these two levels (0.008 – 0.1 µg/g which is 5 – 60 times lower) below the MRL set by EU. The lower recovery of chlorpyrifos from tomato at a spiking level of 0.005 ppm (100 times lower than MRL) using the PDMS-PVA-HS-SPME could be due to matrix effect from the tomato samples. The sol-gel hybrid PDMS-PVA offers an alternative SPME coating of chlorpyrifos from water and vegetable samples such as tomato.

ENHANCED ACTIVITY OF C_3N_4 WITH ADDITION OF ZnO FOR PHOTOCATALYTIC REMOVAL OF PHENOL UNDER VISIBLE LIGHT

(Peningkatan Aktiviti C_3N_4 dengan Penambahan ZnO untuk Fotomangkin Penyingkiran Phenol di bawah Sinaran Tampak)

Abstract

Phenol is a stable and hazardous compound that is commonly found as an industrial effluent. Phenol can be treated by photocatalysis using zinc oxide (ZnO) as a photocatalyst. Unfortunately, the use of ZnO in photocatalysis is limited due to the poor response to the visible light. On the other hand, carbon nitride (C_3N_4) is able to absorb visible light. In the present study, a series of ZnO-C_3N_4 was prepared by impregnation method. The effect of zinc to carbon mol ratio (Zn/C) on the properties and photocatalytic activity was examined. X-ray Diffraction (XRD) patterns of the samples revealed that as the Zn mol ratio increased, the intensity of diffraction peaks for ZnO also increased but the intensity for C_3N_4 decreased. All prepared composite materials have an extended absorption band in the visible light region due to the presence of C_3N_4, as supported by DR UV-Vis spectra. The prepared ZnO-C_3N_4 composites were further investigated in the photocatalytic removal of phenol under visible light for 5 hours. All ZnO-C_3N_4 samples showed higher activity than the bare ZnO with Zn/C mol ratio of 1% showed the highest photocatalytic activity for removal of phenol among all the samples. The high activity observed on the ZnO-C_3N_4 would be due to role of ZnO to suppress electron-hole recombination and C_3N_4 to extend the absorption of ZnO in the visible light region.

Abstrak

Fenol adalah sebatian stabil dan berbahaya yang sering dijumpai sebagai efluen industri. Fenol boleh dirawat dengan cara fotopemangkinan menggunakan zink oksida (ZnO) sebagai fotomangkin. Malangnya, penggunaan ZnO di dalam fotopemangkinan adalah terhad disebabkan sedikit respons terhadap sinaran tampak. Sebaliknya, karbon nitrida (C_3N_4) mampu menyerap sinaran tampak. Dalam kajian ini, siri ZnO-C_3N_4 telah disediakan melalui kaedah pengisitepuan. Kesan nisbah mol zink kepada karbon (Zn/C) kepada ciri dan aktiviti fotomangkin telah diperiksa. Corak pembelauan sinar-x (XRD) daripada sampel – sampel membuktikan bahawa kesan nisbah mol Zn meningkat, keamatan puncak pembelauan untuk ZnO semakin naik tetapi keamatan untuk C_3N_4 semakin kurang. Semua bahan komposit yang disediakan mampu memperluaskan jalur penyerapan di dalam kawasan sinaran tampak disebabkan kehadiran C_3N_4 dan disokong oleh spectrum DR UV-Vis. Komposit ZnO-C_3N_4 yang disediakan selanjutnya dikaji di dalam fotomangkin penyingkiran fenol di bawah sinaran tampak selama 5 jam. Kesemua sampel ZnO-C_3N_4 mempunyai aktiviti yang tinggi berbanding hanya ZnO dengan 1% nisbah mol Zn/C menunjukkan aktiviti fotomangkin tertinggi dalam penyingkiran fenol. Aktiviti tinggi yang dilihat terhadap ZnO-C_3N_4 berkemungkinan disebabkan peranan ZnO untuk membantutkan penggabungan semula lubang elektron dan C_3N_4 untuk memperluaskan penyerapan ZnO di dalam kawasan sinaran tampak.

Introduction

Zinc oxide (ZnO) is one of the crucial multifunctional oxide materials for various applications, such as in sensors, solar cells and photocatalysis [1 – 9]. The ZnO has been investigated due to its unique property of wide band gap (3.37 eV), excitation binding energy (60 meV) at room temperature and good activity for photocatalytic decomposition reactions. Unfortunately, since ZnO has wide band gap and absorption only in the UV region [10], it requires large amount of energy in order to be active as a photocatalyst.

There are various ways to extend the absorption of ZnO to the visible light, such as by incorporating the ZnO with transition metal doping [11 –13], dye sensitizer [14 –15], and CdS [16]. Another feasible modifier is metal free graphitic carbon nitride (C_3N_4). The C_3N_4 has relatively lower band gap energy (2.70 eV) compared to the ZnO (3.37 eV), thus it is also able to absorb visible light region. Furthermore, the C_3N_4 has a strong covalent bond between carbon and nitrogen in the structure that makes it exhibit high stability under visible light irradiation, which can prevent photocorrosion effect that lead to the decreasing of activity. Due to these unique features, C_3N_4 is used as a visible light driven photocatalyst and it can be combined with other photocatalysts for better photocatalytic activity in the complete spectral region [17]. However, only few reports emphasizing on the incorporation of ZnO with the C_3N_4. It was reported that the modification of ZnO with C_3N_4 gave a promising result in the photocatalytic removal of methylene blue under visible light irradiation [18].

In this study, phenol was used as the model for organic pollutant. Phenol is considered as a toxic compound released from the industrial as an effluent. Moreover, phenol is very stable and it will remain in the waste water for a long term [19, 20]. Photocatalytic process is one of the available methods that offer both sustainable energy source and environmental friendly process. Since photocatalytic process involves minimum requirement of energy for decomposition of organic pollutant, it is believed that photocatalytic reaction is a green method for phenol decomposition. Moreover, it provides the possibility to utilize the solar light. Therefore, in this study, photocatalytic removal of phenol was investigated by applying visible light over the ZnO-C_3N_4 photocatalysts.

Materials and Methods

Preparation of carbon nitride (C_3N_4)

Urea ($CO(NH_2)_2$, Merck, 99.5%) was used as a source of carbon and nitrogen for preparation of the C_3N_4. The urea (300 g) was calcined under air atmosphere at a rate of 2.2 °C min^{-1} for 4 h in order to reach a temperature of 550 ^oC and tempered for 4 h at this temperature. The resulting yellow solid was ground before using it as the photocatalyst.

Preparation of ZnO

Zinc acetate dihydrate ($Zn(CH_3COO)_2.2H_2O$, QRëC, 99.5%) was used as the precursor to synthesize the ZnO. The $Zn(CH_3COO)_2.2H_2O$ (15 g) was calcined at 550 °C with a rate of 2.2 °C/min and tempered for another 4 h. The resulted solid was white in colour and was ground before it was used.

Preparation of ZnO-C_3N_4

Various ZnO-C_3N_4 samples were prepared by impregnation method with Zn/C ratios were 1, 5, 10, 20, and 50 mol percentage (mol%). The samples were labelled as ZnO-C_3N_4 (*x*) with *x* shows the ratio of zinc present in the sample. For a typical synthesis of ZnO-C_3N_4 (*1*), $Zn(CH_3COO)_2.2H_2O$ (0.0716 g) was dissolved in methanol (20 mL). The C_3N_4 (1 g) was then added slowly into the solution, stirred and dried at 80 °C on a hot plate until drying. The powder was then calcined at 550 °C for 4 h.

Characterizations

X-ray Diffraction (XRD, Bruker AXS Diffrac plus release 2000) was used to identify the structure of the prepared photocatalysts. The X-ray diffractogram of the catalyst was analyzed at 2θ range of 5-75° with scan rate of 0.05° s^{-1}. Diffuse reflectance Ultraviolet-Visible (DR UV-Vis, Shimadzu UV-2600) spectroscopy was used for measurement of absorption spectra of the prepared photocatalysts. Barium sulphate ($BaSO_4$) was used as the background reference with the scan range of 200-800 nm. Nicolet iS50 Thermo Scientific Fourier Transform Infrared Spectroscopy (FTIR) was used to detect the presence of functional groups in the composites. The measured wavenumber was in the range of 4000-400 cm^{-1} with the scan number of 32. Fluorescence spectroscopy (JASCO

Spectrofluorometer FP-8500) was used to obtain emission spectra of samples. The monitored wavelength was in the range of 200-600 nm. Potentiostat/Galvanostat/ZRA (Gamry Instruments Interface 100) was used for the photoelectrochemical studies. Typically, 0.01 g of C_3N_4, ZnO or ZnO-C_3N_4 composite was added to the solution containing of water (10 mL) and nafion (10 µL). Then, the solution was sonicated for 10 min. Afterward, the prepared sample (20 µL) was deposited onto the screen printed electrode (SPE) and then dried using a dryer for 10 min. Na_2SO_4 (0.01 M) and $K_3[Fe(CN)_6]$ (2.5 mM) aqueous solution was employed as an electrolyte. Before measurement, the prepared SPE was immersed in the electrolyte solution (6 mL) and the electrochemical impedance studies were conducted.

Photocatalytic activity test

The photocatalytic removal of phenol was conducted at room temperature. The photocatalyst (0.05 g) was dispersed in 100 mL of jacketed-beaker containing of phenol (50 ppm, 50 mL). Then, the beaker was placed on a stirring plate with cooling water system in a closed box for 30 minutes to let the adsorption reach the equilibrium. The reaction was carried out for 5 hours under visible light irradiation (150 W, $\lambda > 400$ nm, intensity of 100,000 lux). After reaction, the solution was taken and separated from the photocatalyst. The remaining phenol was measured by Gas Chromatography equipped with Flame Ionization Detector (GC-FID, Agilent 7820A).

Results and Discussion

Properties of C_3N_4, ZnO and ZnO-C_3N_4

In order to reveal the structure of the prepared samples, the diffraction patterns of the samples were recorded. As can be seen from Figure 1(a), the prepared C_3N_4 showed one intense peak at 2θ of 27.65°, which can be assigned as interlayer distances (d) of 0.32 nm, corresponding to the graphite-like C_3N_4 layer. An additional broad diffraction peak at 2θ of 12.95° with a d value of 0.683 nm showed a hole-to-hole distance of nitride pores, reflecting the geometric effect in pore walls of the prepared C_3N_4 sample [21]. The d values were obtained from the Bragg's law as shown in Equation 1.

$$n\lambda = 2d \sin \theta \quad (1)$$

where n is a positive integer, λ is the wavelength of the incident wave, d is the interplanar distance, and θ is the scattering angle. The presence of these diffraction peaks suggested that the C_3N_4 was prepared successfully. As can been observed from Figure 1(g), the diffraction peaks of the prepared ZnO can be indexed as a wurtzite structure, according to JCPDS file (JCPDS 89-1397).

For the ZnO-C_3N_4 composite samples, there were different trends of the diffraction peaks. For samples with low amount of ZnO (1 – 10 mol %), the samples showed the similar pattern as C_3N_4 with dominant peak at 2θ of 27.75°, suggesting the presence of C_3N_4 in these samples (Figure 1(b)-(d)). On the other hand, the samples with high amount of ZnO (20-50 mol %) showed similar diffraction patterns to the ZnO sample. This was reasonable as the amount of ZnO was larger than the C_3N_4. With the increase of the ZnO, the peak intensity of the C_3N_4 decreased. The XRD patterns clearly showed that the C_3N_4 and ZnO can be detected on the ZnO-C_3N_4 composite samples, depending on the amount of C_3N_4 and ZnO.

Figure 2 shows DR UV-Vis spectra for the ZnO and ZnO-C_3N_4 samples. For the C_3N_4 sample, it showed three strong absorption peaks at 277, 330 and 370 nm, corresponding to the N=C groups of aromatic 1,3,5-triazine, uncondensed C=O group and the terminal N-C group of C_3N_4, respectively (Fig. 2(a)). It was obvious that the C_3N_4 sample absorbed visible light up to *ca.* 450 nm. On the other hand, ZnO sample showed one absorption band centered at 320 nm due to the electron charge transfer in the Zn-O linkage, as shown in Fig. 2(g). For the ZnO-C_3N_4 samples, all samples showed the absorption peaks of both C_3N_4 and ZnO (Fig. 2(b)-(f)). As the mol ratio of Zn/C increased, the absorption edge of the samples showed blue-shifting from *ca.* 450 to *ca.* 380 nm. This was reasonable since when the amount of ZnO increased, the samples would behave like the ZnO, thus giving absorption spectra that were similar to that of the ZnO. From the DR UV-Vis measurements, it can be concluded that ZnO-C_3N_4 samples were successfully synthesized.

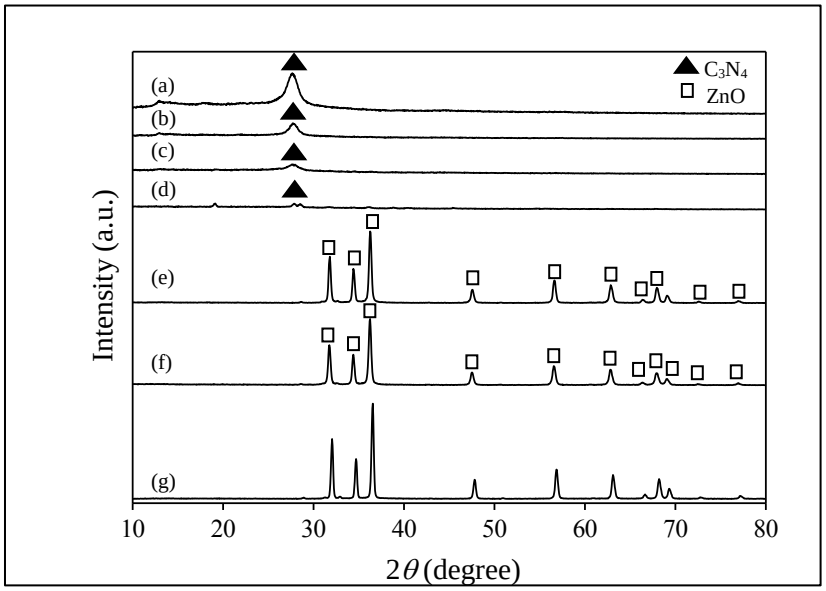

Figure 1. XRD patterns of (a) C_3N_4, (b) ZnO-C_3N_4 (*1*), (c) ZnO-C_3N_4 (*5*), (d) ZnO-C_3N_4 (*10*), (e) ZnO-C_3N_4 (*20*), (f) ZnO-C_3N_4 (*50*), and (g) ZnO.

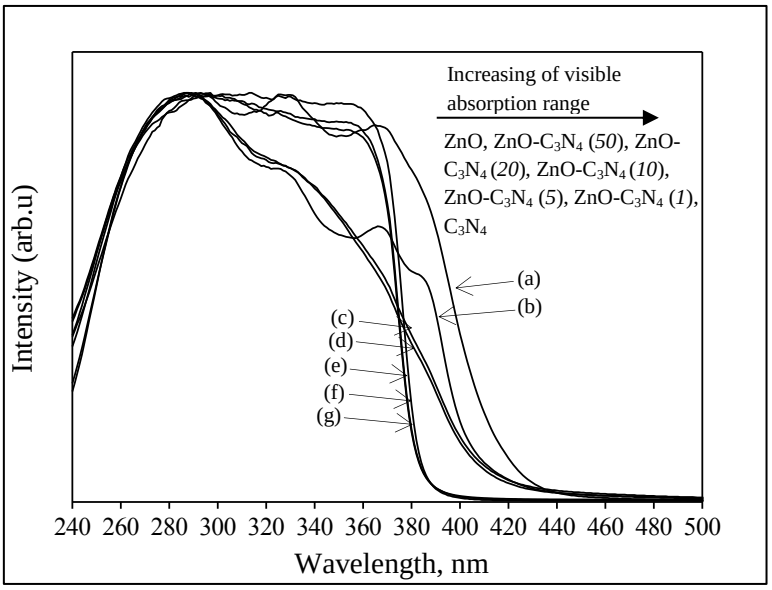

Figure 2. DR-UV Vis spectra of (a) C_3N_4, (b) ZnO-C_3N_4 (*1*), (c) ZnO-C_3N_4 (*5*), (d) ZnO-C_3N_4 (*10*), (e) ZnO-C_3N_4 (*20*), (f) ZnO-C_3N_4 (*50*), and (g) ZnO.

Figure 3 shows the FTIR spectra of C_3N_4, ZnO, and ZnO-C_3N_4 samples. As shown in Figure 3(a), the C_3N_4 showed several peaks due to the vibrations of some bondings occurred between carbon and nitrogen. The absorption peak at 810 cm^{-1} corresponded to the triazine unit of C_3N_4, while peaks at 1200 - 1600 cm^{-1} region corresponded to stretching modes of C-N heterocyclics. The absorption peaks at 1340 and 1640 cm^{-1} were related to the C-N and

C=N stretching modes. The broad absorption band at 3100 – 3300 cm^{-1} can be assigned as primary and secondary amines with their intermolecular hydrogen bonding interactions. All the observed peaks in the FTIR spectrum of C_3N_4 were similar to the absorption peaks reported previously [22 – 24], supporting the successful transformation of the urea precursor to the C_3N_4. The prepared ZnO showed an intense peak in the range of 400 – 500 cm^{-1} (Figure 3(g)), which was belonged to the Zn-O stretching. The FTIR spectra of the prepared ZnO-C_3N_4 samples are shown in Figure 3 (b)-(f). Similar to the results of XRD patterns and DR UV-Vis spectra, samples with low loading of ZnO showed the absorption peaks of C_3N_4 as the dominant species. The peaks assigned to the C_3N_4 decreased with the increase of Zn/C ratio. When the Zn/C ratio reached 50 mol%, the peaks related to the C_3N_4 were completely disappeared and only ZnO peak could be observed on the ZnO-C_3N_4 (50) sample, as shown in Figure 3(f).

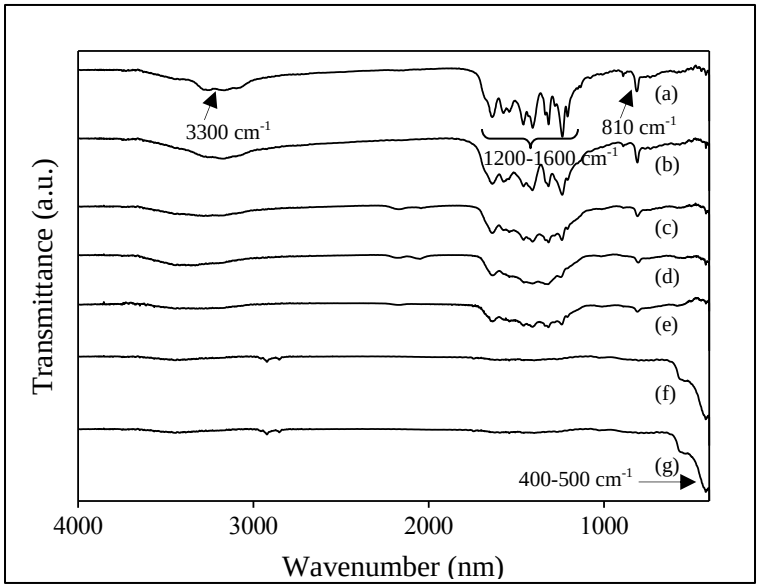

Figure 3. FTIR spectra of (a) C_3N_4, (b) ZnO-C_3N_4 (*1*), (c) ZnO-C_3N_4 (*5*), (d) ZnO-C_3N_4 (*10*), (e) ZnO-C_3N_4 (*20*), (f) ZnO-C_3N_4 (*50*), and (g) ZnO

Since the activity of the ZnO-C_3N_4 samples were evaluated under visible light irradiation, the charge transfer mechanism was investigated from the C_3N_4 site. The C_3N_4 exhibited two excitation peaks around 277 and 370 nm The excitation peaks at 277 nm would be related to the N=C groups of aromatic 1,3,5-triazine, while the peak of 370 nm would be due to the terminal N-C group of C_3N_4 [14, 22]. In order to investigate the effect of addition of ZnO on the emission of the C_3N_4, the emission spectra of the C_3N_4 and the ZnO-C_3N_4 samples were measured at the excitation wavelength of 277 and 370 nm, as shown in Figure 4. For both excitation wavelengths, the C_3N_4 showed two emission sites at 445 and 460 nm (Figure 4(a)). The emission intensity was found to decrease with the addition of ZnO (Figure 4(b)-(f)). The higher the amount of Zn/C ratio, the lower the emission intensity of the ZnO-C_3N_4 samples obtained. This result clearly suggested that there were interactions between the emission sites of C_3N_4 and the added ZnO particles. Since the emission is the result of electron-hole recombination, the low emission intensity would suggest the suppression of the electron-hole recombination. It can be proposed here that the addition of ZnO was able to suppress the electron-hole recombination of the C_3N_4. Therefore, under visible light irradiation, it can be suggested that the electrons from the conduction band of the C_3N_4 would be trapped by the ZnO, which would cause the less electron-hole recombination process. The mechanism of the electron charge transfer can be illustrated as in Figure 5.

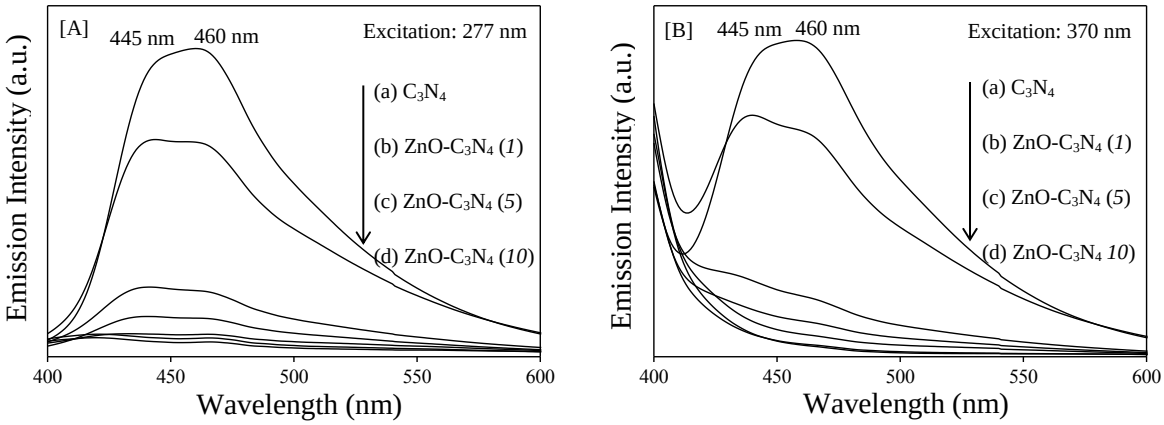

Figure 4. Emission spectra of (a) C_3N_4, (b) ZnO-C_3N_4 (*1*), (c) ZnO-C_3N_4 (5), (d) ZnO-C_3N_4 (*10*), (e) ZnO-C_3N_4 (*20*), (f) ZnO-C_3N_4 (*50*) and (g) ZnO monitored at the excitation wavelength of [A] 277 and [B] 370 nm.

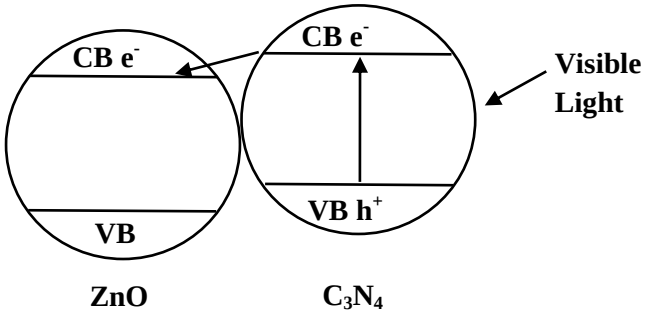

Figure 5. Schematic illustration of the electron charge transfer in the ZnO-C_3N_4 composite. CB and VB are conduction and valence bands, respectively.

In addition to the reduced electron-hole recombination, the lower emission intensity especially for samples with high loading of ZnO would be also caused by the smaller amount of the C_3N_4. This factor would also affect the photocatalytic activity of the ZnO-C_3N_4 composites under visible light irradiation.

Photocatalytic activity test

The C_3N_4, ZnO, and the ZnO-C_3N_4 samples were evaluated for the photocatalytic removal of phenol. Table 1 shows the percentage removals of phenol on the samples. The C_3N_4 showed 32% removal of phenol (Entry 1), while the ZnO showed 15% (Entry 7). The ZnO-C_3N_4 (*1*) showed 43% removal of phenol, which was three times higher than the activity of ZnO alone (Entries 2 and 7). It is worthy noted that the ZnO-C_3N_4 (*1*) showed higher activity than either C_3N_4 or ZnO. This result showed that there was a synergetic effect between the small amount of ZnO and the C_3N_4. As discussed previously, the small amount of ZnO would act to trap electron, thus inhibiting the electron-hole recombination process in the C_3N_4 sample. The less electron-hole recombination would be the key factor to get the improved photocatalytic activity.

Unfortunately, when the Zn ratio was more than 1 mol%, the activity was found to be gradually decreased with the increase of the Zn ratio (Entries 3 – 6). Therefore, the ZnO-C_3N_4 (*1*) showed the highest activity among the composite samples. As shown in the DR UV-Visible spectra, the ZnO-C_3N_4 (*1*) showed the most intense absorption

in the visible light. This property would be also one of the parameters that made it superior among the other composites. Moreover, as discussed in the characterization parts, samples with low loading of ZnO would behave like C_3N_4, while samples with high loading among would behave like ZnO. The ZnO-C_3N_4 (*50*) showed activity closer to the activity of the ZnO (Entries 6 and 7). Even though the activity decreased with the increase of the ZnO loading, it is clear that all ZnO-C_3N_4 composites showed better activities than the unmodified ZnO. This result also strongly suggested that the activity of C_3N_4 can be increased by the addition of ZnO.

Table 1. The percentages of phenol removal on ZnO and ZnO-C_3N_4 samples after 5 hours reaction under visible light irradiation[a]

Entry	**Samples**	**Percentage of phenol removal (%)[b]**
1	C_3N_4	32
2	ZnO-C_3N_4 (*1*)	43
3	ZnO-C_3N_4 (*5*)	34
4	ZnO-C_3N_4 (*10*)	33
5	ZnO-C_3N_4 (*20*)	26
6	ZnO-C_3N_4 (*50*)	21
7	ZnO	15

[a]Photocatalyst used was 0.05 g in the 50 mL solution of phenol (50 ppm)
[b]Percentage removal of phenol was calculated from the percentage ratio of reacted phenol to the initial concentration of phenol

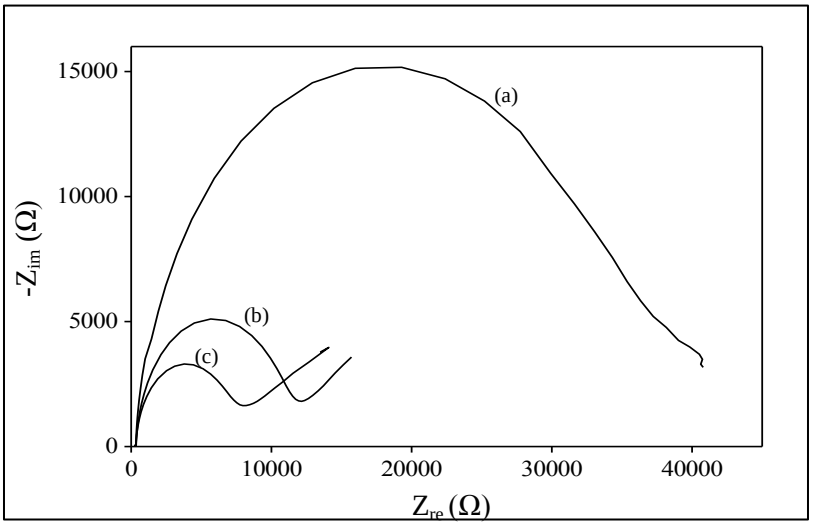

Figure 6. Nyquist plots of (a) ZnO, (b) C_3N_4, and (c) ZnO-C_3N_4 (*1*).

In order to obtain more detail information on the charge transfer and further support the synergetic effect between the ZnO and the C_3N_4, the electrochemical impedance measurement was carried out. Nyquist plots of the C_3N_4, the ZnO and the ZnO-C_3N_4 (*1*) composite were plotted with an open circuit between 1 MHz and 0.1 Hz as shown in

Figure 6. The ZnO-C_3N_4 (*1*) composite showed smaller semicircles compare to the bare ZnO and the C_3N_4, indicating the lower charge-transfer resistance on the surface of the composite [25]. With the suitable amount of ZnO, the charge transfer increased since C_3N_4 can transfer the electron to the ZnO thus, preventing the rapid electron-hole recombination. This synergetic effect resulted in the higher activity in the photocatalytic reaction.

Conclusion

The ZnO-C_3N_4 samples were prepared successfully by impregnation method. All the ZnO-C_3N_4 samples showed higher activity than the bare ZnO. The optimum amount of 1 mol% of Zn ratio gave *ca.* 3 times higher activity than unmodified ZnO. The ZnO-C_3N_4 (*1*) also showed higher activity than the C_3N_4. The synergic effect between the C_3N_4 and the ZnO was proposed, where the addition of C_3N_4 was able to extend the absorption of ZnO to visible light region and the small amount of ZnO would act to trap electron and suppress the electron-hole recombination.

Abstract

A tetradentate ligand with four donor atoms OONN and its platinum metal complex were synthesized. Bis(phenoxy)bipyridine ligand was prepared by Suzuki coupling reaction between 6,6'-dibromo-2,2'-bipyridyl and 2-hydroxyphenylboronic acid with the presence of palladium (II) acetate. The formation of platinum complex was done by introducing the ligand with platinum (II) chloride in benzonitrile. Both ligand and complex structures were confirmed by ^{1}H, 2D cosy and ^{13}C NMR spectroscopy, ESI-MS spectrometry and FTIR spectroscopy. Binding studies of small molecules with DNA are useful to understand the reaction mechanism and to provide guidance for the application and design of new and more efficient drugs or sensors targeted on DNA. In this study, the binding interaction between the synthesized ligand and complex with calf thymus DNA (CT-DNA) has been investigated using UV-Visible and emission DNA titration. From the UV-Visible DNA study, it showed that platinum (II) bipyridine complex had higher affinity towards CT-DNA with binding constant K_b=(3.1 ± 0.02 x 10^5) ± 0.02 M^{-1} compared to that of bis(phenoxy) bipyridine ligand with binding constant (K_b) = (1.19 ± 0.08) × 10^3 M^{-1}. These findings will be valuable for the potential use of platinum (II) bipyridine complex as a phosphorescent probe in optical sensor DNA.

Keyword: bis(phenoxy)bipyridine, intercalating ligand, calf thymus-DNA, DNA interaction

Abstrak

Ligan tetradentat dengan empat atom penderma OONN dan kompleks platinumnya telah disintesis. Ligan bis(fenoksi)bipiridin disediakan melalui tindak balas pengkupelan Suzuki antara 6,6'-dibromo-2,2'-bipiridil dan asid 2-hidroksifenilboronik dengan kehadiran palladium(II) asetat. Pembentukan kompleks platinum dilakukan dengan menambahkan platinum(II) klorida terhadap ligan di dalam benzonitril. Kedua-dua struktur ligan dan kompleks dibuktikan dengan spekroskopi ^{1}H, 2D dan ^{13}C RMN, spektrometri ESI-MS dan spektroskopi FTIR. Kajian pengikatan terhadap molekul kecil dengan DNA sangat berguna untuk memahami mekanisme tindak balas dan untuk panduan bagi aplikasi dan reka bentuk dadah yang baharu dan berkesan atau sensor target kepada DNA. Dalam kajian ini, interaksi ikatan antara ligan dan kompleks terhadap DNA timus anak lembu (CT-DNA) dilakukan dengan kajian titratan ultra lembayung boleh Nampak dan titratan pendaflour. Kaedah tersebut membuktikan bahawa kompleks platinum (II) bipiridin mempunyai ikatan yang lebih kuat terhadap CT-DNA berbanding dengan ligan iaitu sebanyak K_b=(3.1 ± 0.02 x 10^5) ± 0.02 M^{-1} berbanding K_b=(1.19 ± 0.08) x 10^3 M^{-1}. Penemuan ini sangat bernilai dan berpotensi dalam menjadikan kompleks platinum (II) bipiridin sebagai prob fosforesen dalam sensor DNA optik.

Introduction

The mix of pyridine–phenol ligand 6,6'-(2-hydroxyphenyl)-2,2-bipyridine has attracted the author's attention due to its bridging behaviour by phenolate residues attached to the end of a string of pyridyl donors which result in the formation of phenolate-bridged polynuclear complexes with interesting magnetic and spectroscopic properties [1 – 3]. Interestingly, the NNOO tetradentate conjugated aromatic ligands can coordinate with metal centre results in molecular planar and increase the structural flexibility. Since deoxyribonucleic acids (DNA) offers many potential binding sites due to its size and complexity, the coordination compound are able to bind to the DNA by non-covalent bonding through three binding modes which are groove binding, intercalation and external static electronic effects [4].

Metal complex DNA intercalators have been given more attention in the research field because they are widely used in pharmaceuticals as antibiotics, antibacterial and antitumor agents [5]. Some examples of DNA interactions using transition metal complexes include Ru [6] Co, Ni, Cu, Zn [7] and rare-earths compounds [8]. Platinum metal is chosen for the bipyridine complex in this study because it has been widely used in optical devices and has shown to have diverse applications in electroluminescence, photovoltaics, optical limiting, photocatalysis, and molecular probes [4]. Moreover, d^8 square-planar platinum (II) complexes with NNOO tetradentate conjugated aromatic ligands have shown to be highly phosphorescent at room temperature and thus have the potential to be developed as DNA optical sensor for the detection of DNA hybridization [9].

To date, no attempts have been made to explore the potential of platinum (II) bipyridine complex as a new phosphorescent DNA probe. In this present work, the ligand and its platinum metal complex are synthesized and it is the interest of this study to investigate the interaction between both compound and calf thymus DNA (CT-DNA). The overall aim is to investigate their optical properties towards DNA binding. It is predicted that platinum (II) bipyridine will bind stronger to CT-DNA due to the presence of platinum metal that enables the complex to become planar, thus allows them to π-π stack on the DNA bases and bind to DNA via intercalation [10]. It is expected that the bind to DNA will change the optical properties [11]. An enhancement of phosphorescence emission intensity upon the interaction with CT-DNA suggests that the platinum complex has the potential to be developed as a phosphorescence DNA sensor since there is still no report on this ligand and its complex for DNA probes sensor application [12]. Furthermore, there is a great market potential for simple, cheap, rapid, and quantitative detection of specific genes in the area of clinical, veterinary, medico-legal, environmental, and food industry.

Materials and Methods

Chemicals

The chemicals used in this work such as 6,6-dibromo-2,2'-bipyridyl, 2-methoxyphenylboronic acid, palladium (II) acetate, triphenylphospine, dimethoxyethane, pyridine hydrochloride, platinum (II) chloride and benzonitrile were purchased from Sigma-Aldrich and were used without further purification in the synthesis of ligand and complex. Calf thymus-DNA (CT-DNA) was obtained from Sigma (USA), agarose (molecular biology grade).

Physical measurement

^{1}H and ^{13}C NMR spectra of ligand were recorded using Bruker /AVANCE III 600 MHz Fourier transform nuclear magnetic resonance 600 MHz cryoprobe. The mass spectrometry was carried out using Bruker MicroTof Q Mass Spectrometer. IR spectra were recorded on KBr discs using FTIR Perkin-Elmer GX Model in the spectral range of 4000-400 cm^{-1}. The UV-Visible spectra were measured using Shimadzu UV-2450. Melting point was measured by using Barnsted electrothermal melting point IA9100 series.

Synthesis of 6,6'-bis(2-hydroxyphenyl)-2,2'-bipyridine ligand

Bis(phenoxy)bipyridine ligand was synthesized using the method patented by Nii et al. [12] with a slight modification. 6,6'-dibromo-2,2'-bipyridine (0.568 g, 1.81 mmol) and 2-hydroxyphenylboronic acid (0.499 g, 3.62 mmol) were refluxed for 4 hours in a mixture of dimethoxyethane (10 mL) and water (10 mL) with the presence of palladium (II) acetate (0.04 g, 0.18 mmol) under inert condition. After cooling the reaction solution to room temperature, chloroform (20 mL) and water (20 mL) were added to the reaction solution. The organic layer was concentrated and collected. Purification of the organic layer was carried out by column chromatography using dicloromethane:hexane (1:2) to obtain yellow crystal of 6,6'-bis(2-hydroxyphenyl)-2,2'-bipyridyl ligand. All

spectroscopic data for the ligand are in accordance to literature [13]. Yield : 0.3191 g (51%). ^{1}H NMR (600 MHz, $CDCl_3$) δ : 6.99 (t, 1H, , $^{3}J_{HH}$ = 8.4 Hz, arom), 7.09 (td, 1H, , $^{3}J_{HH}$ = 8.4 Hz, arom), 7.38 (td, 1H, , $^{3}J_{HH}$ = 7.2 Hz, arom), 7.89 (t, 1H, , $^{3}J_{HH}$ = 8.4 Hz, arom), 8.04 (m, 2H, bipyridine), 8.14 (dd, 1H, , $^{3}J_{HH}$ = 8.4 Hz H^{2}), 14.29 (s, 1H, -OH). ^{13}C NMR (600 MHz, $CDCl_3$) δ: 118.54, 118.80, 119.17, 119.22, 119.92, 126.64, 131.93, 139.27, 152.05, 157.90, 159.68. IR (cm^{-1}): 3434 (OH alcohol / phenol), 3083 (C-H aromatic), 1355 (C-N), 1563 (C=C aromatic), 1131 (C-O). ESI (+)- MS calculated for $C_{22}H_{16}N_2O_2$ [M+H] : 341.12 a.m.u. Melting point : 238.5 ± 1 ^{0}C.

Synthesis of 6,6'-bis(2-hydroxyphenyl)-2,2'-bipyridyl platinum complex

Platinum (II) chloride (0.133 g, 0.5 mmol) was added to the 6,6'-bis(2-hydroxyphenyl)-2,2'-bipyridine ligand (0.17 g, 0.5 mmol) and heated under reflux in 10 mL benzonitrile for 5 hours under inert atmosphere. After cooling the reaction solution to room temperature, methanol was added to the reaction solution to yield precipitation. The reddish colour precipitate was filtered and wash using methanol and diethyl ether to obtain 6,6'-bis(2-hydroxyphenyl)-2,2'-bipyridyl platinum complex. All spectroscopic data for the complex are in accordance to literature [13]. Yield : 0.0641 g (24%). ^{1}H NMR (600 MHz, $CDCl_3$) δ : 6.78 (m, 1H, , $^{4}J_{HH}$ = 1.8 Hz, arom), 7.15 (m, 1H, , $^{4}J_{HH}$ = 1.8 Hz, arom), 7.38 (m, 1H, , $^{4}J_{HH}$ = 2.4 Hz, arom), 8.24 (t, 1H, , $^{3}J_{HH}$ = 6.3 Hz, arom), 8.41 (t, 1H, , $^{3}J_{HH}$ = 12 Hz, arom), 8.54 (d, 1H, $^{3}J_{HH}$ = 12 Hz, arom) and 8.64 (t, 1H, , $^{3}J_{HH}$ = 12.6 Hz, arom). ^{13}C NMR (600 MHz, $CDCl_3$) δ: 116.65, 120.64, 121.15, 122.64, 124.55, 129.54, 131.84, 137, 149.28, 155.54, 162.16. IR (cm-1): 3089 (C-H aromatic), 1603 (C-N), 1346 (C=C aromatic), 1130 (C-O). ESI(+)- MS calculated for $C_{22}H_{16}N_2O_2$ [M+H] : 533.34 a.m.u.

DNA binding experiments: UV-Vis titration study

A calf-thymus (CT) DNA was dissolved in a 10 mM Tris-HCl /100 mM KCl (pH7.4) buffered overnight. The test compound was dissolved in a mixture of DMSO to give 5 mM stock solution. For working solution, the stock solution was diluted to 1 mM using DMSO and further diluted using the buffer to give appropriate concentrations [11]. A 1 cm pathlength quartz cuvette was used to conduct the measurements. The concentration of DNA used for the binding experiments was determined by measuring the absorption intensity at 260 nm with a molar extinction coefficient value of 6600 M^{-1} cm^{-1} [14]. The absorption titration experiments were performed by keeping the concentration of the ligand constant (20 μM) while varying the DNA concentrations (4.68×10^{-5} M to 1.26×10^{-3} M). Absorbance values were recorded after each successive addition of DNA solution and equilibration (Figure 5). The percentage of hypochromicity was calculated according to Equation (1):

$$\% \text{ hypochromicity} = [(\varepsilon \text{ free} - \varepsilon \text{ bound})/ \varepsilon \text{ free}] \times 100 \quad = \quad 16.04 \% \tag{1}$$

The intrinsic binding constant (K_b) of ligand - DNA was determined according to Equation (2):

$$\frac{DNA}{\Delta\varepsilon ap} = \frac{DNA}{\Delta\varepsilon} + \frac{1}{\Delta\varepsilon \times K} \tag{2}$$

where the apparent molar extinction coefficient, Δεap = |εA- εF|, εA= A observed /[ligand], Δε = |εB- εF|. The εF and εB represent the molar extinction coefficients for free ligand and DNA bound platinum ligand respectively. From the plotted graph of [DNA]/ (Δεap) versus [DNA], the y-intercept is equal to 1/ (Δεap × K), whereas the slope is equal to 1/ Δεap. K is obtained by dividing the slope value by the y-intercept [15]. Excitation wavelengths of 328 nm and 485 nm were used for DNA emission studies.

Emission study

Platinum (II) complex was dissolved in DMSO to yield 5 mM stock solutions. Prior to use, the compounds were diluted to 1 mM using DMSO. This was then further diluted using 10 mM Tris-HCl (pH 7.4) to appropriate concentrations. Aliquots of millimolar stock solution of DNA in Tris-HCl buffer (49 μM) were added to the solutions of the test complex (49 μM). The emission spectra were recorded at λ= 400–700 nm after 1 min equilibration and the luminescence enhancement at λ_{max} = 328 nm and 485 nm were determined.

Results and Discussion

Synthesis of 6,6'-bis(2-hydroxyphenyl)-2,2'-bipyridine ligand and its platinum complex

The 6,6'-bis(2-hydroxyphenyl)-2,2'-bipyridine ligand was successfully prepared via Suzuki coupling reaction using the starting material 2-hydroxyphenylboronic acid. The formation of the ligand was confirmed by spectroscopic and analytical methods. Platinum (II) chloride was introduced to the 6,6'-bis(2-hydroxyphenyl)-2,2'-bipyridine ligand and heated under reflux in 10 mL benzonitrile for 5 hours under inert atmosphere. The reaction scheme is shown in Figure 1. The formation of the platinum (II) complex was also confirmed by spectroscopic and analytical methods.

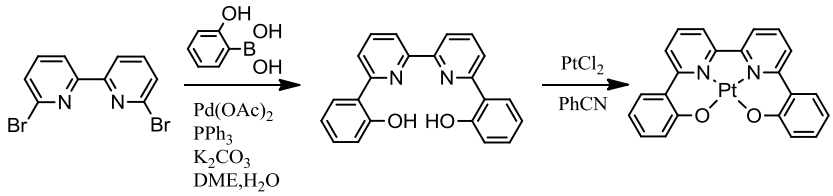

Figure 1. Synthesis of 6,6'-bis(2-hydroxyphenyl)-2,2'-bipyridine ligand via Suzuki coupling reaction and its coordination with metal

Figure 2 shows the NMR spectrum of 6,6'-bis(2-hydroxyphenyl)-2,2'-bipyridine ligand while Figure 3 shows the NMR spectrum of its platinum complex. The resonance at area 14.28 ppm from the spectrum of the ligand is assigned to the OH proton which is highly deshielded due to the large anisotropic field that is generated by the circulation of π electron in the aromatic ring. The disappearance of the resonance in the complex spectrum confirms that the deprotonation of OH groups occurred due to the coordination of oxygen atoms to the platinum (II) metal ion centre. The peaks at area 6.97 to 8.15 ppm in the ligand spectrum are assigned to the aromatic ring proton which is slightly shifted upfield compared to the corresponding peaks in the complex spectrum due to the presence of more electrons withdrawing OH group, and thus increases the shielding of the hydrogen, causing them to move upfield.

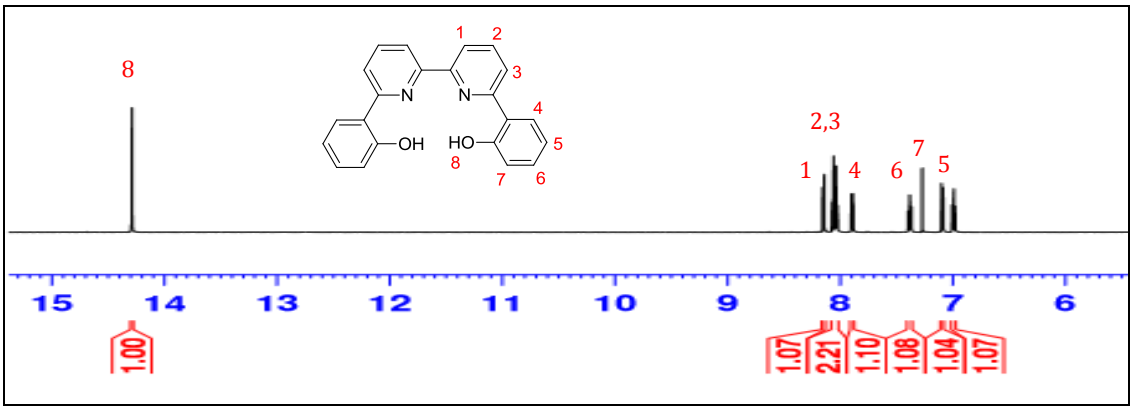

Figure 2. NMR spectrum of 6,6'-bis(2-hydroxyphenyl)-2,2'-bipyridine ligand

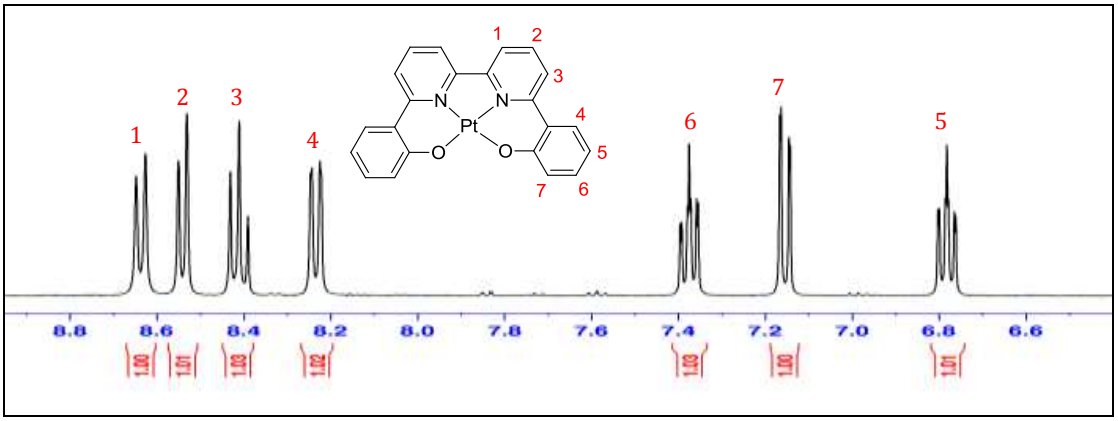

Figure 3. NMR spectrum of platinum (II) bipyridine complex

The assignment of both ^{1}H NMR spectra in $CHCl_3$ was also performed with the help of 2D-^{1}H-^{1}H NMR spectroscopy. The peaks around 7.04 – 8.5 ppm are assigned accordingly to the 2D-COSY NMR as shown in Figure 4(a) and Figure 4(b). The structure obtained was also confirmed by the ^{13}C NMR that shown on Figure 5(a) and Figure 5(b). From the spectrum, it is clearly shown that there was 11 signal peak that represented the presence of 11 carbon in the both structure, ligand and complex.

The infrared spectrum of the complex in Figure 6 represented the absorption band of azomethine –CH=N-, C-O, C=C aromatic and C-H aromatic at 1603 cm^{-1}, 1346 cm^{-1} and 3089 cm^{-1} respectively. The disappearance of hydrogen bonded OH absorption band at 3400 cm^{-1} in the complex spectrum supports the coordination of four donor atom N_2O_2 from ligand to platinum (II) metal ion centre, indicating a square planar geometry and aromatic rings structure. The formation of the ligand and complex was also supported by the mass spectrometry results in which the mass to charge ratio was [M+H] 341.12 a.m.u for the ligand and [M+H] 534.4 a.m.u for the complex. The melting point recorded for this ligand was 238.5 ± 1 ^{o}C.

UV-Vis DNA titration

The application of electronic absorption spectroscopy is one of the most useful techniques in DNA-binding studies. Since no DNA-binding studies have been reported yet on this ligand and its complex, the UV-Vis study was conducted to examine any susceptible interaction between both compound and CT-DNA, and also to study the comparison of the binding affinity between free ligand and with the presence of platinum metal centre ion. Generally, ligands that are coordinated to a metal centre result in a molecule planar and could increase its ability to intercalate between the DNA bases of double helix [15]. Therefore, the presence of metal ion will proposed the square planar geometry and thus will strongly bind to CT-DNA, presumably via intercalation mechanism compared to free ligand. The binding of intercalative compounds to DNA can be characterized by absorption spectral titrations, where lowering in absorbance (hypochromism) and shift to longer wavelengths (red shift) were observed [11]. Hypochromic effect is the spectral features of DNA concerning its interaction between the

electronic states of the compound and DNA base while red shift occurs due to the decrease in energy gap between HOMO and LUMO molecular orbitals after binding the complex to DNA [16].

The UV-Vis absorption spectra of the platinum complex showed three intense bands at 328 nm, 485 nm and 528 nm (Figure 7(a)). UV-Vis absorption spectra of the complex in Figure 7(a) demonstrated that the addition of increasing amounts of CT-DNA resulted in 16 % hypochromism at 528 nm and a slight red shift (3 nm). The hypochromism value was less compared to the absorption spectra of the ligand (Figure 8) which gave 46% hypochromicity upon the addition of increasing amounts of CT-DNA at 341 nm with the same red shift (3 nm). These results showed that there was an interaction between the electronic states of the chromophores in the both ligand and complex conjugates with DNA [5]. However, the intrinsic binding constant value (K_b) of the ligand was found to be $(1.19 \pm 0.08) \times 10^3$ M^{-1} which was 260-folds less the metal complex whose binding constant is $(3.1 \pm 0.02) \times 10^5$ M^{-1}. This means that the complex binds better than the ligand due to its planar aromatic rings structure. Square planar geometry can make the molecule planar, hence increases its intercalation properties [14].

The observed spectroscopic characteristics suggest that the complex interacts with CT-DNA through a mode that involves π-π stacking interaction between the aromatic rings of ligand and the base pairs of CT-DNA while the ligand bind to CT-DNA via outside binding mode interaction such as electrostatic [17] . Our results support the theory by Liu and Sadler [10], which stated that the square-planar platinum(II) complexes containing heterocyclic aromatic ligands bind to DNA duplexes non-covalently by intercalating between the base pairs. Besides, it is in good agreement with the data for other well-known intercalator metal complexes: hypochromicity values (15-30 %), red shift (3-5 nm) and binding constants 5.20×10^4 M^{-1} and 8.60×10^4 M^{-1} for 3-ethylpiperidineoxy-2-[(2-(piperidin-1-yl)ethoxy)phenyl]-pyridine)-2(N,O)-(5-nitro-8-quinolinolato) platinum (II) and *N,N'*-bis[4-[[1-(2-ethyl)piperidine]oxy]salicylidene]-4-(2-(piperidin-1-yl)ethoxy)-1,2-phenylenediamine-platinum(II), respectively [11].

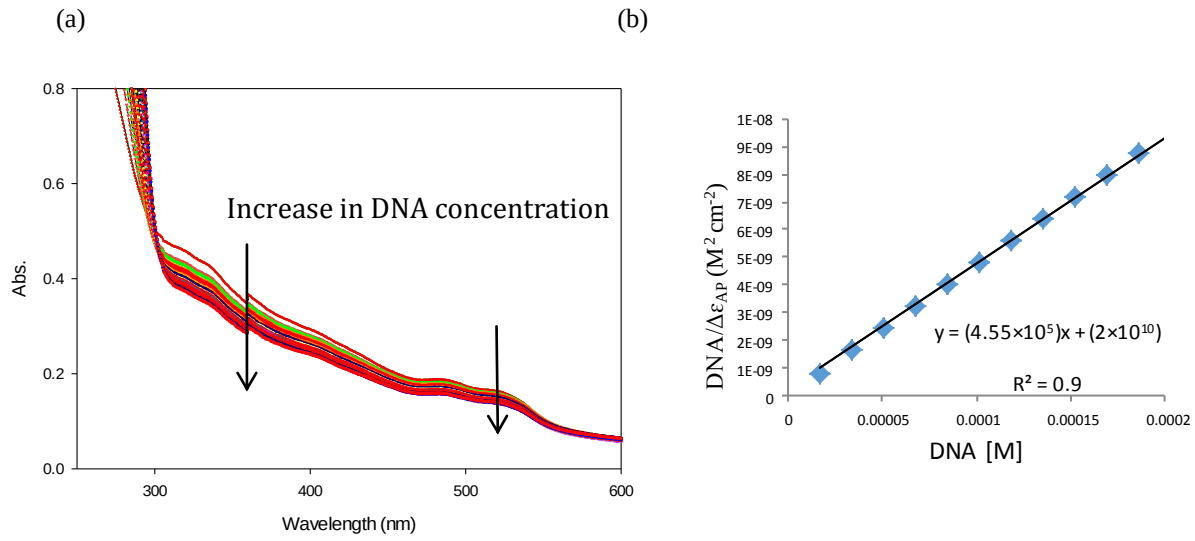

Figure 7. (a) Absorption spectral changes of complex (30 μM) in TRIS.HCl buffer (pH = 7.4) in absence and presence of increasing concentration of CT-DNA (4.68×10^{-5} M to 1.26×10^{-3} M) (b) the reciprocal plot that fits the absorbance data to obtain the binding constant.

Emission study

Platinum (II) complexes with a wide range of aromatic ligand are known to possess luminescent properties. Thus, it was the interest of this study to investigate whether the platinum bipyridine complex in this study is emissive and thus investigate their optical properties changes upon interaction with DNA. Emission titration experiments with 1:1 ratio were performed using constant concentration of complex and CT-DNA (49 µM) at different excitation wavelengths. Figure 9 shows the phosphorescence emission spectra in both the absence and presence of DNA in the Tris-HCl buffer. The platinum complex was found to be slightly emissive at λ_{max} = 328 and 485 nm respectively. Interestingly, the addition of CT-DNA resulted in an enhancement of phosphorescence emission intensity in both spectra. The emission spectra of the complex showed an increase in the intensity of emission by a factor of 1 indicating the interaction of the complex with DNA. These results confirmed that there was an interaction between phosphorescence platinum(II) bipyridine complex and DNA. These findings will be valuable for the potential use of platinum(II) bipyridine complex as a phosphorescence probe in optical sensor DNA.

Conclusion

The bis(phenoxy)bipyridine ligand and its platinum complex has been successfully synthesized and characterised. The ^{1}H, ^{13}C NMR, IR and mass spectrometry observations were used to elucidate the structure. UV-Vis DNA study showed that platinum complex might be a promising candidate compared to ligand for further applications as a DNA binder and anticancer drugs due to the interaction with CT-DNA via intercalation rather than outside binding. The coordination of ligand with metal centre increases the structural flexibility and thus increases the ability of the complexes to stack and intercalate between the DNA bases. An enhancement of phosphorescence emission intensity upon the interaction with porcine DNA suggests that the platinum complex has the potential as a phosphorescence DNA sensor. These findings will be valuable for the potential use of platinum (II) bipyridine complex as a phosphorescence probe for the detection of porcine DNA in food products.

Abstract

Well ordered and vertically oriented titania nanotubes (TNT) are of great scientific interest due to their high surface area, fewer interfacial grain boundaries and excellent charge transfer between interfaces; all are critical properties in photoelectrochemical and photocatalysis application. In this study, self-assembled TNT electrodes were synthesized by anodization of pure Ti in 0.5 wt.% NH_4F solution (NH_4F/H_2O), in mixture of aqueous-organic solution (NH_4F/H_2O/EG) and in an organic solution (NH_4F/EG). Choice of electrolytic medium has an influence on the crystalline structure, regularity, elemental composition and band gap of TNT. All the samples showed a red shift and stronger absorption in the wavelength between 500-700 nm ascribed to the surface colour and increase crystallinity upon calcination. TNT formed in NH_4F/H_2O solution has the highest direct band gap of 3.34 eV due to quantization effect. From Liner Sweep Photovoltammetry analysis, the lowest photocurrent was recorded for TNT anodized in NH_4F/H_2O and a twofold and fivefold increase on the magnitude of photocurrent was obtained for those formed in NH_4F/H_2O/EG and NH_4F/EG solution, respectively. Hence, highest photoefficiency of 2.79 % was recorded for TNT formed in NH_4F/EG probably due to the formation of longer length tube.

Keywords: titania, nanotube, anodization, photoefficiency, band gap energy

Abstrak

Nanotiub titanium dioksida yang bertertib rapi dan berorientasi mencancang (TNT) telah menarik perhatian disebabkan luas permukaan yang tinggi, sempadan butiran antara muka yang rendah dan pemindahan cas yang cemerlang di antara muka, yang mana semua ini merupakan ciri – ciri kritikal dalam aplikasi fotoelektrokimia and fotopemangkinan. Dalam kajian ini, swahimpunan TNT telah disintesis melalui penganodan plat titanium tulen dalam larutan 0.5 wt.% NH_4F (NH_4F/H_2O), campuran larutan akua-organik (NH_4F/EG/H_2O) dan larutan organik (NH_4F/EG). Pilihan media elektrolisis memberi kesan ke atas struktur hablur, keteraturan, komposisi unsur dan julang jalur TNT. Semua sampel mempamerkan anjakan merah dan penyerapan yang lebih kuat dalam julat gelombang 500 – 700 nm disebabkan warna permukaan sampel dan peningkatan kehabluran selepas pemanasan. Dari analisis fotovoltammetri pengimbasan linear, TNT yang teranod dalam larutan NH_4F/H_2O mencatatkan fotoarus yang terendah manakala peningkatan lipat ganda dua dan ganda lima dalam magnitud fotoarus boleh didapati untuk TNT yang teranod dalam larutan NH_4F/H_2O/EG dan NH_4F/EG. Oleh yang demikian, TNT yang dibentuk dalam latutan NH_4F/EG mencatatkan kecekapan foto yang tertinggi sebanyak 2.79 % mungkin disebabkan oleh pembentukan tiub yang lebih panjang.

Introduction

Titania (TiO_2) appears to be the most promising material to be used in photoelectrochemical applications due to its high efficiency, low cost, chemical inertness and photostability [1 – 4]. However, bulk TiO_2 materials have low surface area and therefore exhibit low adsorption property. Moreover, fast recombination rate of the photogenerated charge carriers deteriorate the performance of such materials especially in photoelectrochemical applications. In order to overcome such problems, much effort has been focused on fabrication of highly efficient materials with suitable architecture to minimize the recombination of electron-hole pairs. In this context, formation of highly ordered and oriented nanotubular or porous geometry is advantageous due to high surface-to-volume ratio and short diffusion path within enclosed nanoscale compartment [5]. Self-organized growth of TiO_2 nanotube arrays are of great interest due to its unique physical properties including larger surface area in a small geometrical area, fewer interfacial grain boundaries and superior charge transport, of which all are important properties governing its performance as photoanode in a photoelectrochemical cell. Therefore, the study aimed at synthesizing titania nanotubes in various electrolytic compositions in order to investigating the effects of electrolyte nature on the microstructure, optical and photoelectrochemical performance of the synthesized TNT.

Materials and Methods

Fabrication of titania nanotube arrays

A Ti foil (99.7%, Sigma Aldrich) was used for producing vertically oriented nanotubes. Prior to anodization, the Ti foils were cleaned by sonication in acetone, isopropanol, and deionized (DI) water respectively, followed by subsequent etching in 6 M HNO_3. They were then rinsed with DI water and dried in air. An electrochemical cell with a two-electrode configuration was used. The Ti foil served as the working electrode and high density graphite was used as the counter electrode and they were separated by approximately 2 cm. All the experiments were driven by a DC power source (Consort Mini, Cleaver Scientific Ltd) and were carried out at room temperature in three different types of electrolytes for 2 hours to form TNT. The composition of the three electrolyte solutions and voltage used for anodization were summarized in Table 1. After the anodization process, the samples were rinsed with DI water and dried in air. Subsequently, they were calcined at 500 ^oC in air for 2 hours with a heating rate of 2 ^oC/minutes. The resultant calcined TNT are hereinafter designated as C5TNT/H_2O, for the 0.5 wt% NH_4F solution adjusted to pH 4, C5TNT/EGH_2O, for the mixture of ethylene glycol containing 50 vol.% H_2O and 0.5 wt.% NH_4F and C5TNT/EG, for ethylene glycol containing 0.5 wt.% NH_4F. For comparison, the as-anodized samples without heat treatment were produced and were designated as AOTNT/H_2O, AOTNT/EGH_2O and AOTNT/EG, respectively.

Table 1. Summary of electrolyte compositions and voltage used producing TNT during anodization

Samples	Electrolyte composition	Voltage / V
TNT/H_2O	0.5 wt.% NH_4F adjusted to pH 4	20
TNT/EGH_2O	0.5 wt.% NH_4F + ethylene glycol + 50 vol.% H_2O	20
TNT/EG	0.5 wt.% NH_4F + ethylene glycol	65

Characterization of titania nanotube arrays

Phase identification was carried out using an X-ray diffractometer (XRD, Shimadzu D6000) with Cu K_α radiation (λ= 1.5406 Å). The morphology of the samples was characterized on TEM Hitachi H-1700 operating at an accelerating voltage of 200 kV. Quantitative measurements were done using image analysis software (Image J). Energy dispersive analysis of x-rays (EDX) was performed on JOEL FESEM JSM-7600F JOEL, Japan attached with Oxford INCA Energy 200 EDX to determine the purity and elemental composition in the as-anodized and

calcined samples. The optical absorbance behavior of TNT was characterized using a diffuse reflectance UV-VIS-NIR spectrophotometer (Model: UV-3600, Shimadzu Corporation, Kyoto, Japan) equipped with an integration sphere. $BaSO_4$ was used as a reflectance standard. The band gap energy (E_g) can be calculated using the absorbance data obtained following the Tauc Plot relation (Equation 1):

$$\alpha h\nu = A(h\nu - E_g)^n \quad (1)$$

where α is the absorption coefficient, h is the Planck's constant, ν is the wavenumber and A is a constant. The "n" depends on the types of band-to-band transition (for titania, n=2 for a direct band gap and n= ½ for a indirect transition between bands). The band gap energy could be obtained by extrapolating the straight line in the plot of $\alpha^{1/2}$ or $\alpha h\nu^2$ against $h\nu$ to the base line where $\alpha^{1/2}$ or $\alpha h\nu^2 = 0$. Thus, the E_g is equivalent to $h\nu$.

Photoelectrochemical test

Photoelectrochemical response of TNT was demonstrated using a three-electrode system with the synthesized TNT as the working electrode, a platinum wire as the counter electrode, and Ag/AgCl as the reference electrode. The photocurrent was measured with a scanning potentiostat (μAutolab type III) during a voltage sweep from +2.0 to –0.2 V with the sweep rate of 20 mV/s in 10 ppm methyl orange with 0.1 M KCl as the supporting electrolyte. All the potentials were quoted against Ag/AgCl reference electrode. A tungsten halogen lamp (300 W, 120 V) was used for illuminating the TNT samples and the light was intermittently chopped at a constant frequency to evaluate both the photocurrent and dark current. A UV lamp (B-100AP) with the incident power of 11 mW/cm^2 was used to evaluate the efficiency of photocurrent generated by TNT prepared in different electrolytic medium and the radiation source was placed 15 cm away from the cell. The solution used was 0.1 M KOH

Results and Discussion

Electrolyte composition is an important parameter influencing the structure, morphology and geometry (and thus the specific surface area) of the resulted nanotubes. The crystallinity and the isomorphs of TNT are critical in influencing their properties and potential applications. Figure 1 illustrates the XRD patterns of TNT as a function of electrolytic medium. No peak shift was observed as a function of electrolytic medium. For TNT/H_2O, a mixture of anatase at $2\theta = 25.4^o$ (JCPDS No. 21-1272) and rutile at $2\theta = 27.6^o$ (JCPDS No. 21-1276) was observed after calcination at 500 ^oC. As opposed to TNT/H_2O, only pure anatase phase at $2\theta = 25.4^o$, 38.0^o, 48.2^o, 54.0^o and 55.2^o corresponding to (101), (004), (200), (105) and (211) plane, respectively was obtained for TNT/EG and TNT/EGH_2O upon calcination at 500 ^oC as shown in Figure 1 (b-c). Our finding is in contradiction with the work reported by other researchers that the crystalline structures remained unaffected with different electrolytic media [6, 7]. It is also discernible that the (101) reflection exhibited greatest intensity as compared to the other anatase peaks for all samples, demonstrating the preferred growth orientation for nanotubes at this plane. For TNT/EG sample, almost tenfold increase on the intensity magnitude of (101) reflection compared to TNT/H_2O and a threefold increase for TNT/EGH_2O sample, probably ascribed to increase in length for samples prepared in different electrolytic medium.

TEM analysis was performed to gain information on the microstructure of the sample. Figure 2 shows the TEM image of all samples. Apparently, a single nanotube consisted of a closed bottom with a barrier layer thickness of 37 nm and ripples on sidewall were obtained in NH_4F/H_2O solution. Same observation on the formation of ripples was obtained for TNT/EGH_2O. These ripples could be formed due to current fluctuations occurred during anodization process. In contrast, well-dispersed and straight nanotubes with uniform wall thickness and smooth tube wall throughout the length of the nanotubes can be observed for TNT formed in NH_4F/EG. Therefore, the electrolyte composition is a crucial factor determining the morphology of the outer wall where ripples are observed in nanotubes grown in aqueous electrolytes, whereas nanotubes prepared in ethylene glycol can be either smooth or are having ripples depending on the water content (50 vol. % in this study).

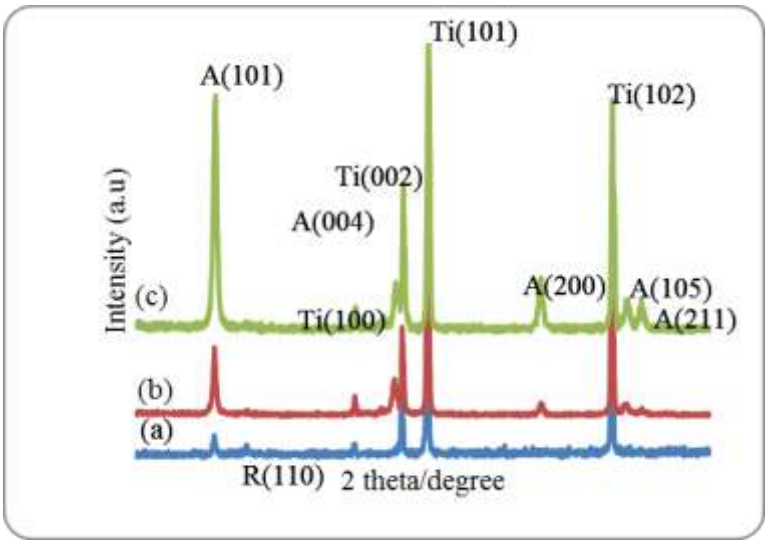

Figure 1. XRD patterns of calcined TNT synthesized at 20 V in different electrolytic medium with (a) NH_4F/H_2O (b) NH_4F/EG and (c) $NH_4F/EG/H_2O$ solution. A, R and Ti represent anatase, rutile and titanium, respectively

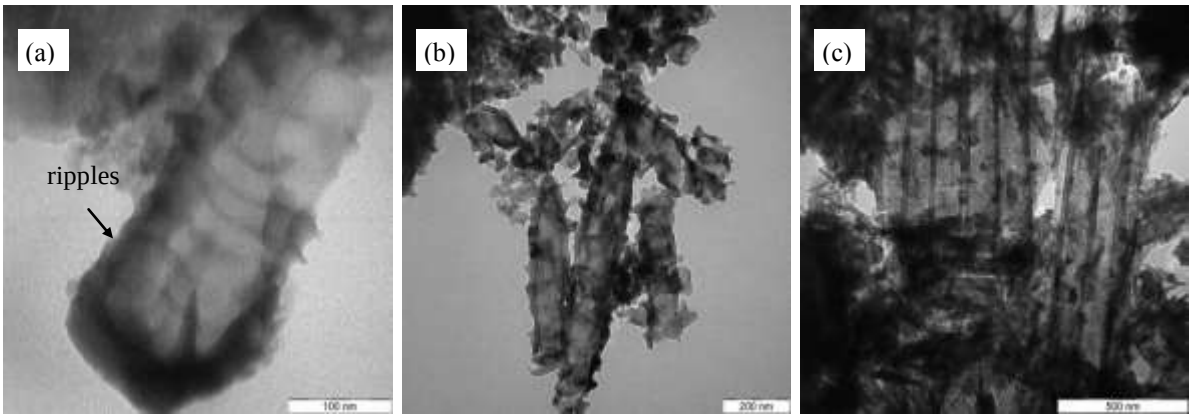

Figure 2. TEM images for (a) TNT/H_2O (b) TNT/EGH_2O and (c) TNT/EG

EDX analysis was done on blank Ti plate, as-anodized TNT and their calcined counterparts. The detailed compositions of the samples before and after calcination are shown in Table 2. For blank Ti, only Ti element was detected and C peak observed is due to carbon tape holding the sample. Evidently, Ti, O and F are found in the spectrum for $AOTNT/H_2O$, $AOTNT/EGH_2O$ and AOTNT/EG, with trace of carbon from the ethylene glycol observed for AOTNT/EG sample. The fluorine observed is due to the NH_4F added in the solution, which acts as a pore initiating agent. Calcination at 500 ^oC leads to a complete loss of the fluorine for C5TNT/EG and thus it is free from fluoride content and this result is similar with the work reported by Sreekantan et al. [8]. However, traces of F still can be detected for $C5TNT/H_2O$ and $C5TNT/EGH_2O$ but with almost negligible amount, indicating that the F is precipitated on the surface of sample during anodization and not incorporated into the TiO_2 lattice. In addition, all samples showed an increase in Ti and O content upon calcination. The molar ratio of Ti to O for calcined samples was close to the stoichiometric proportion, suggesting the samples were TiO_2.

For TNT/EG sample, a carbon rich layer could be probably obtained due to the voltage induced decomposition of the ethylene glycol as high voltage (65 V) is used during anodization of Ti. Therefore, higher C content (2.33 wt.%) was observed for AOTNT/EG sample. However, no C uptake from the solution occurs for C5TNT/EG given the C weight percent present is comparable to the blank Ti plate upon calcination at 500 ^{o}C. This result indicates that C from the ethylene glycol in AOTNT/EG could be easily removed via thermal treatment.

Table 2. Elemental analysis for Ti, as-anodised TNT and calcined TNT/H_2O, TNT/EGH_2O and TNT/EG

Sample	Weight percent (%)			
	Ti	O	C	F
Ti	99.44	-	0.45	-
AOTNT/H_2O	58.22	31.27	-	10.51
AOTNT/EGH_2O	51.20	38.53	-	10.27
AOTNT/EG	46.71	35.90	2.33	15.06
C5TNT/H_2O	61.83	36.11	-	2.06
C5TNT/EGH_2O	53.30	44.22	-	2.48
C5TNT/EG	63.11	36.60	0.29	-

Figure 3 shows the diffuse reflectance UV-Vis absorbance of both the as-anodized and calcined TNT prepared in different electrolytic medium. The absorbance response for AOTNT/H_2O, AOTNT/EGH_2O and AOTNT/EG exhibited lower absorption in the visible region, whereas the calcined counterparts showed a red shift and stronger absorption in the wavelength between 500−750 nm, with exception for C5TNT/EGH_2O. This can be attributed to the surface color and changes in crystalline structure of TNT. Generally, the color of C5TNT/H_2O was yellowish, dark green for C5TNT/EGH_2O and dark grey green for C5TNT/EG, respectively. In contrast, the as-anodized films were bright green, bright purple and bright grey for AOTNT/H_2O, AOTNT/EGH_2O and AOTNT/EG, respectively and this causes more adsorption in ultraviolet region and more reflection in the visible region. As shown in Figure 2, the absorption onset for C5TNT/H_2O, C5TNT/EGH_2O and C5TNT/EG was around 370, 380 and 390, respectively which was probably caused by increasing anatase content after thermal treatment. This is consistent with the changes in crystalline structure observed in XRD scan (Figure 1).

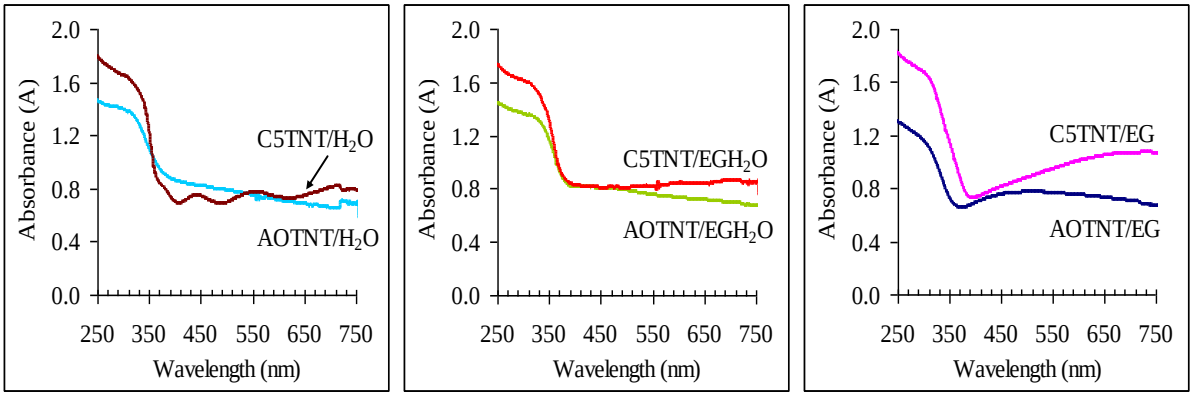

Figure 3. UV-Visible absorbance spectra of TNT/H_2O, TNT/EGH_2O and TNT/EG sample

In addition, the absorbency of visible light (< 550 nm) is higher for C5TNT/EG sample, which could mean that it possesses a higher efficiency of sunlight utilization compared to C5TNT/H_2O and C5TNT/EGH_2O sample. It is thus

expected that C5TNT/EG sample will result in an improvement in solar cell fabrication and in photocatalytic activity. Red shift in absorption wavelength in the visible region for C5TNT/EG might due to oxidation of ethylene glycol to carbonate type species which get adsorbed on the nanotube walls as an outer layer. Sohn et al. [9] also observed the introduction of carbon into TNT, which facilitates the improvement in visible light absorbance when employing ethylene glycol as electrolyte.

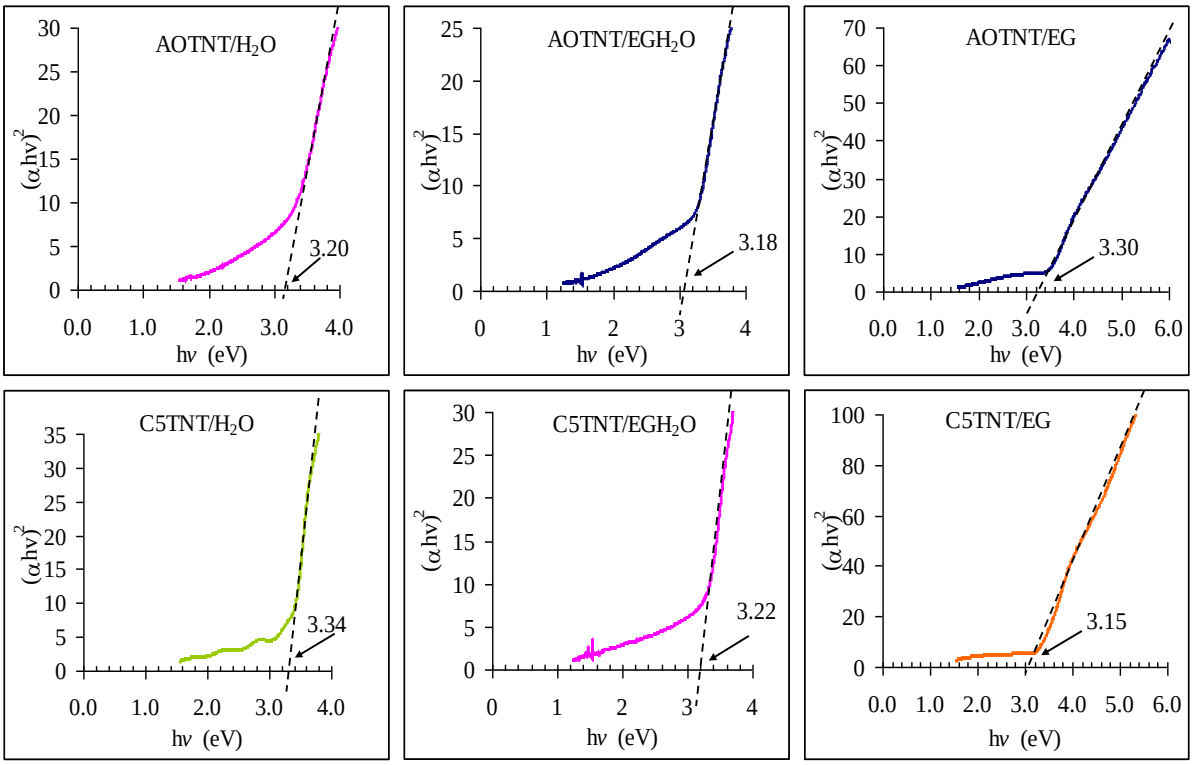

Figure 4. Plot of $(\alpha h\nu)^2$ versus $h\nu$ for AOTNT/H_2O, AOTNT/EGH_2O and AOTNT/EG and their calcined counterparts

Figure 4 shows the plot of $(\alpha h\nu)^2$ versus $h\nu$ for TNT prepared in different electrolytic medium. All the three as-anodised samples, AOTNT/H_2O, AOTNT/EGH_2O and AOTNT/EG have band gap energy of 3.18 – 3.30 eV with a direct transition and this result is similar with the work reported by Song et al. [10]. For the calcined samples, C5TNT/H_2O has the highest direct band gap of 3.34, which was higher than 3.2 eV for bulk anatase due to quantization effect of the nanosized titania. However, C5TNT/EGH_2O and C5TNT/EG exhibited a direct bandgap of 3.22 and 3.15 eV respectively, which was comparable to that of bulk anatase. The calcined samples demonstrated higher band gap than their as-anodised counterpart except for C5TNT/EG sample. From the EDX analysis (Table 2), no carbon was found for both the AOTNT/H_2O and AOTNT/EGH_2O samples whereas a 2.33 wt.% carbon content was found for AOTNT/EG sample.

The photocurrent generated by unmodified Ti and all as-anodized samples (AOTNT/H_2O, AOTNT/EGH_2O and AOTNT/EG) was almost negligible (~2 $\mu A/cm^2$) as they are amorphous without heat treatment. Therefore, the efficiency of generating photocurrent under halogen and UV lamp illumination in methyl orange was compared for all C5TNT/H_2O, C5TNT/EGH_2O and C5TNT/EG samples as shown in Figure 5. Apparently, the photocurrent generated for all samples illuminated with UV lamp was much higher than that observed with halogen lamp, demonstrating that the light from UV lamp (365 nm, 11 mW/m^2) is more efficient in generating and promoting the

electron-hole pairs activity than a halogen lamp (150 mW/m^2). Though halogen lamp exhibits higher photointensity, however, most of the light is given out as heat instead of promoting electron-hole activity. From the DR UV-Vis analysis as shown in Figure 4, the band gap energy for C5TNT/H_2O, C5TNT/EGH_2O and C5TNT/EG is 3.34, 3.22 and 3.15 eV, respectively. Therefore, the light from the UV lamp contains more number of photons with energy exceeding the band gap of TNT, and thus it can excite the TNT samples better compared to halogen lamp. Even though UV rays have higher energies than the light from halogen lamp, the hazardous effects possess by UV radiation is the draw back for the usage of such lamp in activating TNT.

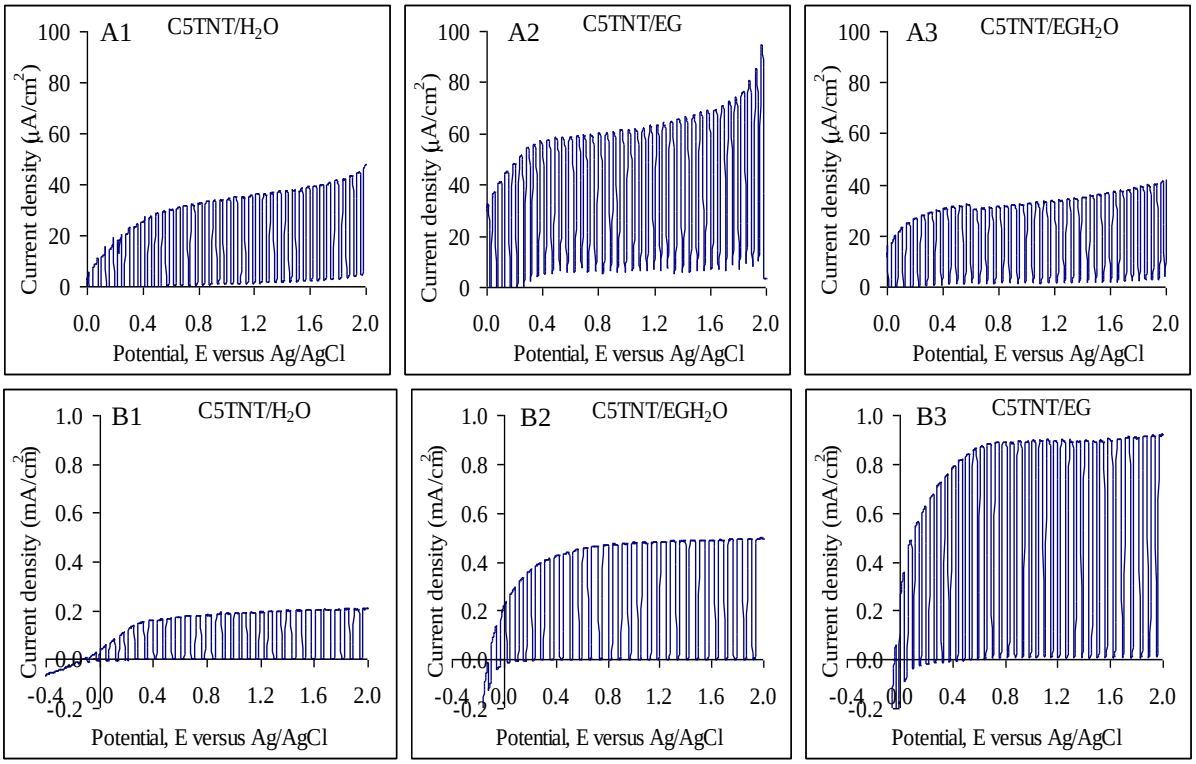

Figure 5. Comparison of the photocurrent potential curve for C5TNT/H_2O, C5TNT/EGH_2O and C5TNT/EG under illumination of halogen lamp (A) and UV lamp (B) in 50 mL 10 ppm methyl orange with 0.1 M KCl as supporting electrolyte

Table 3 shows the dimensional data and photocurrent current for TNT synthesized in different electrolytic medium when illuminated with UV lamp. The magnitude of photocurrent correlates to the efficiency of holes transfer at the oxide-electrolyte interface and electrons transport through nanotubes to the Ti substrate. The lowest photocurrent generated was found for C5TNT/H_2O and a twofold increase on the magnitude of photocurrent was observed for C5TNT/EGH_2O and the highest photocurrent was recorded for C5TNT/EG. Higher photocurrent response obtained for C5TNT/EG sample clearly indicates improved charge separation and greater electrons transport for sample with longer length and larger diameter tubes. In addition, longer length tubes also demonstrated greater surface areas that enhance the absorption of the incident photon, which in return increase the photocurrent response. However, the magnitude of photocurrent did not increase linearly with increasing length as the light intensity usually attenuates as it penetrates into the nanotubes. If the nanotubes have longer length than the effective depth of light penetration, the amount of incident photon absorb by the lower part of nanotubes will be lesser than that by the upper part. Therefore, light absorption by the TNT film will not increase further when the tube length exceeds a certain range.

Table 3. Dimensional data and photocurrent of TNT prepared in different electrolytic medium

Sample	Diameter (nm)	Length (μm)	Photocurrent[a] (mA/cm^2)
C5TNT/H_2O	75 ± 9	0.4 ± 0.01	0.16
C5TNT/EGH_2O	99 ± 10	2.6 ± 0.1	0.47
C5TNT/EG	141 ± 13	11.2 ± 0.3	0.79

[a] *Photocurrent is measured at 0.5 V versus Ag/AgCl in 10 ppm methyl orange solution*

Photoconversion efficiency, η% of light energy to chemical energy in the presence of an external applied potential for different nanotubes was calculated using Equation (2).

$$\eta\% = j_{ph} \left(\frac{[E^{o}_{rev} - |E_{app}|]}{I_o} \right) \times 100 \quad (2)$$

where I_o is the power density of the incident light (mW/cm^2), j_{ph} is the photocurrent density (mA/cm^2), E^{o}_{rev} is the standard reversible potential for water splitting reaction which is 1.23 V versus NHE and the applied potential, $E_{app} = E_{meas} - E_{aoc}$, where E_{meas} is the electrode potential (versus Ag/AgCl) of the working electrode at which photocurrent was measured under illumination and was taken as 0.5 V versus Ag/AgCl in this study. E_{aoc} is the electrode potential (versus Ag/AgCl) of the same working electrode under open circuit conditions, under the same illumination, and in the same electrolyte as shown in Table 4.

Table 4. Photoelectrochemical data and photoconversion efficiency of TNT prepared in different electrolytic medium

Sample	Photocurrent[a] (mA/cm^2)	E_{aoc} (mV)	Photoconversion efficiency (%)
C5TNT/H_2O	0.13	–435	0.49
C5TNT/EGH_2O	0.52	–550	1.23
C5TNT/EG	1.04	–539	2.79

[a]*Photocurrent was done in 0.1 M KOH at 0.5 V versus Ag/AgCl*

As the solar cell parameters such as open circuit potential and short circuit current are best obtained from a non-potentiostated cell configuration, therefore the assessing of the photoefficiency and the use of Equation 2 are only meant to afford figure-of-merit estimates. As shown in Table 4, the highest photoconversion efficiency was obtained for C5TNT/EG in agreement with the highest photocurrent density. Long nanotubes with ordered and well-defined morphology are necessary for good photoelectrochemical performance. The nanotube length obtained for C5TNT/EG is 11.2 μm, which is much longer than that for C5TNT/EGH_2O and C5TNT/H_2O and therefore showed a higher photoefficiency. Other researchers have reported higher photoefficiency with nanotubes length reaching up to 220 μm. For example, Mor et al. [11] had demonstrated that a photoconversion efficiency of 6.8 % was obtained for nanotubes formed in mixture of HF and acetic acid under UV illumination (337 nm). Later, TNT of 6 μm length, under a similar illumination shows a photoconversion efficiency of about 12.25 % [12]. 14.4 μm long TNT fabricated using a formamide-based electrolyte had achieved a photoconversion efficiency of 14.42 % and increased to 16.26 % for 24 μm long TNT fabricated in an ethylene glycol based electrolyte [13]. Nevertheless, it has been reported that the photoefficiency increased with increasing nanotube length up to 5 μm and thereafter tending toward a plateau [14]. Gratzel-type solar cells were fabricated after dye sensitizing the nanotubes layers. The

greatest overall light to electricity conversion efficiency reported for dye-sensitized solar cells based on the nanoparticles TiO_2 have achieved 11% [15]. For pure nanotubes layer, the record efficiency stands at 5.2 % [16] and 7 % for nanotube/nanoparticles mixtures [17].

Conclusion

In summary, titania nanotube arrays were successfully synthesized via electrochemical anodization of Ti in various electrolytic compositions. Choice of electrolytic composition has an effect on the microstructure, element composition, band gap and crystal structure of TNT. In addition, photocurrent response is enhanced using the calcined nanotubes and is affected by the morphology, dimensional changes; with higher photocurrent and photoefficiency conversion is associated with smooth and longer length tube. Highest efficiency was obtained for TNT/EG than those prepared in aqueous solution.

Abstract

Monoepoxidation linoleic acid (MEOA) has advantages for industrial applications. MEOA was synthesized using immobilized *Candida antarctica* lipase (Novozym 435®). At optimum conditions, higher yield (82.14 %) and medium oxirane oxygen content, OOC (4.91 %) of MEOA were predicted at 15 µL of H_2O_2, 120 mg of Novozym 435® and 7 hours of reaction time. Fourier Transform Infrared Spectroscopy (FTIR) spectra of the MEOA showed monoepoxide group at 820 cm^{-1}. ^{1}H NMR analysis confirmed the monoepoxide group at 2.92 – 3.12 ppm while the monoepoxide signals of ^{13}C NMR appear at 54.59 – 57.29 ppm. LC-MS analysis shows that of MEOA gives m/z at 296.22 as final product. MEOA exhibited good pour point (PP) of -41 ºC. Flash point (FP) of MEOA increased to 128 ºC comparing with 115 ºC of linoleic acid (LA). In a similar fashion, viscosity index (VI) for LA was 224 generally several hundred centistokes (cSt) more viscous than MEOA 130.8. MEOA was screened to measure their oxidative stability (OT) which was observed at 168 ºC. It is evident that increasing the hydrogen peroxide amount has a strong effect on the reaction kinetics; however, a large excess of hydrogen peroxide results in accumulation of peracid in the final product.

Keywords: linoleic acid, Novozym 435®, self-epoxidation, renewable energy

Abstrak

Mono-pengepoksidaan asid linoleik (MEOA) mempunyai kelebihan untuk aplikasi industri. MEOA telah disintesis menggunakan *Candida Antartika* lipase (Novozym 435 ®) pegun. Pada keadaan yang optimum, peratus hasil MEOA sebanyak 82.1 % dengan kandungan oksigen oksirana (OOC) sebanyak 4.91 % diperolehi dengan menggunakan 15 µL H_2O_2, 120 mg Novozym 435 ® dan 7 jam tindak balas. Analisis ^{1}H NMR mengesahkan kumpulan terepoksida pada 2.92 –3.12 ppm manakala isyarat ^{13}C NMR menunjukkan bacaan pada 54.59 – 57.29 ppm. Analisis LC-MS menunjukkan bahawa MEOA memberikan m/z 296.22 sebagai produk akhir. MEOA menunjukkan takat tuang yang baik pada suhu -41 ºC. Takat kilat MEOA meningkat pada suhu 128 ºC berbanding pada suhu 115ºC oleh asid linoleik (LA). Dalam keadaan yang sama, kebiasaanya VI untuk LA pada 224 beberapa ratus sentistok (cSt) lebih likat daripada MEOA 130.8. MEOA mempunyai kestabilan oksidatif pada suhu 168 ºC. MEOA berpotensi untuk dijadikan sebagai produk pertengahan dalam aplikasi tenaga keterbaharuan.

Introduction

Bio-renewable materials, such as plant oils and unsaturated fatty acid derivatives, have recently received increasing attention as a means of addressing environmental and economic concerns. Epoxidized oils are currently produced by the epoxidation of plant oils such as soybean, linseed oil [1] and *Jatropha curcas* seed oil [2].

Although the monoepoxidation of linoleic acid or its methyl ester has been carried out repeatedly in the past, it was only recently that a study of positional selectivity in the monoepoxidation of methyl linoleate was reported [3]. There are several methods to epoxidize the double bonds of unsaturated fatty acids, such as Prileshajev monoepoxidation reaction. In this reaction, a peracid from a short or long chain fatty acid and hydrogen peroxide (H_2O_2) under strong acidic conditions is used as the oxidizing agent. The peracid can either be added to the reaction mixture or is formed in situ, the latter being preferred due to safety reasons. The presence of the strong acid in the reaction mixture, however, causes the formation of side products, such as vicinal diols, estolides and other dimers. Although the careful choice of the peracid and the reaction conditions can help to minimize the epoxide loss, the selectivity of industrial monoepoxidation of unsaturated fatty acids rarely exceeds 80% [4].

The effect of reaction parameters on lipase-mediated chemo-enzymatic monoepoxidation of linoleic acid (LA) has been investigated [4]. H_2O_2 was found to have the most significant effect on the reaction rate and degree of epoxidation. An excess of H_2O_2 with respect to the amount of double bonds was necessary in order to yield total conversion within a short time period, as well as at temperatures above 50 °C to compensate for H_2O_2 decomposition. The reaction rate also increased by increasing the hydrogen peroxide concentration (between 10 and 50 wt-%), albeit at the expense of enzyme inactivation. LA was completely epoxidized when used at a concentration of 0.5-2 M in toluene at 30 °C, while in a solvent-free medium, the reaction was not complete due to the formation of a solid or a highly viscous oily phase, creating mass transfer limitations. Increasing the temperature up to 60 °C also improved the rate of epoxide formation. The monoepoxidation of methyl linoleate was examined using transition metal complexes as catalysts [5]. With a catalytic amount of MTO (4 mol%) and pyridine, methyl linoleate was completely epoxidized by aqueous H_2O_2 within 4 h. Longer reaction times (6 h) were needed with 1 mol% catalyst loading. Manganese tetraphenylporphyrin chloride was found to catalyze the partial epoxidation of methyl linoleate. A monoepoxidized species was obtained as the major product (63%) after 20 hours.

Objective of this study was attempted to improve the efficiency of monoepoxidation under milder conditions that minimize the formation of byproducts. Chemo-enzymatic monoepoxidation uses the immobilized lipase from *Candida Antarctica* (Novozym 435®) to catalyze conversion of fatty acids to peracids with 60% hydrogen peroxide. The fatty acid is then self-epoxidized in an intermolecular reaction. The lipase is remarkably stable under the reaction conditions and can be recovered and reused 15 times without loss of activity. Different lipase catalysts have been studied, of which Novozym 435®, a commercial preparation of *Candida Antarctica* lipase B, has been shown to be the most effective so far. Most of the investigations have involved dilution of the substrate in organic solvent. Recently, lipase mediated monoepoxidation in a solvent-free medium has also been reported [4]. LA, bearing two C=C double bonds, is one of the major components in *Jatropha curcas* seed oil. This study focuses on the impact of various reaction parameters on the monoepoxidation process, with the aim to determine optimal reaction conditions with regard to reaction efficiency and enzyme stability using D-optimal design. LA was used as the model substrate.

Materials and Methods

Experimental procedure

The enzymatic monoepoxidation was carried out using Novozym 435®, a commercial catalyst made up of lipase, from Candida Antarctica, immobilized on a polyacrylate resin [4]. Table 1 shows the different ratios of hydrogen peroxide (H_2O_2), different amounts of enzyme and different reaction times using D-optimal design. Three factors (variables) including hydrogen peroxide (µL, X_1), enzyme (mg, X_2) and reaction time (h, X_3) were performed for 18 experiments at the same experimental conditions.

In a typical chemo-enzymatic monoepoxidation of linoleic acid, 9(12)-10(13)-monoepoxy 12(9)-octadecanoic acid (MEOA), the LA (1.4 g) was dissolved in 10 mL toluene and the lipase was added. After stirring for 15 min, 15-20 µL of 30 % H_2O_2 was added and every 15 min the addition was repeated for 6 – 8 hours. Afterwards the lipase was removed by filtration, the mixture was washed with water to remove excess H_2O_2 and the organic phase was then

dried over anhydrous sodium sulphate; the solvent was evaporated in a vacuum rotary evaporator. The oxirane ring content (OOC %) [6], yield% and iodine value (IV) [7] were measured. The FTIR, ^{1}H, ^{13}C NMR and LC-MS were analyzed and the physicochemical properties of the product were studied [7].

Table 1. Independent variables and their levels for D-optimal design of the monoepoxidation reaction

Independent variables		**Coded Levels**		
		-1	**0**	**+1**
H_2O_2 (µL)	X_1	15	17.5	20
Enzyme (mg)	X_2	80	100	120
Time (h)	X_3	6	7	8

Experimental design and statistical analysis

To explore the effect of the operation variables on the response in the region of investigation, a D-optimal design at three levels was performed. H_2O_2 (µL, X_1), amount of enzyme (mg, X_2) and reaction time (h, X_3) were selected as independent variables. The range of values and coded levels of the variables are given in Table 1. A quadratic polynomial regression model was assumed for predicting Y variables. The model proposed for each response of Y was:

$$Y = ß_0 + \sum ß_i x_i + \sum ß_{ii} x_i^2 + \sum \sum ß_{ij} x_i x_j \quad (1)$$

Where $ß_0$; $ß_i$; $ß_{ii}$ and $ß_{ij}$ are constant, linear, square and interaction regression coefficient terms, respectively, and x_i and x_j are independent variables. The Minitab software version 14 (Minitab Inc., USA) was used for multiple regression analysis, analysis of variance (ANOVA), and analysis of ridge maximum of data in the response surface regression (RSREG) procedure. The goodness of fit of the model was evaluated by the coefficient of determination R^2 and the analysis of variance (ANOVA). Response surfaces and contour plots were developed using the fitted quadratic polynomial equations obtained from RSREG analysis and holding the independent variables with the least effect on the response at two constant values and changing the levels of the other two variables [8].

Results and Discussion

Reaction and mechanism of the monoepoxidation linoleic acid

Figure 1 demonstrates the scheme for the monoepoxidation reaction of LA (MEOA). MEOA results in a mixture of two monoepoxides (cis-9, 10-epoxy 12c- 18:1 and cis-12, 13 epoxy 9c- 18:1) with yield% of 75.82. H_2O_2 is an important reactant for the formation of peracids from fatty acids; hence, the influence of its amount on the monoepoxidation reaction was studied.

The addition of H_2O_2 solution to the reaction medium (toluene with LA) leads to the formation of two distinct phases, an organic phase and an aqueous phase show in Figure 2. The Novozym 435®, being adsorbed on a hydrophobic carrier, is mainly present in the organic phase. H_2O_2 will be partitioned in both the aqueous and the organic phases, with the concentration being higher in the aqueous phase (Figure 2) due to consumption of H_2O_2 for peracid formation in the organic phase.

The ratio of H_2O_2 to H_2O tends to decrease slightly in organic phase. Hence, for the reaction to proceed optimally, it is essential that the transport of the H_2O_2 from the aqueous phase to the organic phase is faster than its utilization in the enzymatic reaction [4].

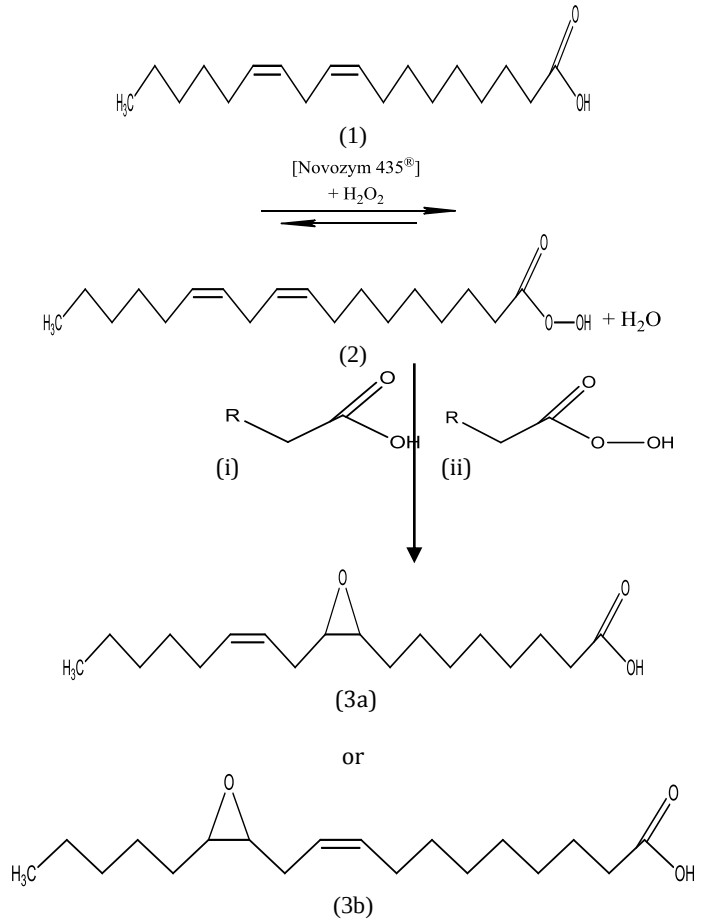

Figure 1. Chemo-enzymatic monoepoxidation of LA

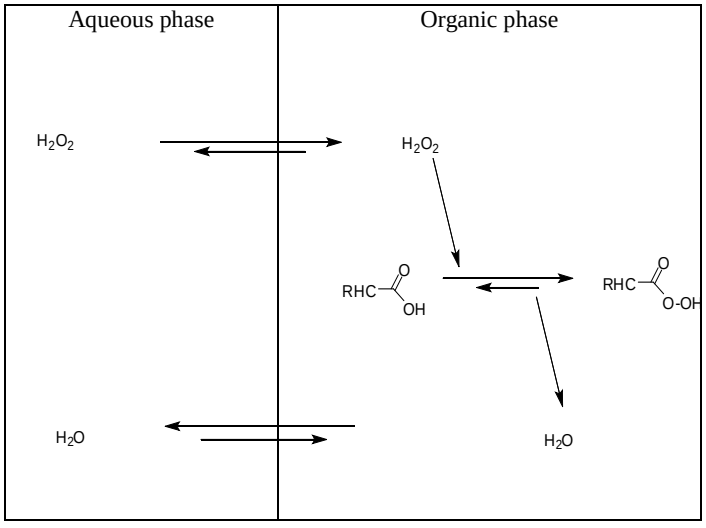

Figure 2. Transport of H_2O_2 and water in an organic-water biphasic system

The reaction synthesis was determined by varying amounts of H_2O_2 (15, 17.5 and 20 µL), which was added every 15 min, the addition was repeated 24 times. The different amounts of Novozym 435® (80, 100 and 120 mg) and different times (6, 7 and 8 hours) also have been used. A stoichiometric excess of the required amount of the H_2O_2 was used to compensate for its possible decomposition by light and temperature. Epoxide contains oxygen as one of the ring atoms. The mechanism of converting the peracid to epoxide involves one-step and the relative stereochemistry of the alkene is maintained in the epoxide [7]. The mechanism is shown schematically in Figure 3.

The double bond acts as the nucleophile with the π-electrons attacking the peracid oxygen. In one-step, the oxygen-oxygen bond breaks and the electrons shift over to form a new π-bond between oxygen and carbon. This causes the π-bond of the existing carbonyl to break and those electrons attack the terminal hydrogen. Finally, the electrons from the O-H bond, which is breaking, add to the alkene carbon to form the three-member ring epoxide [9].

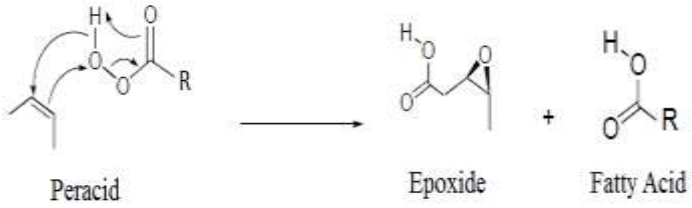

Figure 3. Mechanism of converting peracid to epoxide

Effect of process parameters and statistical analysis

This study demonstrates the application of the proposed response surface methodology (RSM) framework for the optimization of MEOA by using Novozym 435® catalytic monoepoxidation process. Hence, the knowledge about the process is relatively limited, and the design is used to obtain 18 design points within the whole range of three factors for experiments.

The designs and the responses yield percentage of MEOA (Y_1), oxirane oxygen content percentage (OOC, Y_2) and iodine value (IV mg/g, Y_3) are given in Table 2. Following the reaction experiments, the response surface is estimated by D-optimal design. Table 2 shows that the yield% of MEOA of Y_1 increased to (82.14 %) while OOC% of Y_2 (4.91) and IV of Y_3 (77.65) which is considerable compared to the theoretical OOC*t* (9.02) and initial iodine value IV◦ (157.35 mg/g). The conversion percentage of the MEOA is 81.35%. Subsequent experiments were performed using different amounts of H_2O_2 15, 17.5 and 20 µL for every 1.4 gm of LA in one single step. As seen in Table 2, there is a clear increase in the reaction rate (OOC percentage) and decrease iodine value (IV mg/g) with increasing H_2O_2 amount. With 15 µL, monoepoxidation was achieved at 7 h using 120 mg Novozym 435®.

The quadratic regression coefficients obtained by employing the least squares method technique to predict quadratic polynomial models for the yield percentage of MEOA (Y_1), OOC percentage (Y_2) and IV mg/g (Y_3) have been explained. For the yield percentage of MEOA (Y_1), the linear term of Novozym 435® catalyst amount (X_2), quadratic terms of H_2O_2 (X_{11}) and Novozym 435® catalyst amount (X_{22}) were significant ($p< 0.05$). The interaction between H_2O_2 (X_{11}) and Novozym 435® catalyst amount (X_{12}), and the interaction between H_2O_2 (X_{11}) and reaction time (X_{13}) were significant ($p< 0.05$), while its quadratic term of reaction time (X_{33}) was highly significant ($p<0.01$). Highly significant terms ($p< 0.01$) of OOC% (Y_2) and IV mg/g (Y_3) for the H_2O_2 (X_1) were linear. The linear term of IV mg/g for the reaction time h (X_3) was significant ($p< 0.05$).

The lack of fit *F*-value for all the responses shows that the lack of fit was not significant ($p> 0.05$) relative to the pure error. This indicates that all the models predicted for the responses were adequate. Regression models for data on responses Y_1, Y_2, and Y_3, were highly significant ($p<0.01$) with satisfactory R^2 (0.90, 0.69 and 0.79, respectively). However, the R^2 for Y_2 (0.69) was lower although the model was significant. Table 3 summarizes the analysis of variance (ANOVA) of all the responses of this study.

Table 2. D-optimal design arrangement and responses for MEOA

Run No.	Coded Independent			Responses					
	H_2O_2 (X_1)	Catalyst[a] (X_2)	Time (X_3)	Yield (Y_1, %)	OOC (Y_2, %)	RCO (%)	IV (Y_3, mg/g)	X (%)	SE

	Pure error	11	1787.93	162.539			

These results suggest that linear effect of H_2O_2 is the primary determining factor for MEOA. The H_2O_2 had a very large effect on the results of their monoepoxidation study. The final equations in terms of actual factors are:

$$Y_1 = +87.53 -2.82X_1-4.50X_2 -0.14X_3 -9.06X_1^2 -5.43X_2^2 -9.81X_3^2 -9.74X_1X_2 -7.14X_1X_3 -7.80X_2X_3 \quad (2)$$

$$Y_2 = +5.59 +1.00X_1+ 0.58X_2 +0.51X_3 -0.37X_1^2 -0.099X_2^2 +0.31X_3^2 -0.22X_1X_2 -0.55X_1X_3 -0.27X_2X_3 \quad (3)$$

$$Y_3 = +56.24-18.82X_1-8.91X_2-10.57X_3 +8.06X_1^2+4.15X_2^2 4.41X_3^2+11.59X_1X_2+10.81X_1X_3 +5.42X_2X_3 \quad (4)$$

The significant interaction variables in the fitted models were chosen as the axes (amount of H_2O_2; X_1, amount of Novozym 435®; X_2 and reaction time; X_3) for the response surface plots. The relationships between independent and dependent variables are shown in the three-dimensional representation as response surfaces. Figures 4 to 6 are the Design plots for all the responses. In the MEOA, performing the technique using a low amount of H_2O_2 would give the desired OOC% of MEOA, as shown in Figure 5, while IV (Figure 6) was higher at this condition. As shown in Figures 5 and 6, increasing the amount of H_2O_2 led to an increase in the OOC percentage and a reduction of IV. The relationships between the parameters and MEOA were linear or almost linear. High OOC percentage could be obtained by using a high amount of H_2O_2 at high reaction time. Experimental variables should be carefully controlled in order to recover a medium percentage of MEOA of interest with reasonable yield [4].

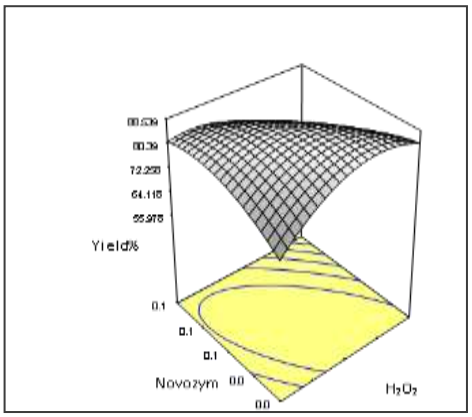

Figure 4. Response surface for the effect of the H_2O_2 (X_1, µL) and catalysts Novozym 435® (X_2, mg) on the yield% of MEOA

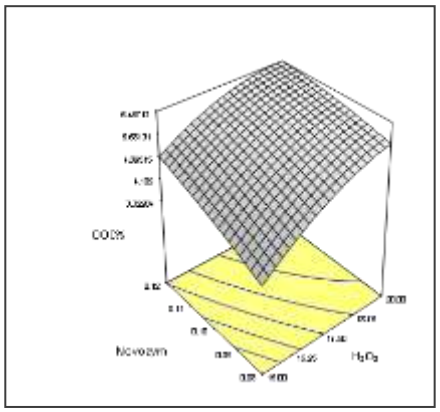

Figure 5. Response surface for the effect of the H_2O_2 (X_1, µL) and catalysts Novozym 435® (X_2, mg) on the OOC% of MEOA

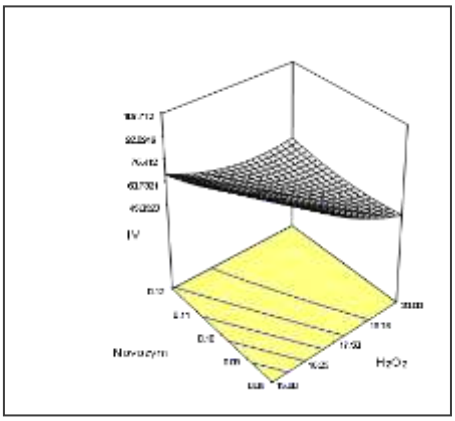

Figure 6. Response surface for the effect of the H_2O_2 (X_1, µL) and catalysts Novozym 435® (X_2, mg) on the IV mg/g of MEOA

The optimum conditions of the experiment to obtain a higher yield percentage of MEOA and medium OOC percentage were predicted at amount of H_2O_2 of 15 µL, catalyst Novozym 435® of 120 mg and 7 h reaction time. At this condition, the yield percentage of MEOA was 82.14%, 4.91% of OOC and 77.65 mg/g of IV. Reconfirmation of the optimal condition experiment was carried out at three replicate. While full epoxidation was observed within 10 h using 30 µL of H_2O_2, increasing the H_2O_2 amount used for the reaction results in the increasing formation of peracid. In the state of MEOA, the amount of peracids accumulated is not significant [10], due to the chemical reaction in which they are consumed is very fast. The reaction could indicate that with a high amount of catalyst, the utilization of H_2O_2 is so fast that the epoxidation of the double bonds does not keep pace with the formation of peracids. However, once all the double bonds are epoxidized, the remaining peracid is not consumed [4]. The observed value was reasonably close to the predicted value, as shown in Figures 7 – 9 respectively.

FTIR analysis of MEOA

In order to prove the presence of the oxirane ring of MEOA, the final product was tested by FTIR. The oxirane ring of MEOA can be detected at 820 cm^{-1} [9]. For the carboxylic acid carbonyl functional groups (C=O), FTIR spectrum showed absorption bands of LA and MEOA at 1719 and 1711 cm^{-1}, respectively, while stretching vibration peak of C=C can be detected at wavenumber 3009 cm^{-1} [11]. Peaks at 2927 – 2856 cm^{-1} indicate the CH_2 and CH_3 scissoring of LA and MEOA. FTIR spectrum also shows absorption bands at 722, 723 cm^{-1} for (C-H) group vibration.

^{1}H and ^{13}C NMR Analysis of MEOA

The ^{1}H NMR spectroscopy shows the main signal assignments in LA, MEOA and di-epoxide LA. The ^{1}H NMR spectra for the products show some of the key features for a typical (-CH-O-CH-) at about 2.92 – 3.12 ppm of MEOA and about 2.99 – 3.13 ppm of di-epoxide LA. The distinguishable groups are the protons of the terminal methyl of the fatty acid chain. The signals at 0.88 – 0.86 ppm indicate the methylene group ($-CH_3$) of LA, which also appear in MEOA 0.86 – 0.88 ppm and di-epoxide LA 0.88 – 0.92 ppm next to the terminal methyl ($-CH_2$) at 1.30 – 2.06 ppm of LA, 1.29 – 2.03 of MEOA and 1.34 – 1.75 ppm of di-epoxide LA. However, the methane proton signals (-CH=CH-) were shifted upfield at about 5.35 – 5.36 ppm of LA and 5.38 – 5.49 ppm of MEOA while they disappeared in di-epoxide LA [12]. The signal at 7.27 ppm referred to the solvent D_2O for LA, MEOA and di-epoxide LA [7].

The ^{13}C spectroscopy shows the main signals assignment of the LA. The signals at 180.49 ppm refer to the carbon atom of the carbonyl group (carboxylic acid). The signals at 128.27 – 130.38 ppm refers to the unsaturated carbon atoms (olefinic carbons); 24.86 – 29.79 ppm due to methylene carbon atoms in fatty acid moieties of LA [13]. The results confirm the oxirane ring of MEOA 54.59 – 57.29 ppm and di-epoxide LA at about 54.61 – 57.32 ppm. Indeed, it appears that the signals were present in the MEOA, as four peaks of roughly equal intensity (132.89, 132.72, 130.15, and 124.02 ppm) were observed in the alkenic carbon region in the ^{13}C-NMR spectrum, [5], while they had disappeared in the di-epoxide LA.

The ^{13}C-NMR spectra indicate the existence of the carbonyl group (carboxylic acid) in their structure MEOA 179.32 ppm and di-epoxide LA at about 178.79 ppm. The other distinctive signals were aliphatic carbons MEOA at about 22.69 – 29.38 ppm and di-epoxide LA at about 22.77 – 29.44 ppm, which are common for these types of compounds [14]. The signals at 76.91 – 77.23 ppm refer to the solvent D_2O for LA, MEOA and di-epoxide LA [6].

Physicochemical Characteristics

This approach is used to study the low temperature flow behavior of fatty acids by monoepoxide ring. MEOA increased the pour point (PP) to 15 °C significantly comparing with LA at -2 °C. It can be assumed that the presence of the oxirane ring has a tendency to form crystalline structures that make it semi solid at low temperature through uniform stacking of the 'bend' epoxy ring [9]. Flash point (FP) is another important factor in determining how well oil will behave as a potential biolubricant. FP is often used as a descriptive characteristic of oil fuel, and it is also used to describe oils that are not normally used as fuels. FP refers to both flammable oils and combustible oils. Although there are various international standards for defining each, most agree that oils with a flash point of less than 43°C are flammable, while those having a FP above this temperature are combustible [7]. The FP of MEOA, which increased to 128 °C compared with 115 °C of LA, which means the result agrees with the various international standards. The efficiency of the biolubricant in reducing friction and wear is greatly influenced by its viscosity. Generally, the least viscous biolubricant that still forces the two moving surfaces apart is desired. If the biolubricant is too viscous, it will require a large amount of energy to move; if it is too thin, the surfaces will rub and friction will increase. The viscosity index highlights how the viscosity of a biolubricant changes with variations in temperature. The best oils (with the highest VI) will not vary much in viscosity over such a temperature range, and, therefore, will perform well throughout. In MEOA, the decreased viscosity index (VI) of 130.8 of MEOA is the result of less double bonds [7].

The ability of a substance to resist oxidative degradation is another important characteristic of biolubricants. Therefore, MEOA was screened to measure their oxidation stability using PDSC through the determination of OT.

PDSC is an effective method for measuring oxidation stability of oleochemicals in an accelerated mode [15]. The OT is the temperature at which a rapid increase in the rate of oxidation is observed at a constant, high pressure (200 psi). A high OT would suggest high oxidation stability of the material. OT was calculated from a plot of heat flow (W/g) versus temperature that was generated by the sample upon degradation and by definition. In this study, the OT of MEOA at 168°C was higher compared to LA at 159°C, indicating that the epoxy function either reduces the abstractibility of α-hydrogens or quenches the oxidation process [16].

Liquid Chromatography Mass Spectroscopy for the MEOA

Formed upon partial LA and MEOA were confirmed the liquid chromatography mass spectroscopy detection (LC-MS). The ion source was operated in the negative mode to produce $[M - H]^-$ precursor ions, which are prone to charge-remote fragmentation [4]. LC-MS analysis shows that of LA and MEOA gives m/z as 280.2335 and 296.2278 (Figure 10). LC-MS spectra obtained upon charge-remote fragmentation are usually straightforward to interpret and have been widely used for structural determination of fatty acids and related ester compounds [17].

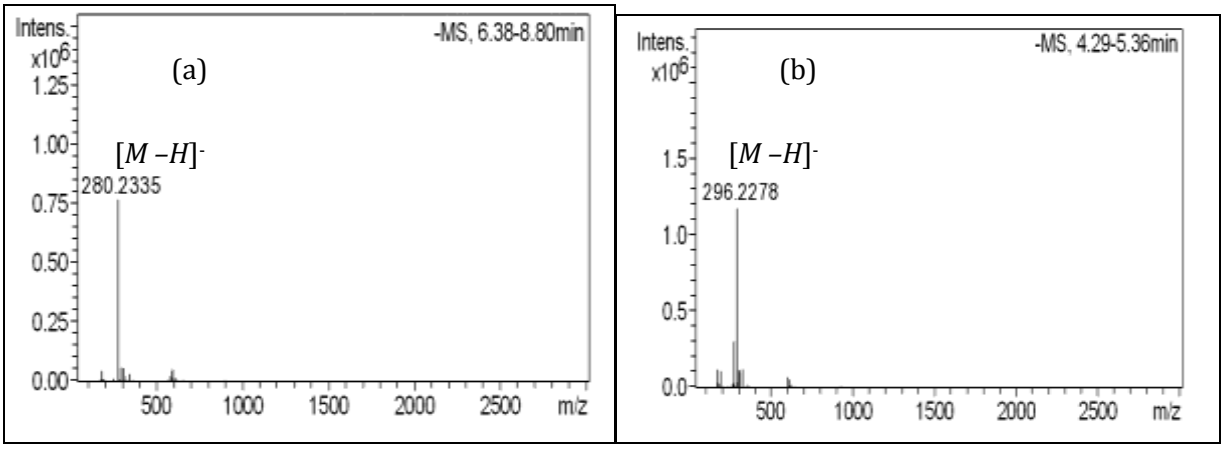

Figure 10. LC-MS analysis of LA (a) and MEOA (b)

Conclusion

It is evident that H_2O_2 is the most critical parameter influencing the chemo-enzymatic monoepoxidation reaction. Increasing the H_2O_2 amount has a strong effect on the reaction kinetics; however, a large excess of H_2O_2 results in the accumulation of peracid in the final product. At optimum conditions, a higher yield percentage of 82.14 and medium oxirane oxygen content OOC percentage of 4.91 and IV of 77.65 mg/g were predicted at 15 μL of H_2O_2, 120 mg of Novozym 435, and 7 h of reaction time. The conversion percentage of the MEOA is 81.35%. The MEOA exhibited high PP of 15°C. In a similar fashion, VI for LA was 224 generally several hundred centistokes more viscous than that MEOA (130.8).

Abstract

Fresh water scarcity has become an important issue in this world today. Water reuse is known as one of the strategies to overcome this problem. Grey water is one of the sources of reused water. Several researches were carried out on water reuse, but limited attention was focused on reusing grey water from wet market, which contains high nutrient and organic matters. This study was carried out on nutrient removal from grey water using sequencing batch reactor (SBR). The grey water sample was taken from a wet market (Pasar Peladang, Skudai). About 1L of grey water was fed into the reactor with a total volume of 4L. Anoxic-aerobic phase were divided with a ratio of 30%-70% of total time respectively. Mixing was maintained at 30 rpm during the start of each cycle until settling phase to achieve uniform condition. Influent and effluent were set for 30 minutes. The SBR was operated with 3 cycles/day, temperature 30°C, cycle time 8 hours and hydraulic retention time (HRT) 1.2 days. Aeration at 35 L/min was induced for ammonia conversion and assisting nitrification.. The results show that the bacteria growing in alternating anoxic/aerobic systems could remove organic substrates and nutrient. The COD, Total Nitrogen and Total Phosphorus removal efficiencies were maximum at the levels of 94%, 88% and 70% respectively. Anaerobic-Aerobic-Anoxic phase was proposed to increase the removal percentage.

Keywords: SBR system, nutrient removal, grey water, hydraulic retention time, chemical oxygen demand

Abstrak

Kekurangan bekalan air bersih menjadi isu penting di dunia pada masa kini. Penggunaan semula air sisa yang telah diolah dikenali sebagai salah satu langkah strategik untuk mengatasi masalah ini. Penggunaan semula air basuhan telah menjadi salah satu sumber yang penting sebagai air sisa kitar semula. Beberapa kajian tentang perkara ini telah dijalankan, tetapi fokus yang berkaitan penggunaan semula air basuhan dari pasar basah, yang mengandungi nutrien dan permintaan oksigen kimia (COD) yang tinggi, agak terbatas. Kajian ini mengenai penyingkiran nutrien di dalam air basuhan dari pasar basah menggunakan reaktor kelompok urutan (SBR). Sampel air basuhan diambil dari pasar basah (Pasar Peladang, Skudai).Sebanyak 1L air basuhan telah dimasukkan ke dalam reaktor dengan jumlah isipadu total 4L. Nisbah tahap anoksik-aerobik ditentukan 30% -70% daripada jumlah masa total. 30 rpm pengaduk pencampuran dikekalkan pada awal setiap kitaran untuk mencapai tahap keadaan seragam. Influen dan efluen ditetapkan selama 30 minit. SBR telah dikendalikan dengan 3 kitaran / hari, suhu 30 ° C, masa kitaran 8 jam dan masa tahanan hidraulik (HRT) 1.2 hari. Pengudaraan pada 35 L/min telah dipasang untuk penukaran ammonia dan membantu nitrifikasi. Hasil kajian menunjukkan bahawa bakteria yang membiak dalam sistem anoksik / aerobik boleh menyingkir substrat organik dan nutrien. Tahap kecekapan maksimum penyingkiran COD, Nitrogen Jumlah dan Fosforus masing-masing adalah pada kadar 94%, 88% dan 70%. Fasa anaerobik-aerobik-Anoxic dicadangkan untuk meningkatkan peratusan penyingkiran.

Kata kunci: Sistem SBR, penyingkiran nutrien, air basuhan, masa tahanan hidraulik, permintaan oksigen kimia

Introduction

Scarcity of fresh water has become a global issues nowadays, which is already faced by almost one-fifth of the world's population (1.2 billion) [1]. Malaysia is not exempted from this problem. Although Malaysia received heavy rains all year around, approximately 2600 mm a year, it still cannot accommodate the increasing demand of fresh water. Fresh water problem in Malaysia needs to be viewed from economical consideration. While water rates keep increasing, the burden suffered by consumers especially high load consumer will help them when reuse water will lower the total costs of operation [2]. The need of water reuse is acceptable to cover such big activities as agriculture. Among all potential new sources of reused water is grey water that contribute 60 –75 % to domestic wastewater [3]. According to Lamine et. al. [4], grey water is wastewater produced from bath, showers, hand basin, washing machines, dishwashers, kitchen sink. This type of wastewater can be generated from household, office building and schools. Grey water is differentiated from black water, where sewage is excluded from grey water.

Grey water reuse has been applied in many countries, especially in the Middle East countries such as Lebanon and Palestine [5, 6]. These countries face a shortage of clean water hence grey water reuse has come into special focus to meet their basic needs. On the other hand, western countries such as Germany also applied grey water reuse even though the scarcity of fresh water did not come as special focus [7]. Grey water reuse can be applied to many hygienic activities. It can be used for toilet flushing, lawn, athletic field, cemeteries, park and golf courses, domestic garden, washing vehicle activities, fire protection, boiler feed water and concrete production [8 – 12]. However, different reuse purposes require different quality standards and thus different type of treatment [13].

Wet markets are fresh food markets that possess advantages in terms of costs, freshness and food preparation, which make them more attractive to consumers. According to Gorton [14], it is an important location to acquire the daily needs especially raw food at reasonable prices. Places that are easily approachable, affordable prices and a broad choice of goods and items make it more attractive to consumers. As wastewater generated from wet market is separated from toilet trench, it can be considered as grey water.

The purpose of this study was to investigate the application of sequencing batch reactor (SBR) technology for treating grey water collected at wet market effluent chamber. This study aimed to establish an approach in removing nutrients from grey water in an SBR. Wet market in Pasar Peladang, Skudai area was chosen for investigation to determine the process treatment of each type of wastewater and its possible re-use.

Materials and Methods

Wastewater characteristic

The grey water was collected from wet market effluent chamber. The sample was characterized to determine the properties of the water as it varies from source to source.

System configuration

Sequencing batch reactor (SBR) system was used in this study. It was fabricated from a transparent glass cylinder with a total volume of 5L and a working volume of 4L as shown on Figure 1.

Air (35 L/min) was provided by set of air pumps, model Atman HP-4000, equipped with two peristaltic pumps in charge of influent feeding and effluent discharging, respectively. A mechanical agitation (30 rpm) was operated whereby the wastewater is stirred or agitated so that well mixed wastewater achieved. The operation program of the SBR system consisted of five steps: fill, react (aeration), settle (sedimentation/clarification), draw (decant) and idle [15].

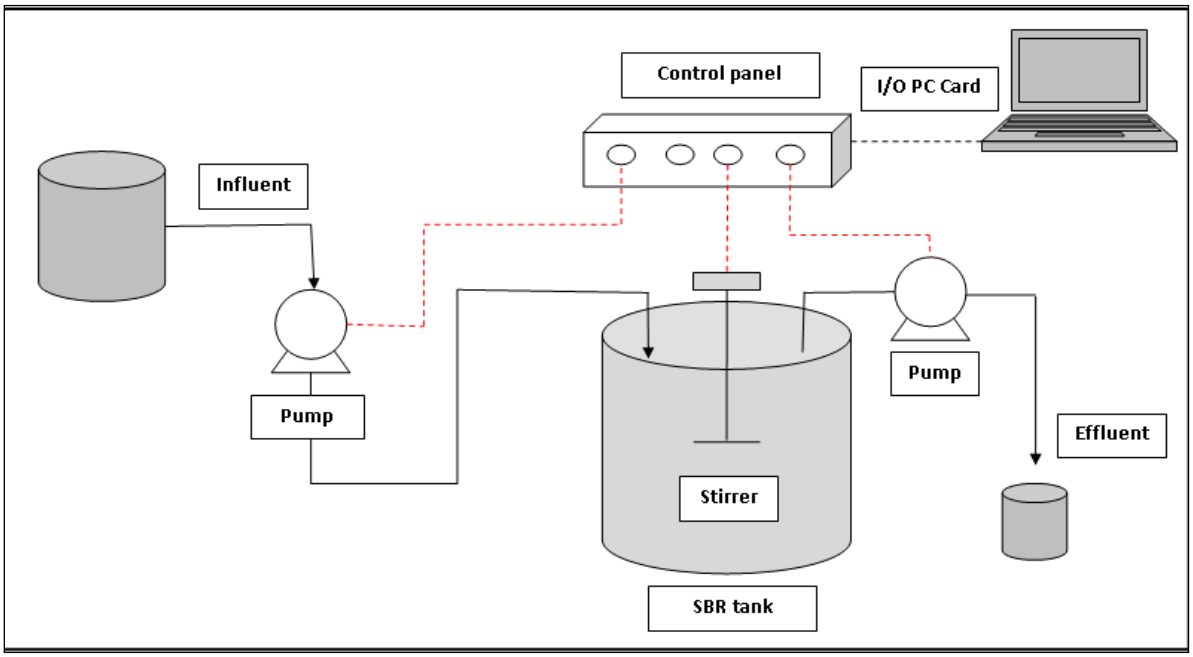

Figure 1. Schematic diagram of SBR system

Start-up of SBR

Bio-sludge to be used as inoculum during the start-up of the SBR was obtained from the sludge storage tank of a local municipal wastewater treatment plant (Taman Harmoni Wastewater Treatment Plant). The SBR was operated under alternating anoxic–aerobic conditions over 28 days. Activated sludge contained in the aeration basin in the activated sludge process (MLSS) was maintained at 3000 – 5000 mg/L. Within the process, pH was set at range 7.0 to 7.5 to ensure successful nitrification process. The reactor was operated at room temperature without control.

The process operates on batch basis. The SBR system worked at three cycles per day with 1.2 days hydraulic retention time (HRT). Each operating cycle consisted of four phases. They are FILL, REACT, SETTLE, and DRAW phases. During the filling process (0.5h), air pump was shut down to promote anoxic condition. The anoxic phase was then continued for 2 hours after feeding. Aeration phase was started for 4 hours when air pump was automatically switch on while mechanical agitation continuously operated. Aeration was then shut down for 1 hour. After 1 hour settling phase was occurred when aerobic phase finished. At the end of each cycle, supernatant of 1000 mL was removed from the SBR (0.5h).

Analytical procedure

Chemical oxygen demand (COD), Total Nitrogen (TN), Total Phosphorus (TP), Ammonia were analyzed using Spechtrophotometer DR5000. The pH value was measured using pH meter (HACH-Germany). Total suspended solids (TSS), MLSS and sludge volume index (SVI) concentrations were determined using standard method. [16].

Results and Discussion

The SBR performance was initially evaluated by measuring COD, TSS, TP, TN and Ammonia compounds in the effluent. The determined characteristics during the full operations are presented in Table 1.

The percentage COD removal in the grey water is shown in Figure 2. At the beginning of the run during start-up, the percentage COD removal was slow with the removal percentage of approximately 40 %. It was observed that

the removal percentage gradually increased, where after a month an increased in the measurement of oxygen equivalent of the organic material in wastewater that can be oxidized chemically was achieved. During the total operational period, high COD removal was achieved in the reactor and the effluent COD was nearly 90 %. This indicates that carbon removing bacteria were able to utilize carbon at pH level 7.0 to 7.5. The performance of grey water treatment in the SBR stabilized with low sludge production. The low production of sludge with good settling properties were also reported by Hernandez et. al. [17] for grey water treatment using SBR at an HRT of 12 hours and 1 day.

Table 1. Characteristics of effluent grey water

Parameters	**HRT = 1.2 days, Cycle time: 8 hours**		
	Average Influent	**Max Effluent**	**Average Removal**
COD (mg/l)	1708	97	94%
TSS (mg/l)	140	40	71%
TN (mg/l)	288	13	88%
TP (mg/l)	66	22	67%
NH_4-N (mg/l)	98	7	93%
NO_2-N (mg/l)	0.040	0.058	-
NO_3-N (mg/l)	0.01	38	-

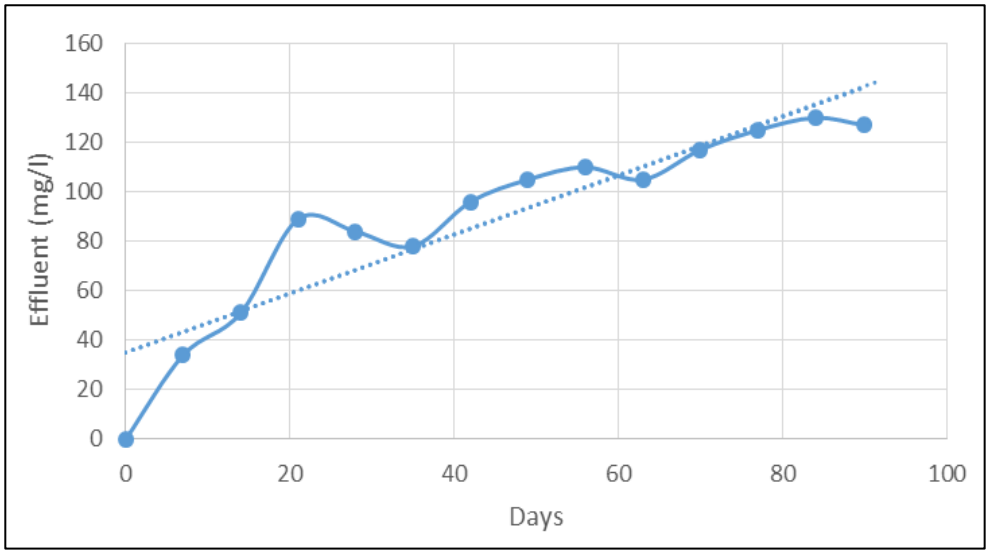

Figure 2. Percentage COD removal of grey water

The 8 hours cycle time with 4 hours aeration period was found to be enough in converting organic materials to CO_2, ammonia and water as expressed in Equation 1.

$$C_nH_aO_bN_c + dCr_2O_7^{2-} + (8d + c)\,H^+ \longrightarrow nCO_2 + \frac{a+8d-3c}{2}H_2O + cNH_4^+ + 2dCr^{3+} \quad (1)$$

The percentage removals of Total Nitrogen and Ammonia-Nitrogen are shown on Figure 3. This type of removal involved two step biological processes in which ammonia (NH_4-N) is oxidized to nitrite (NO_2-N) and nitrite is

oxidized to nitrate (NO_3-N) during the nitrification process. Akunna and Shepherd [18] using SBR to treat a mixture of black and grey water achieved ammonia-nitrogen content from 20 – 59 mg/L NH_3-N to 5 – 25 mg/L NH_3-N. This was then continued with denitrifcation process, where nitrate was reduced to small amount of nitric oxide and nitrous oxide, and mostly in the form of nitrogen gas, which escapes into the atmosphere. From the observation made, the slowly and persistence growth of bacteria occurred within two month. It was assumed that biological uptake of nitrogen for the growth of biomass, *Nitrosomonas* and *Nitrobacter* (nitrification bacteria) and *Nitrococcus*, *Nitrispira* and *Nitroeystis* in wet market wastewater was achieved.

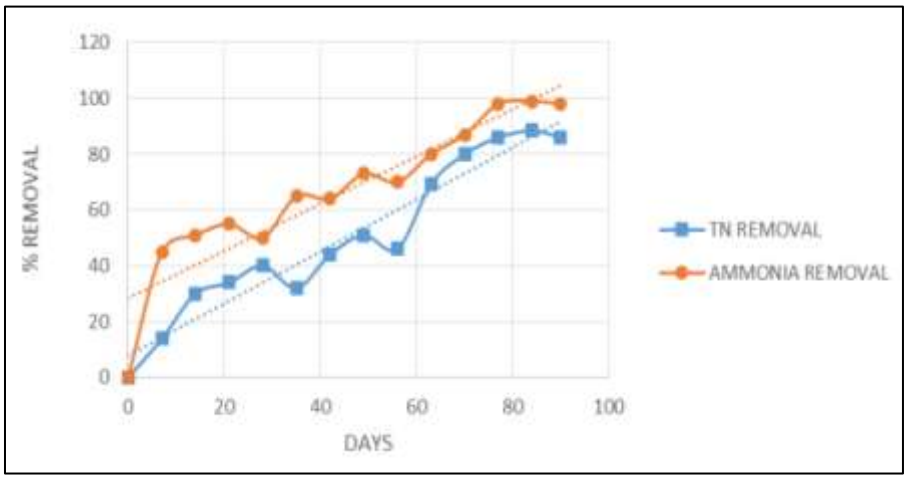

Figure 3. Percentage of Ammonia vs Total Nitrogen removal of grey water

The two lines of different removal (Ammonia-nitrogen and Total Nitrogen) showed that both parameters interlinked with each other. Successful total nitrogen removal must be started with great indicator of ammonification process which ammonia-nitrogen (NH_3-N) is converted to inorganic ammonium or ammonia with assistance of the catalysing by heterotrophic biomass concentration. Figure 4 illustrates the percentage removal of ammonia to nitrite and nitrate to nitrate in the grey water.

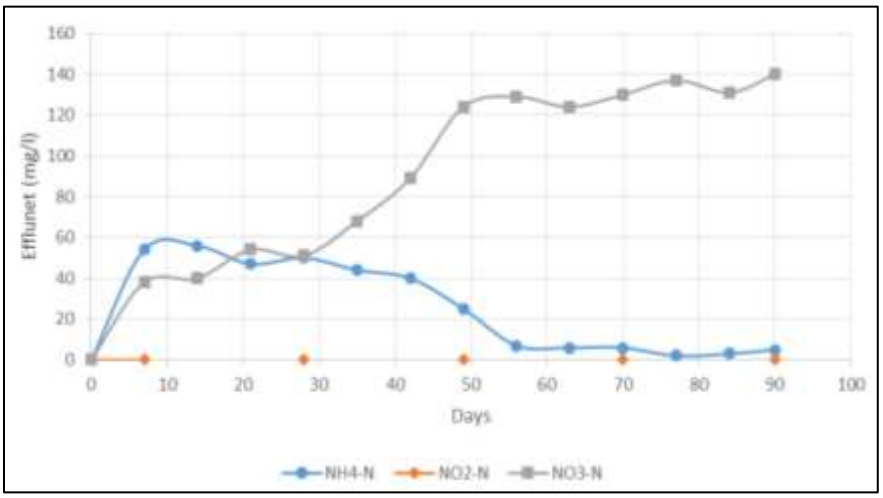

Figure 4. Percentage of Ammonia vs Nitrite vs Nitrate removal of grey water

The data was obtained by taking the effluent samples and tested for the removal performance. It was found that conversion of ammonia to nitrite and nitrate occurred successfully within four hours of aeration and two hours of anoxic stage. This indicated that the nitrification occurred during the first aerobic phase, where ammonia decreased to around 7 mg/L while nitrate increased until it peaked at 140 mg/L. This agrees with the result obtained by Puig et. al. [19], where the ammonia reduced from 9.6 to 0.7 mg/L with nitrate concentration peaking at 6.2 mg/L. The whole process of nitrification requires oxygen. Aerobic autotrophic bacteria are responsible for nitrification in activated sludge. In the first stage, ammonia (NH_4-N) is oxidized to nitrite (NO_2-N) by one group of autotrophic bacteria. In the second stage, nitrite (NO_2-N) is oxidized nitrate (NO_3-N) by another group of autotrophic bacteria.

It should be noted that at 0 – 20 days, the exchange of ammonia to nitrate is very low. This can be observed when the nitrate is in the range of 40 – 60 mg/L. This may cause the bacteria responsible for nitrification to grow much more slowly than heterotrophic bacteria. However, it is good to see uptrend movement despite of slow growth. On day 60 – 80 days, obvious conversion can be seen when the low ammonia and high nitrate effluent results were obtained. Nitrate is converted to nitrogen gas during the settling stage and the rest will be converted at anoxic stage in the next cycle. Also observed lower total nitrite stimulated seem invisible. This may be due to nitrite produced was directly converted to nitrate in the same cycle. If the number of high nitrite (NO_3-N) was seen in the effluent sample, this may be probably due by to the inadequate amount of oxygen or inappropriate pH level found in the system.

The total phosphorus removal average within 60 –70% as seen in Figure 5. The average result of removal may be caused by the initial phosphorus uptake becoming stunted by the long aeration time as observed by Hauschild et. al. [20] in their study. Phosphate accumulating organisms (PAOs), organisms that are capable of storing orthophosphate in excess of their biological growth requirements, are slow growing and normally surpassed by faster growing organisms (non-PAOs). It is suggested that an anaerobic zone is placed ahead of the aerobic zone [21]. This concurred with the finding by Puig et. al. [19], where the polyphosphate was found to be released during the anaerobic phase, while in the aerobic phase the PAOs in the reactor will quickly take up the phosphate.

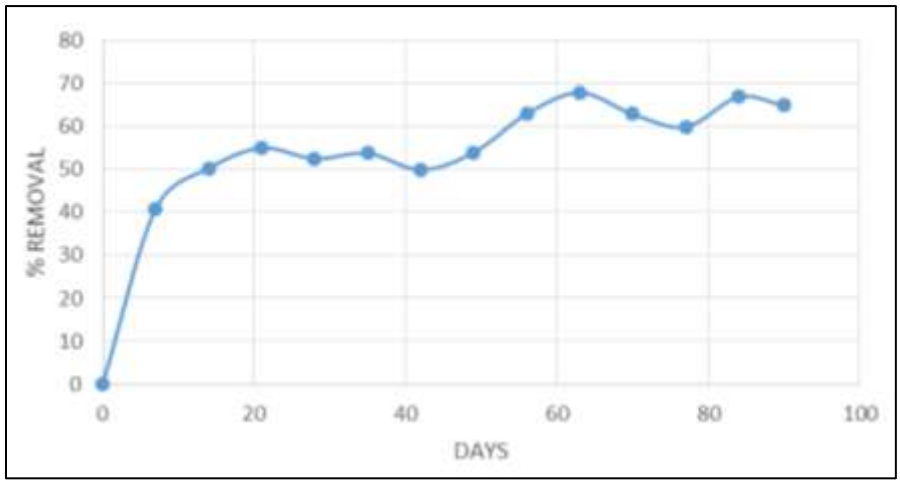

Figure 5. Percentage of Total Phosphorus removal of grey water

Conclusion

The SBR system can effectively remove nutrients and promote biodegradation of organic matter for wet market grey water when the reactor was operated with 1.2 day HRT (8 hours cycle time). The nitrification rate increased while the SBR reactor achieved above 90 % COD removal. The pH should be kept in the range 7.0 –

7.5 in order to prevent inhibition of the nitrifiers. Total phosphorus removal achieved was not above 80 %. It is suggested that aeration time should be increased to enhance poly P uptake.

Abstract

Graphene-based magnetic hybrid nanocomposite has the advantage of exhibiting better performance as platform or supporting materials to develop novel properties of composite by increasing selectivity of the targeted adsorbate. The hybrid nanomaterial was prepared by mixing and hydrolyzing iron (II) and iron (III) salt precursors in the presence of GO dispersion through co-precipitation method followed by in situ chemical reduction of GO. The effect of weight loading ratio of Fe to GO (4:1, 2.5:1, 1:1 and 1:4) on structural properties of the hybrid nanomaterials was investigated. The presence of characteristic peaks in FTIR spectra indicated that GO has been successfully oxidized from graphite while the decrease in oxygenated functional groups and peaks intensity evidenced the formation of hybrid nanomaterials through the subsequent reduction process. The presence of characteristic peaks in XRD pattern denoted that magnetite nanoparticles disappeared at higher loading of GO. TEM micrograph showed that the best distribution of iron oxide particles on the surface of hybrid nanomaterial occurred when the loading ratio of Fe to GO was fixed at 2:5 to 1. The reduced graphene oxide (RGO) sheets in the hybrid materials showed less wrinkled sheet-like structure compared to GO due to exfoliation and reduction process during the synthesis. The layered morphology of GO degrades at higher concentrations of iron oxide.

Keywords: graphene, graphene oxide, surface modification, chemical co precipitation, magnetic nanoparticles

Abstrak

Nano komposit hibrid magnetik berasaskan grafin mempunyai kelebihan dengan mempamerkan prestasi yang lebih baik sebagai platform atau bahan sokongan untuk mengembangkan sifat-sifat baharu komposit dengan meningkatkan pemilihan bahan terjerap yang disasarkan. Bahan nano hibrid telah disediakan dengan mencampurkan dan menhidrolisasikan pemula garam ferum (II) dan ferum (III) ke dalam sebaran GO melalui kaedah mendakan kimia diikuti oleh pengurangan kimia GO secara in situ. Kesan nisbah muatan berat Fe ke GO (4: 1, 2.5: 1, 1: 1 dan 1: 4) terhadap sifat struktur bahan nano hibrid telah dikaji. Kehadiran puncak berciri dalam spektrum FTIR menunjukkan bahawa GO telah berjaya teroksida daripada grafit manakala penurunan dalam kumpulan berfungsi oksigen dan keamatan puncak membuktikan bahawa terdapat pembentukan bahan nano hibrid berikutan melalui proses pengurangan. Kehadiran puncak berciri dalam corak XRD menandakan bahawa nano zarah magnetit hilang apabila muatan GO lebih tinggi. Mikrograf TEM menunjukkan bahawa pengagihan zarah ferum oksida yang terbaik di atas permukaan bahan nano hibrid berlaku apabila nisbah muatan berat Fe ke GO ditetapkan pada 2: 5 ke 1. Kepingan grafin oksida yang melalui proses pengurangan (RGO) dalam bahan hibrid menunjukkan struktur kedutan yang berkurang berbanding GO disebabkan oleh proses pengelupasan dan pengurangan semasa sintesis. Lapisan morfologi GO berkurang pada kepekatan ferum oksida yang lebih tinggi.

Introduction

Exposure to polluted water containing heavy metals and industrial waste can lead to major drawbacks to environment and pose risk to human health. In order to tackle these issues, various alternatives including membrane filtration [1], adsorption [2, 3], and ion exchange [4, 5] have been established. Recently, practical approaches have been made to develop a rapid nanocomposite adsorbent by incorporating magnetic nanoparticles (NPs) or nanocrystals into graphene or derivatives of graphene.

Graphene, a one-atom layer thick packed into a two-dimensional honeycomb sp^2 carbon lattice is currently an emerging new material in the world of science and technology because of their unique and outstanding properties [6, 7]. The production of graphene or reduced graphene oxide is preferably by using chemical route prior to its economical bulk synthesis. Meanwhile, high surface area and specific affinity for heavy metal adsorption from aqueous systems or wastewater samples can be provided by development of nanostructure metal oxides.

Among a wide range of magnetic materials, Fe_3O_4 NPs are becoming the topic of interest due to their unique magnetic separation performances by simply applying an external magnetic field. Besides that, magnetite nanoparticles are very well known for their established application in water treatment. In addition, magnetic particles-based composite adsorbents allowed rapid isolation from aqueous solutions for recycling or regeneration. The great advantage that arises from these two outstanding materials is essential to reduce the cost and time required for water or wastewater treatment.

Wu et al. reported the preparation of a graphene-based magnetic nanocomposite for the extraction of carbamate pesticides from environmental water samples [8]. Sheng et al. developed a versatile magnetic graphene oxide which has performed an efficient removal of arsenate [9]. Fan et al. also fabricated magnetic β-cyclodextrin-chitosan/graphene oxide as nanoadsorbent and applied into the application of removal and dye adsorption [10]. Despite having a lot of advantages, the formation of magnetic nanoparticles with graphene or its derivatives may involve particles aggregation thus the process remains challenging.

In this study, a graphene-based magnetic hybrid nanocomposite consisting magnetic nanoparticles that were incorporated on the surface of reduced graphene oxide through chemical co-precipitation of iron chloride salts solution and subsequent reduction of graphene oxide was developed. The properties of this hybrid material prepared with different loading ratios of graphene oxide and iron salt precursors were investigated. The synthesized nanomaterials were characterized by X-ray diffraction (XRD) and transmission electron microscopy (TEM) to study the nanoparticles crystallinity and morphology, respectively. The chemical compositions of the hybrid materials were investigated by Attenuated Total Reflectance Infrared spectroscopy (ATR-IR). It was expected that the further optimization of these hybrid materials based on various parameters such as type of reducing agent, reaction time, stirring rate and synthesis temperature can be implemented to produce a promising adsorbent for water treatment.

Materials and Methods

The materials used in the experiments were included of commercial graphite powder (60 – 85%) supplied by Superior Graphite Co. while hydrochloric acid (HCl, 37 %), sodium hydroxide (NaOH), hydrazine hydrate ($N_2H_4.H_2O$), and sulfuric acid (H_2SO_4, 95 – 97 %) were from Merck. Potassium permanganate ($KMnO_4$, 99 %) was purchased from Bendosen. Hydrogen peroxide (H_2O_2, 35 %), ferric chloride hexahydrate ($FeCl_3.6H_2O$) and ethanol (C_2H_6O) were supplied from QReC. Sodium nitrate ($NaNO_3$) and ferrous chloride tetrahydrate ($FeCl_2.4H_2O$) were obtained from Systerm. All materials were used as received. Distilled water was used throughout this study.

Preparation of Graphene Oxide (GO) films

Graphite oxide was first prepared from graphite powder in the presence of strong oxidizing agents according to modified Hummers method [11]. The proportion was scaled down during the synthesis process. Graphite powder (2 g) and $NaNO_3$ (1 g) were gradually added to a cold concentrated H_2SO_4 (98 %, 46 ml) followed by 30 minutes stirring in an ice bath. Subsequently, $KMnO_4$ (6 g) was slowly added to the mixture while maintaining the temperature below 20 ºC. After 2 hours stirring, the ice bath was removed and the mixture was stirred at 35 ºC for 30 minutes until it became pasty brownish. The reaction was continued with the addition of distilled water (92 mL)

resulting in sudden increase of the reaction temperature to 90 – 98 ºC which was maintained for 15 minutes. The mixture was diluted with distilled water and subsequently, H_2O_2 (30 %, 10 mL) was added to stop the oxidation process resulting the mixture turned to bright yellow with few bubbles existed. The mixture was left overnight with continuous stirring to make sure its homogeneity. The mixture then was centrifuged, rinsed with 5 % HCl solution to remove the residual metal ions followed by distilled water for several times to obtain neutral pH. Graphite oxide solution was subjected to ultrasonication to produce graphene oxide (GO). The resulting slurry was dried at 70 ºC for 24 hours to obtain GO films.

Preparation of Fe_3O_4-RGO Hybrid Nanomaterials

The procedure was modified from the previous literature where the molar ratio of Fe^{3+}:Fe^{2+} was fixed as 2:1 to synthesize the Fe_3O_4 nanoparticles [12]. GO (200 mg) was dispersed in distilled water (200 mL) by ultrasonication for 30 minutes to transform the carboxylic acid groups to carboxylate anions. Then $FeCl_3 \cdot 6H_2O$ (0.04 mol) and $FeCl_2 \cdot 4H_2O$ (0.02 mol) were dissolved in distilled water (100 mL), which then was added drop wise to GO dispersion at room temperature with vigorous stirring followed by sonication process for 30 minutes. Subsequently, 50 wt% NaOH solutions was added drop wise. The pH was constantly monitored to make solution of pH 11 – 12. The temperature of the solution was raised to 80 ºC and hydrazine hydrate (1.5 mL) was added with constant stirring for reduction of GO, resulting in a black solution. After being rapidly stirred for 5 hours the solution was continuously stirred for 12 hours at room temperature. The resulting precipitate was thoroughly washed with distilled water (3 times) and then followed by ethanol (3 times) to remove any impurities. The products were centrifuged for 15 minutes at 3000 rpm to discard excess water. The precipitate then was dried at 60 ºC for 8 hours. The dry product was then grinded into a fine powder. The same procedures were repeated to prepare different Fe to GO weight loading ratios of 1:1, 2.5:1. 4:1 and 1:4 (labeled as Fe/RGO 1:1, Fe/RGO 2.5:1, Fe/RGO 4:1, Fe/RGO 1:4 respectively).

Characterization of GO films and hybrid nanomaterials

FTIR was used to determine the chemical compositions of the prepared GO and hybrid nanomaterials. The prepared samples were characterized by using Attenuated Total Reflectance-Fourier Transform Infrared spectrometer (ATR-FTIR) with a resolution of 4 cm^{-1}. The crystallinity of GO and hybrid nanomaterials were examined based on XRD patterns obtained from PANalytical X'Pert Pro MPD HR-X-ray diffractometer, powered by Philips PW3040/60 with Cu-K_α radiation (λ = 1.5418 Å) generated from a Cu anode supplied with 40 kV and a current of 30 mA. The scan range for 2θ was from 5 to 90º. The surface morphology of the prepared samples was studied based on the TEM images captured with FEI/Philips CM12 transmission electron microscope operated at 120 kV.

Results and Discussion

Fourier Transform Infrared spectrometer (FTIR)

Figure 1 shows the FTIR spectra of graphite and graphene oxide (GO). The presence of few significant characteristic peaks in GO can be associated to the presence of oxygenated functional groups which were resulted from successful oxidation of graphite. The broad adsorption band at 3230.2 cm^{-1} is assigned to the O-H stretching vibrations while two adsorption bands appear at 1716.7 cm^{-1} and 1625.6 cm^{-1} are corresponding to the C=O stretching (from carbonyl and carboxyl groups) and aromatic C=C vibration (resulted from skeletal vibration from unoxidized graphitic domains) respectively. The peak observed at 1386.1 cm^{-1} can be assigned to the combination of C-O (carboxy) stretching vibration and deformation vibration of hydroxyl groups. Another peak presents at 1048.8 cm^{-1} can be attributed to the C-O (alkoxy) stretching vibration.

Figure 2 illustrated the FTIR spectra of GO and the hybrid nanocomposite with different loading ratio. The appearance of peak at 500-600 cm^{-1} differs GO from the hybrid nanocomposite in which it denoted the presence of Fe-O. The peak intensity of the hybrids was found to be very similar to each other except for Fe/RGO 1:4 which probably due to the higher loading ratio of GO presented in the hybrid. In general, the FTIR absorption bands of the hybrid nanocomposite showed much lower intensity compared to that of GO. The observation suggested that the oxygenated functional groups were partially removed from GO during the reduction process using hydrazine hydrate where GO has transformed into reduced graphene oxide (RGO) during the synthesis [13].

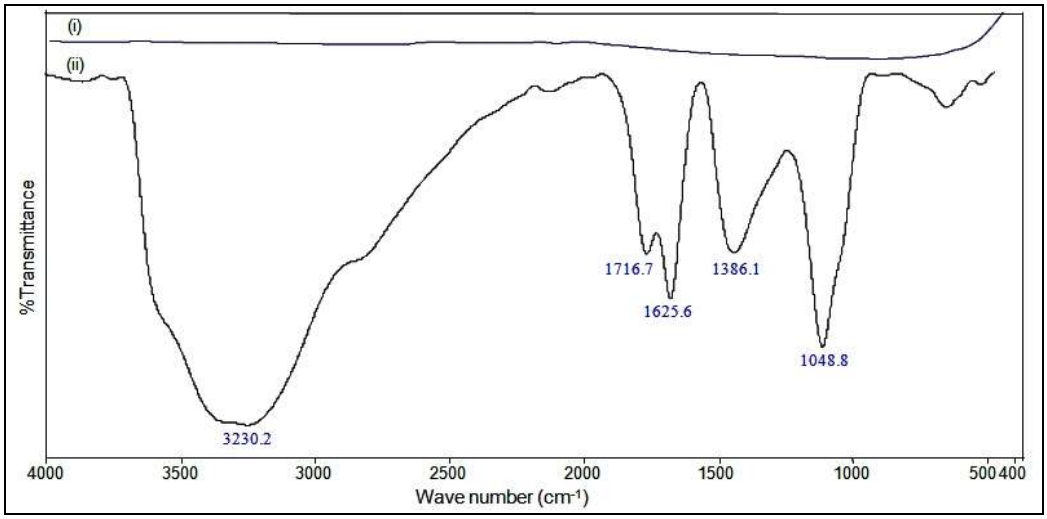

Figure 1. FTIR spectra comparison of (i) graphite and (ii) GO

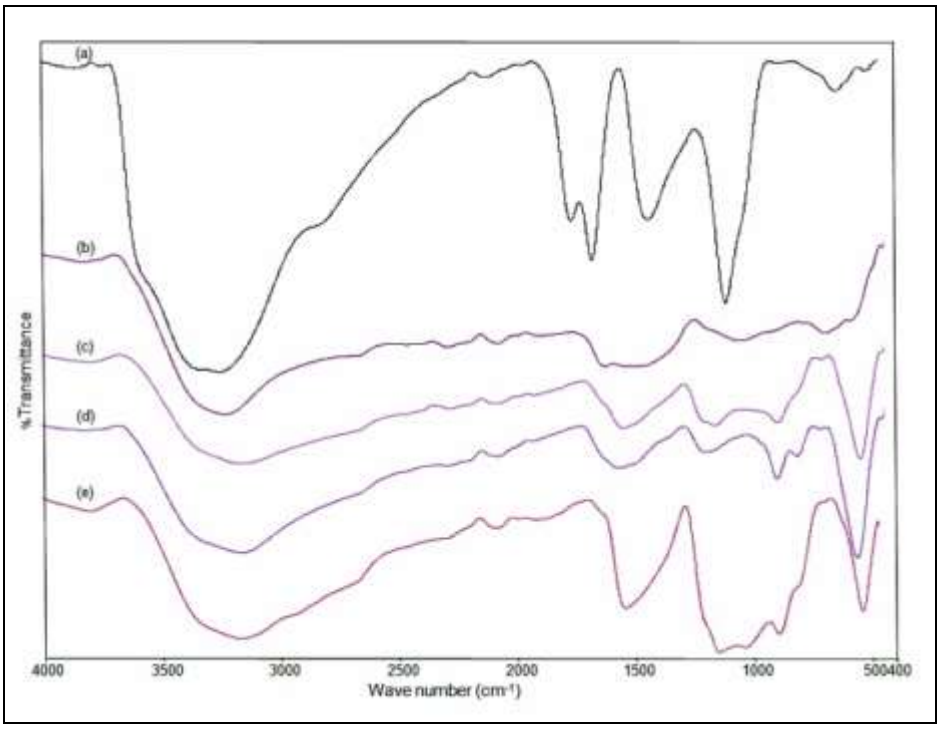

Figure 2. FTIR spectra comparison of (a) GO and hybrid nanomaterials with different weight loading ratios (b) Fe/RGO 1:4, (c) Fe/RGO 2.5:1, (d) Fe/RGO 4:1, and (e) Fe/RGO 1:1 respectively

X-Ray Diffraction (XRD)

XRD analysis was used to further confirm and compare the crystalline structure and composition of the obtained hybrid nanomaterials. XRD patterns of graphite, graphene oxide (GO) and hybrid materials synthesized at different weight loading ratios are shown in Figure 3. Graphite shows a very sharp diffraction peak at 2θ = 26.5° which corresponds to *d*-spacing of 0.34 nm with an index (002). Meanwhile, GO exhibits typical diffraction peaks centered at 2θ = 11.5° (001) corresponding to interlayer distance of ~ 0.77 nm and 2θ = 22.3° (100) which is consistent with the previous report [14]. The diffraction peak appears from GO is originated from (002) layer plane from graphite. The interlayer *d*-spacing of graphene oxide (0.77 nm) tends to be much larger than graphite (0.34 nm) due to the presence of many oxygen functionalities that attached to the surfaces of GO with some potential defects related to the strong oxidation process. A broad diffraction peak appears at $2\theta \approx 22.3^{o}$ due to the short range order of stacked graphene sheets.

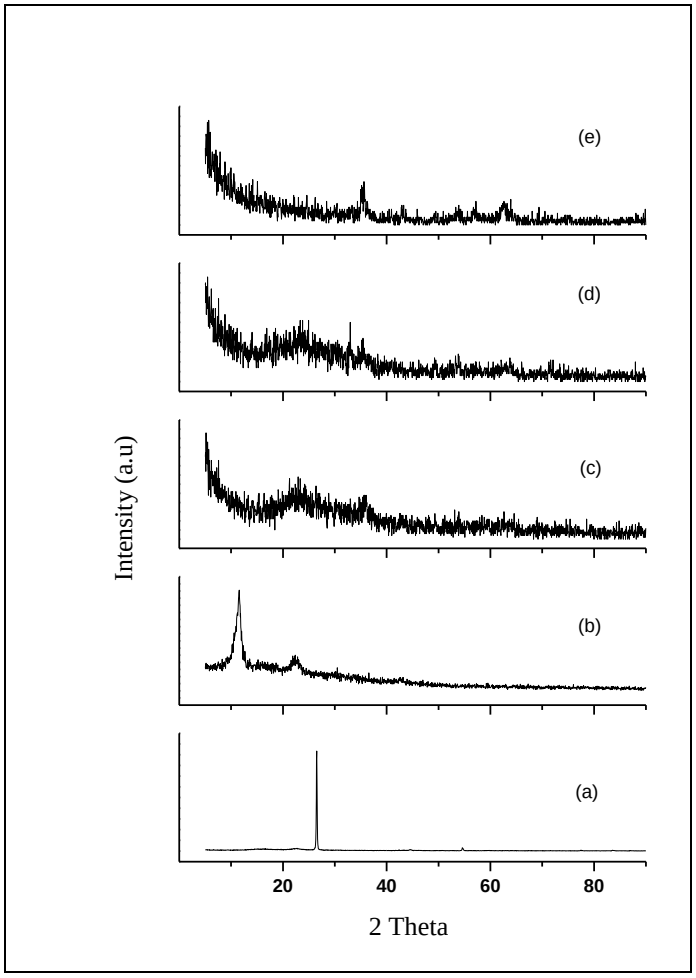

Figure 3. XRD patterns of (a) graphite, (b) GO, (c) Fe/RGO 1:1, (d) Fe/RGO 1:4, and (e) Fe/RGO 2.5:1

The XRD patterns of Fe/RGO nanocomposite with ratio of 1:1 and 1:4 are very similar. Both Fe/RGO 1:1 and Fe/RGO 1:4 showed the most intense diffraction peaks at $2\theta \approx 24^{o}$ and 23° respectively corresponding to the peak resulted from GO. However, both Fe/RGO 1:1 and Fe/RGO 1:4 do not show any peak that is corresponding to the magnetite compound. The Fe/RGO 1:1 is less likely to show magnetic properties due to the presence of minute amount of Fe_2O_3 particles in their composite. There are some diffraction peaks that are indexed to Fe_3O_4 particles in

Fe/RGO 2.5:1 with low intensity as compared to pure magnetic particles. The peaks of Fe/RGO 2.5:1 appear at $2\theta \approx 19.3^{o}$ (111), 35.4^{o} (311), 43.1^{o} (400), 53.7^{o} (422) and 62.5^{o} (440) indicated the characteristic of Fe_3O_4 nanoparticles while $2\theta \approx 24.5^{o}$ corresponds to the peak resulted from GO. However, formation of magnetite particles was not pure and might contain Fe_2O_3 particles and it was shown by at least two peaks of (220) and (511) indexes were missing. The synthesis reaction that was not carried out under nitrogen flow might be the reason for the unsuccessful magnetite formation since the ratio between Fe^{2+} and Fe^{3+} was probably disturbed during the fabrication process [15]. By using Scherer formula, average particle size of Fe/RGO 2.5:1 is estimated as 11.8 nm.

Transmission Electron Microscope (TEM)

The surface morphology of GO and the hybrid nanocomposites were studied by TEM whereby only GO and Fe/RGO nanocomposite with weight loading ratio of 2.5:1 and 1:4 were chosen as the representative samples (Figure 4). TEM analysis was performed on these two hybrids because Fe/RGO 2.5:1 presented the most significant characteristic peaks of XRD pattern while the analysis on Fe/RGO 1:4 was carried out to confirm that the higher loading ratio of GO might contribute to the disappearance of Fe-O absorption peak in the respective FTIR spectra. From the obtained TEM micrographs, there is significant difference between the as-prepared GO and RGO sheets in Fe/RGO 2.5:1 and Fe/RGO 1:4 hybrid. The RGO sheets present in the Fe/RGO 2.5:1 hybrid show less wrinkled sheet-like structure compared to GO and Fe/RGO 1:4 hybrid probably due to the exfoliation and reduction process during the synthesis. It has also been reported that, the layered morphology of GO tends to degrade at higher concentrations of iron oxide [16].

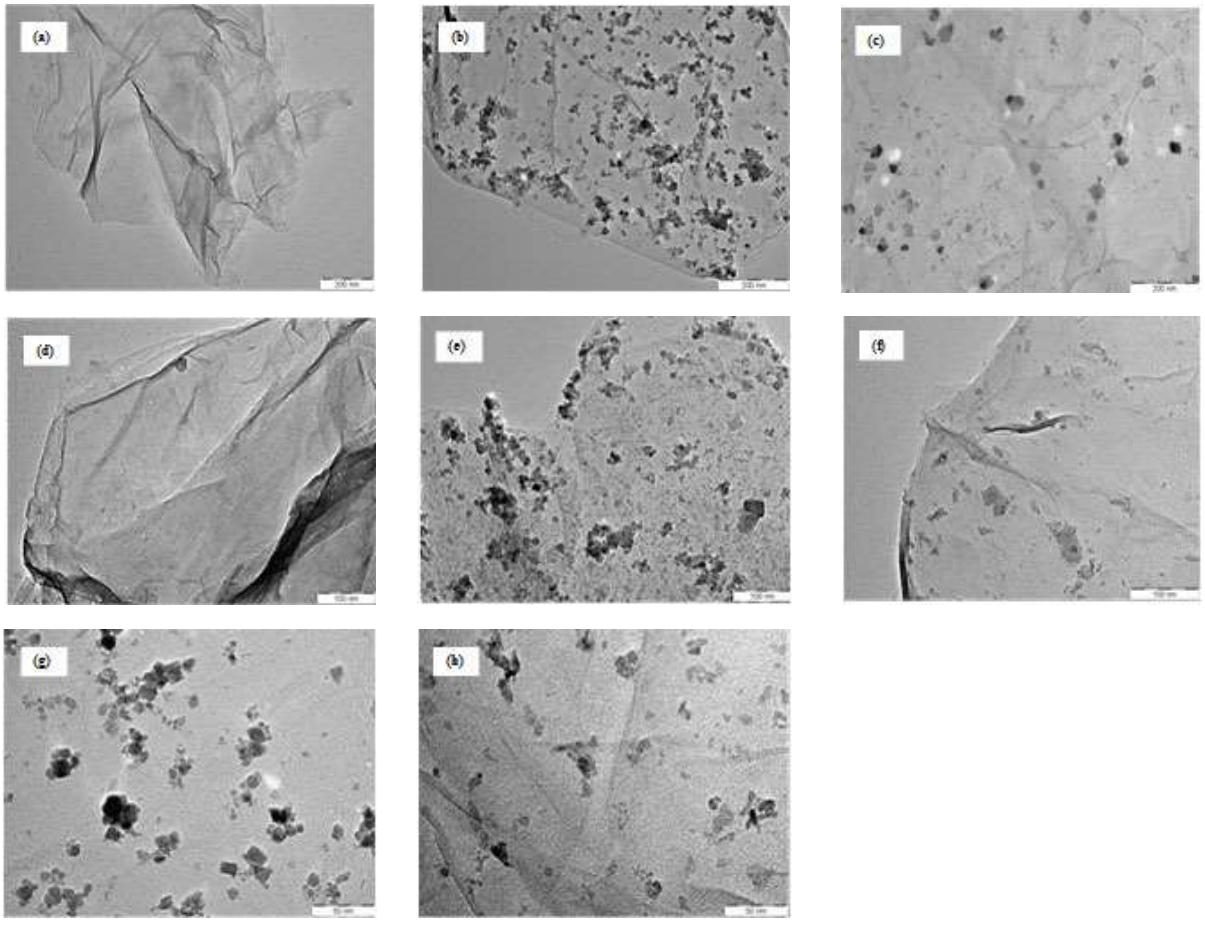

Figure 4. TEM micrographs of GO, Fe/RGO 2.5:1 and Fe/RGO 1:4 at magnification of 200 nm: (a, b, c), 100 nm: (d, e, f) and 50 nm: (g, h) respectively

Conclusion

The study on fabrication of hybrid nanomaterials was conducted by incorporating graphene oxide (GO) and magnetic nanoparticles altogether to achieve enhanced properties of conventional nanocomposite. The oxygen-rich functional groups allow GO to carry out secondary functionalization for the preparation of hybrid nanomaterials. In this study, magnetic hybrid materials were developed through chemical co precipitation from the mixture of iron (II) and iron (III) salt precursors, followed by in situ chemical reduction process of GO. From the FTIR spectra, it was shown that GO exhibited significant difference from graphite in terms of the amount of oxygenated functional groups. On the other hand, the hybrid nanomaterials exhibited absorption bands with much lower intensity compared to that of GO due to the partial removal of oxygenated functional groups during the reduction process. As higher loading of GO may have restricted the formation of iron particles onto the GO surface, the characteristic peaks that corresponding to magnetite nanoparticles were absent in the XRD patterns. The layered morphology of RGO sheets in hybrid nanocomposites showed less wrinkled sheet-like structure as compared to GO due to the exfoliation during the reduction process and probably because of the increasing iron oxide content. This study has shown that weight loading ratio of Fe to GO has significant effect in term of morphological and structural properties of the hybrid nanocomposites.

Abstrak

Dalam kajian ini, hidrogel berasaskan kanji daripada ubi *Stemona curtisii* disintesis melalui kaedah pempolimeran radikal bebas menggunakan penyinaran gelombang mikro. Dalam kajian ini terdapat 3 jenis hidrogel dengan nisbah kanji kepada akrilamida yang berbeza dianalisis iaitu 1:3, 1:4 dan 5:3. Berdasarkan kepada ujian pembengkakan, hidrogel 1:3 mempunyai peratus pembengkakan paling tinggi dan ini dibuktikan dengan keputusan yang diperolehi daripada Mikroskop Pengimbas Elektron (SEM) di mana mikrograf SEM mempamerkan saiz liang pada hidrogel 1:3 adalah yang paling besar. Analisis menggunakan Spektroskopi Inframerah Transformasi Fourier-Jumlah Pantulan Teratenuat (ATR-FTIR) menunjukkan kehadiran puncak pada 1112 cm^{-1}, 1152 cm^{-1} dan 1150 cm^{-1} pada hidrogel 1:4, 1:3 dan 5:3 masing-masing yang menandakan pembentukan ikatan C-O-C hasil daripada proses pempolimeran taut silang. Analisis menggunakan Difraktometer Sinar-X (XRD) pula menunjukkan bahawa ketiga – tiga jenis hidrogel adalah amorfus. Kalorimeter Pengimbas Kebedaan (DSC) pula memberikan maklumat bahawa semua bahan yang digunakan untuk sintesis hidrogel adalah pada tahap kebolehcampuran yang baik dan hidrogel 1:4 menunjukkan suhu peralihan kaca (T_g) yang paling tinggi. Daripada termogram TGA/DTG pula, hidrogel 5:3 didapati lebih stabil terhadap haba berbanding hidrogel yang lain. Keputusan ujian Tegangan menggunakan Mesin Ujian Universal (UTM) telah mendapati bahawa hidrogel berasaskan kanji Ubi *Stemona curtisii* yang disintesis mempunyai potensi untuk diaplikasikan sebagai pembalut luka. Dalam ujian ini, hidrogel 1:4 yang mempunyai kandungan kanji yang paling rendah telah menunjukkan nilai modulus elastik Young yang paling tinggi.

Kata kunci: *Stemona curtisii*, hidrogel, pempolimeran radikal bebas, gelombang mikro

Abstract

In this study, hydrogel based on starch of *Stemona curtisii* was synthesized via free radical polymerization method by using microwave irradiation. In this study, there were three type of hydrogels formulated with different type of starch to acryamide been anaylyzed which were 1:3, 1:4 and 5:3. Based on swelling test, hydrogel with 1:3 was reported to have the highest swelling percentage where this is prove by Scanning Electron Microscope result. The SEM micrograph shows that hydrogel 1:3 have the largest pores size compare to the other two types of hydrogels. The polymerization reaction has been proven to occur successfully based on the analysis using Attenuated Total Reflection-Fourier Transform Infrared Spectroscopy (ATR-FTIR). Cross-linking polymerization process was determine by the present of peak at 1112 cm^{-1}, 1152 cm^{-1} and 1150 cm^{-1} in hydrogels 1:4, 1:3 and 5:3 respectively which indicate the formation of C-O-C bond.X-Ray Diffractometer (XRD) results showed that all starch-based hydrogels were amorphous. Differential Scanning Calorimeter (DSC) gave information that all the blending materials for hydrogel synthesis were of good miscibility and the hydrogel 1:4 was found to have the highest glass transition temperature. From the TGA/DTG thermogram, hydrogel 5:3 was reported to be more stable to heat as compared to other hydrogels. The results from Tensile test using Universal Testing Machine (UTM) have discovered that hydrogels based on the

starch of *Stemona curtisii* possess a potential to be applied as wound dressing. In this test, hydrogel with the lowest starch content, 1:4 showed the highest Young's elastic modulus value.

Keywords: *Stemona curtisii*, hydrogel, free radical polymerization, microwave

Pengenalan

Kajian tentang hidrogel telah mendapat perhatian semenjak 50 tahun yang lalu kerana sifatnya yang unik yang membolehkan ia digunakan di dalam pelbagai aplikasi. Selain itu, hidrogel juga mempunyai tahap fleksibiliti yang hampir sama dengan tisu tabii kerana kandungan airnya yang tinggi. Keupayaan hidrogel untuk menyerap air bergantung kepada kumpulan berfungsi hidrofilik yang terdapat pada tulang belakang polimer manakala ketahanannya terhadap pemelarutan berpunca daripada kewujudan taut-silang antara rantai rangkaian [1].

Pada awalnya, hidrogel disintesis secara kimia sama ada melibatkan proses satu langkah atau proses pelbagai langkah. Proses satu langkah yang sering digunakan seperti pempolimeran dan taut-silang selari yang dihubungkan oleh beberapa monomer. Proses pelbagai langkah pula melibatkan sintesis molekul polimer yang mempunyai kumpulan reaktif. Hidrogel boleh direka bentuk dan disintesis dengan kawalan berskala terhadap struktur hidrogel seperti ketumpatan pertautan-silang, ciri biodegradasi, kekuatan mekanikal, tindak balas kimia dan biologi hidrogel terhadap rangsangan [2]. Hidrogel kanji-akrilamida merupakan sejenis hidrogel yang peka terhadap suhu dan pH. Kepekaan hidrogel ini akan menentukan nisbah pengembangannya berdasarkan nilai pH apabila direndam dalam larutan penimbal. Secara tabiinya, hidrogel yang peka pH membengkak di dalam air pada pH tertentu. Hidrogel kanji-akrilamida boleh digunakan sebagai penyerap untuk kegunaan sisa buangan seperti pewarna metilena biru [3].

Para saintis telah mengkaji pempolimeran hidrogel berasaskan kanji dengan menggunakan gelombang mikro. Hasil kajian mereka menunjukkan terdapat tiga keadaan tindak balas akan berlaku dengan penggunaan gelombang mikro: pertama, semua kandungan tindak balas dalam larutan yang homogen adalah larut tanpa ada pemisahan fasa; kedua, bahan tindak balas sama ada polisakarida atau monomer yang tidak larut akan berada dalam larutan tindak balas sebagai ampaian; ketiga, apabila polisakarida dan pemula meresap pada penyokong pepejal tabii, mereka akan wujud sebagai fasa pepejal. Kajian awal turut menunjukkan penggunaan gelombang mikro dapat meningkatkan pembentukan kopolimer dan memberikan produk yang tinggi dalam masa yang singkat berbanding cara pemanasan langsung [4]. Secara umumnya, sinaran gelombang mikro merupakan satu cara pemanasan yang amat menarik. Gelombang ini boleh memanaskan bahan tindak balas terpilih secara langsung dan mempunyai pertukaran haba yang sederhana. Selain itu, kelebihan cara gelombang mikro yang paling ketara sekali adalah tindak balas pempolimeran menggunakan cara ini boleh dilakukan tanpa pemula atau kepekatan pemula yang sangat rendah. Tambahan pula, hidrogel yang dihasilkan melalui cara ini adalah bersifat lebih poros berbanding hidrogel daripada cara konvensional [5].

Ubi Kemili atau nama saintifiknya, *Stemona curtisii* (*Stemonaceae*) adalah sejenis ubi yang menjadi makanan ruji bagi penduduk di kawasan pantai timur Semenanjung Malaysia. Ubi ini juga dikenali sebagai sejenis herba saka berumpun yang ditanam sebagai tanaman semusim dengan pokoknya hanya boleh mencapai 60 – 90 cm sahaja. Oleh itu, kebanyakan hasil ubinya hanya bersaiz lebih kurang 2 – 4 cm panjang dan 0.5 – 2.0 cm lebar. Sejak dahulu, Ubi Kemili telah dikenali sebagai Galak Tua, Pokok Seratus atau Pecah Kelambu di kalangan masyarakat Melayu dan 'Bai-bu' dalam masyarakat Cina [6]. Kajian awal telah menunjukkan bahawa ubi spesies *Stemona curtisii* telah digunakan secara meluas dalam perubatan tradisional di China, Jepun dan Thailand untuk merawat penyakit pernafasan, batuk dan anti-kanser.Selain itu, kajian farmakologi telah menunjukkan bahawa ekstrak daripada spesies ini dapat menghalang pertumbuhan pelbagai jenis bakteria dan kulat di mana mereka telah digunakan sebagai racun serangga [7].

Bahan dan Kaedah

Pengekstrakan kanji daripada Ubi *Stemona curtisii*

Rajah 1 menunjukkan ubi *Stemona curtisii* yang digunakan dalam penyelidikan ini diperolehi dari Terengganu dan Kelantan, Proses pengekstrakan kanji dimulakan dengan proses basuhan ubi bagi menyingkirkan sebarang kotoran. Ubi dicuci dengan air yang mengalir dan kulitnya dibuang secara menggosok dengan tangan di bawah aliran air.

Langkah ini perlu diberi perhatian kerana ubi ini mudah teroksida. Oleh itu, ubi harus direndam dalam air suling sebaik sahaja dibuang kulitnya. Ubi dipotong kecil dan dikisar dengan menggunakan pengisar elektronik. Hampas ubi ditapis dengan menggunakan penapis kopi yang diperbuat daripada kain. Proses ini diulang beberapa kali bagi mendapatkan kandungan kanji yang tertinggi. Hasil tapisan dibiarkan selama lima jam untuk membenarkan kanji mendak ke dasar bikar. Kanji yang diperolehi dibasuh dengan menggunakan metanol dan dicuci sebanyak tiga kali lagi dengan air suling bagi menyingkirkan baki metanol yang terdapat pada kanji. Seterusnya kanji dikeringkan secara pengeringan sejuk beku dan dikisar menjadi serbuk.

Rajah 1. (a) ubi kemili (*Stemona curtisii*) dan (b) isi ubi kemili yang bewarna putih susu [7]

Sintesis hidrogel berasaskan kanji daripada Ubi *Stemona curtisii*

Untuk menghasilkan hidrogel mengikut kaedah yang dilaporkan oleh Pandey [8], sebanyak 2 g kanji ubi *Stemona curtisii* dilarutkan dengan menggunakan 15 mL larutan natrium hidroksida berkepekatan 1 M. Campuran ini dikacau berterusan sehingga kedua-dua fasa menjadi homogen dan larutan jernih berwarna kuning-keperangan terhasil. Kemudiaan, 4 g akrilamida dan 0.05 g kalium persulfat serta 0.2 g *N,N'*-metilenabisakrilamida (5 % daripada berat akrilamida) ditimbang dan dimasukkan ke dalam larutan kanji. Akrilamida dilarutkan terlebih dahulu dengan menggunakan 5 mL air suling manakala kalium persulfat dan *N,N'*-metilenabisakrilamida masing-masing dilarutkan dengan 2 mL air suling. Kesemua campuran dikacau dengan menggunakan pengacau bermagnet pada kelajuan 500 rpm selama 3 minit. Apabila larutan menjadi sedikit likat, ia dituang ke dalam piring petri kaca dan didedahkan kepada gelombang mikro berkuasa tetap 100 W selama 5 minit. Hidrogel yang dihasilkan dibiarkan kering semalaman di dalam kebuk wasap. Proses basuhan dilakukan bagi menyingkirkan bahan – bahan kimia yang tidak bertindak balas. Hidrogel kering direndam selama 2 jam di dalam air suling dan kemudiannya dikeringkan di dalam ketuhar pada suhu 40 °C selama 24 jam. Jadual 1 menunjukkan komposis berbeza bahan – bahan yang digunakan untuk mensintesis hidrogel.

Jadual 1. Komposisi kanji, AAm, KPS dan MBA yang berbeza di dalam penghasilan hidrogel

Nisbah kanji : akrilamida (AAm) (g/g)	**Pemula (Kalium Persulfat, KPS) /g**	**Agen taut silang (*N,N'*-metilenabisakrilamida,MBA)/g**
0:3	0.05	0.15
1:4	0.05	0.20
1:3	0.05	0.15
5:3	0.05	0.15

Ujian Pembengkakan Hidrogel
Dalam kajian ini, ujian pembengkakan hidrogel dilakukan dengan merendam hidrogel ke dalam air suling pada suhu bilik dan beratnya ditimbang setiap 10 minit selama 2 jam. Peratus pembengkakan dikira dengan menggunakan persamaan yang telah dilaporkan oleh Gulrez seperti persamaan berikut [9];

$$\text{Pembengkakan } (\%) = \frac{W_s - W_d}{W_d} \times 100$$

di mana, W_s adalah jisim hidrogel yang membengkak pada masa t (minit) dan W_d adalah jisim asal hidrogel.

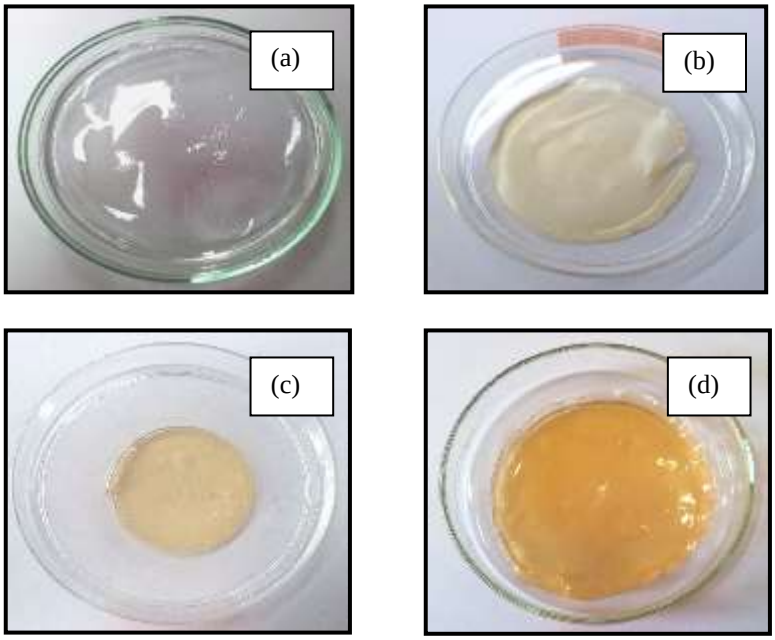
Mikroskop Pengimbas Elektron (SEM)
Mikroskop Pengimbas Elektron (SEM) digunakan untuk menganalisis sifat morfologi permukaan hidrogel, keporosan hidrogel dan saiz keporosannya. Sebelum analisis dijalankan, sampel hidrogel dikeringkan terlebih dahulu dengan menggunakan pengering sejuk-beku. Sampel hidrogel kering diletakkan di atas stub aluminium dan disalut dengan emas menggunakan mesin penyalut (SC500, BioRad, UK). Imej morfologi hidrogel dicerap dengan menggunakan mikroskop pengimbas elektron (LEO 1450 VP, Germany)

Spektrometer Inframerah Transformasi *Fourier*-Jumlah Pantulan Teratenuat (ATR-FTIR)
Analisis menggunakan Spektroskopi Infra Merah adalah bertujuan untuk menentukan proses cangkukan telah berlaku di antara kanji dengan akrilamida. Spektrum Infra Merah direkodkan dengan menggunakan teknik spektroskopi Infra Merah (FTIR/NIR) model: *spectrum 400 FT-NIR and spotlight 400 imaging system*, Perkin Elmer USA. Sampel hidrogel dikeringkan terlebih dahulu dan spektrum dirakam pada nombor gelombang 400 – 4000 cm^{-1}. Jenis kristal yang digunakan dalam ATR adalah berlian.

Difraktometer Pembelauan Sinar-X (XRD)
Difraktometer Pembelauan Sinar-X (XRD) telah digunakan secara meluas dalam penentuan penghabluran pada granul kanji daripada ubi dan hidrogel [11,12]. Hidrogel yang disintesis dalam kajian ini dijadikan serbuk dan diuji dengan menggunakan instrumen XRD berjenama Bruker (Siemen) D-5000 pada sudut 2θ (5˚ - 80˚).

Kalorimeter Pengimbas Kebedaan (DSC)
DSC merupakan suatu teknik untuk merakam tenaga yang diperlukan untuk mendapatkan perbezaan suhu sifar di antara sampel dan bahan rujukan terhadap masa atau suhu apabila kedua-duanya didedahkan kepada persekitaran yang dipanaskan atau disejukkan pada kadar terkawal. Dengan memerhatikan perbezaan dalam aliran haba antara sampel dan bahan rujukan, jumlah haba yang diserap atau dibebaskan semasa peralihan itu dapat ditentukan (perubahan entalpi). Alat ini hanya boleh mengesan perbezaan suhu sampel di antara julat suhu (−70 ˚C hingga 700 ˚C) dengan bantuan gas nitrogen atau oksigen sebagai gas pembawa. Dalam kajian ini, DSC berjenama Mettler Toledo/822 e digunakan untuk menentukan suhu peralihan kaca (T_g) dan kebolehcampuran setiap komponen dalam sampel.

Analisis Termagravimetri (TGA)
TGA adalah satu kaedah yang digunakan untuk menentukan perubahan sifat-sifat fizikal dan kimia bahan polimer terhadap suhu. Biasanya, pemanasan yang berterusan dikenakan ke atas sampel untuk mengetahui kehilangan berat bahan polimer. Dalam kajian ini, TGA yang berjenama TA−60WS, Shidmazu Corporation (Kyoto, Japan) digunakan untuk mengetahui kestabilan hidrogel terhadap haba. Sampel hidrogel dikisar menjadi halus lalu pemanasan dilakukan pada julat suhu 0-600 ˚C dengan kadar pemanasan 20 ˚C/minit. Pada nilai suhu yang tertentu, hidrogel yang stabil akan menunjukkan perubahan jisim yang ketara di mana pengurangan jisim dapat dilihat pada cerun termogram pada nilai suhu itu [13].



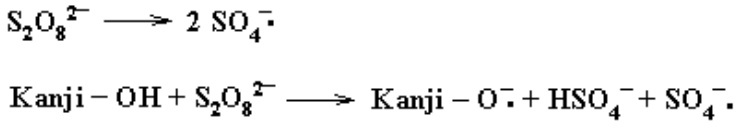
Ujian regangan hidrogel
Ujian regangan hidrogel ini dilakukan dengan menggunakan Mesin Ujian Universal (*Universal Testing Machine, UTM*) berjenama Instron/5566. Mesin ujian regangan universal adalah alat yang digunakan untuk mengukur kekuatan regangan, mampatan dan kekuatan ricih pada bahan. Sebelum ujian regangan dilakukan, sampel dipotong mengikut bentuk *'dumbell'* berdasarkan piawai ASTM (D 638−02a). Ketebalan sampel diukur terlebih dahulu

dengan menggunakan kaliper. Kemudian, sampel diapit pada Mesin Ujian Universal lalu duji pada kelajuan 3 mili meter/minit.

Keputusan dan Perbincangan

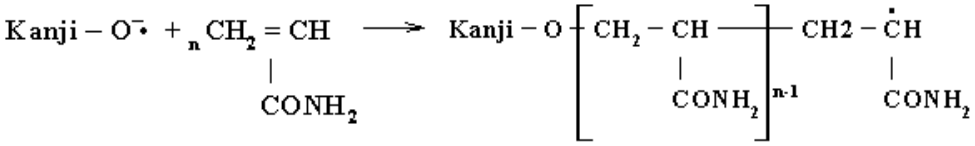
Penghasilan hidrogel

Rajah 2 menunjukkan hidrogel yang berjaya disintesis. Dalam penyelidikan ini, hidrogel berasaskan kanji daripada Ubi *Stemona curtisii* dihasilkan melalui aruhan gelombang mikro dengan menggunakan kalium persulfat, $K_2S_2O_8$ sebagai pemula radikal, akrilamida (AAm) sebagai monomer dan *N,N'*-metilenabisakrilamida (MBA) sebagai agen taut-silang telah berjaya dihasilkan.

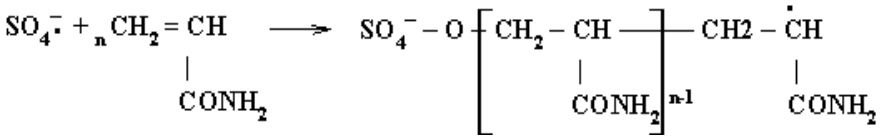


Rajah 2. (a) Hidrogel akrilamida (b) hidrogel dengan nisbah 1:4 (c) hidrogel dengan nisbah 1:3 dan (d) hidrogel dengan nisbah 5:3

Pemerhatian yang teliti terhadap hidrogel yang dihasilkan dari aspek fizikal seperti tahap kekenyalan, tekstur, permukaan dan warna seperti disenaraikan dalam Jadual 2. Cadangan tindak balas adalah seperti yang ditunjukkan dalam Rajah 3.



Jadual 2. Pemerhatian yang teliti terhadap hidrogel yang dihasilkan dari aspek fizikal seperti tahap kekenyalan, tekstur, permukaan dan warna.



Hidrogel	Pemerhatian
Akrilamida	Berwarna putih lutsinar dengan permukaan yang sangat licin, mempunyai tekstur yang kurang lembut dan tidak kenyal.
Nisbah 1:4	Berwarna kekuningan dengan permukaan yang licin, mempunyai tekstur yang lembut dan sangat kenyal.
Nisbah 1:3	Berwarna kuning pudar dengan permukaan yang licin, mempunyai tekstur yang lembut dan kenyal.
Nisbah 5:3	Berwarna kuning gelap dengan permukaan yang kurang licin, mempunyai tekstur yang lembut dan kurang kenyal.

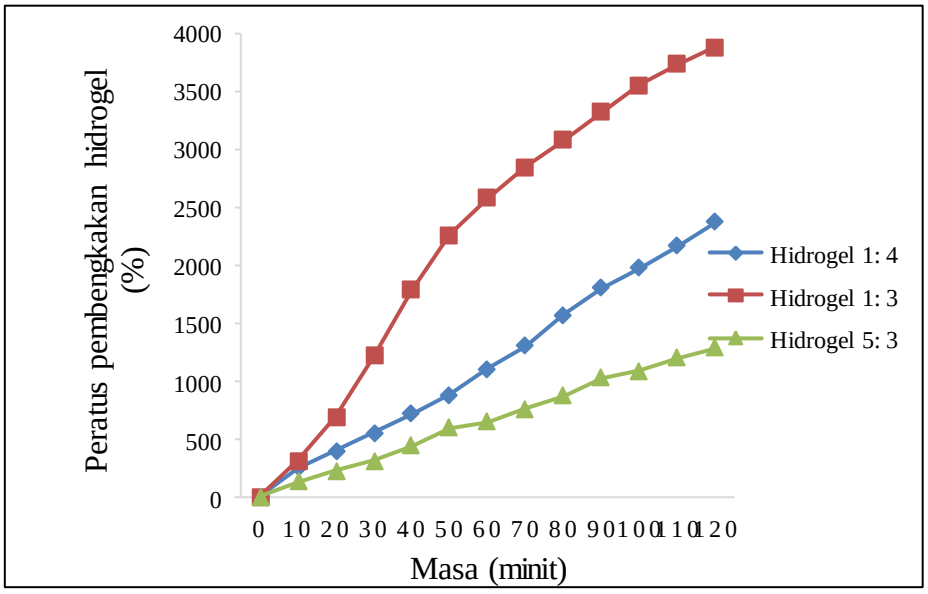
Rajah 3. Cadangan tindak balas penghasilan hidrogel

Mikroskopi Pengimbas Elektron (SEM)

Dalam kajian ini, 4 jenis sampel hidrogel dengan nisbah yang berbeza yang telah dikeringkan secara pengeringan sejuk-beku telah dianalisis menggunakan SEM. Pengimbasan semua sampel telah ditetapkan pada 1,000 kali gandaan pembesaran dan mikrograf yang diambil seperti ditunjukkan dalam Rajah 4.



Rajah 4. Mikrograf bagi hidrogel dengan nisbah (a) 0:3, (b) 1:4, (c) 1:3 dan (d) 5:3 pada kuasa pembesaran 1000x

Perbandingan di antara mikrograf bagi sampel hidrogel (a), (b), (d) dan (d) jelas menunjukkan bahawa hidrogel 0:3 (a) mempunyai permukaan yang licin dan tidak poros. Ini membuktikan bahawa penambahan kanji ke dalam formulasi hidrogel dapat meningkatkan keporosan jaringan pada hidrogel [12].

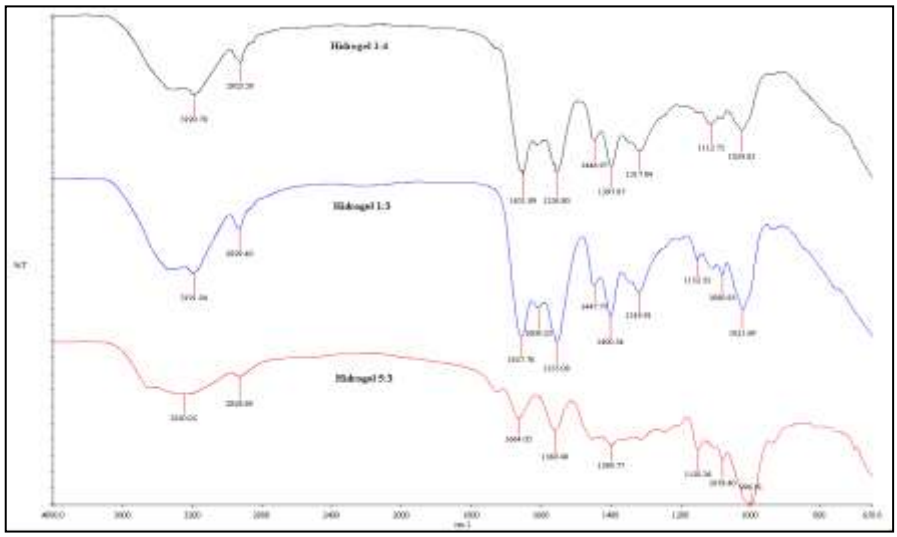
Hidrogel 5: 3 (d) dengan kandungan kanji yang paling tinggi mempunyai banyak liang yang bersaiz kecil (13 –19 μm). Fenomena ini berlaku kerana penambahan kanji mengisi ruang antara rangkaian dan memadatkan lagi rangkaian taut-silang dalam hidrogel [13]. Dalam kata lain, darjah taut-silang yang tinggi dan rangkaian hidrogel yang tumpat akan mempunyai saiz poros yang kecil dan menghadkan ruang di dalam jaringan hidrogel. Berdasarkan mikrograf (c) hidrogel 1:3 mempunyai saiz liang yang lebih besar berbanding liang (d) hidrogel 1:4. Julat saiz bagi hidrogel 1:4 dan hidrogel 1: 3 adalah masing-masing di antara 11 – 22μm dan 10 – 26 μm.

Ujian pengembangan hidrogel

Berdasarkan kepada keputusan ujian pembengkakan yang ditunjukkan pada Rajah 5, hidrogel 1:3 mempunyai peratus pembengkakan paling tinggi iaitu 3881 % diikuti dengan hidrogel 1:4 sebanyak 2373 % dan seterusnya hidrogel 5:3 yang mencatatkan peratus pembengkakan paling rendah iaitu 1285 %.

Rajah 5. Graf peratus nisbah pengembangan hidrogel (%) bagi hidrogel 1:4, 1:3 dan 5:3 selama 2 jam

Hidrogel dengan kandungan kanji yang banyak akan meningkatkan sifat kebolehbasahan, sifat hidrofilik dan darjah pembengkakan [14]. Namun, darjah pembengkakan hidrogel bukan sahaja bergantung pada keadaan hidrogel dan media pembengkakan tetapi ia juga amat bergantung pada ketumpatan taut-silang hidrogel dan kepekatan bahan campur adun seperti kepekatan agen taut-silang dan kepekatan monomer [15].

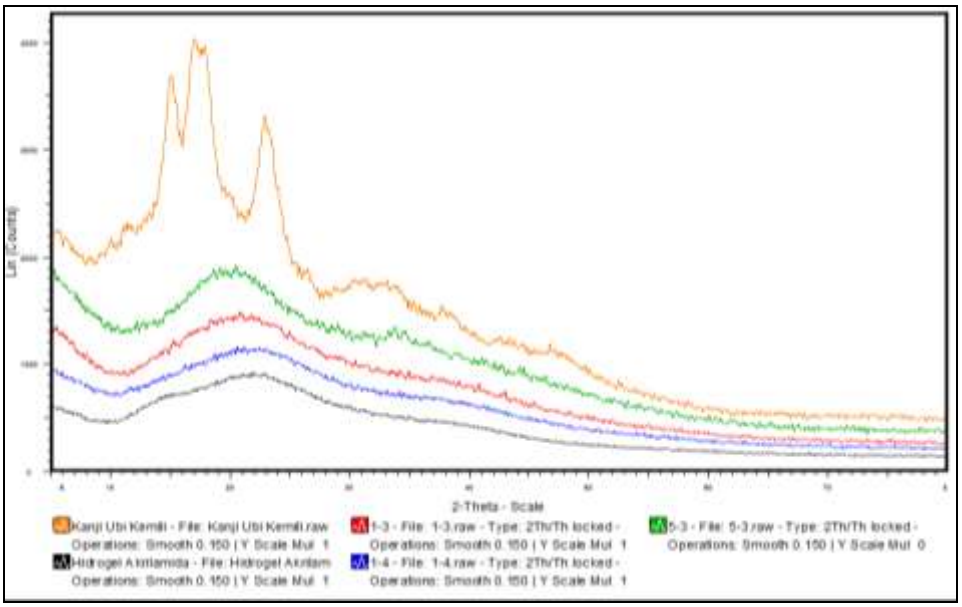


Dapat diperhatikan pada Rajah 5, hidrogel dengan kandungan kanji yang paling tinggi, 5: 3 mempunyai peratus pembengkakan yang paling rendah. Kandungan kanji yang tinggi dalam hidrogel mengakibatkan rangkaian hidrogel menjadi semakin tumpat. Ini menghadkan ruang di dalam jaringan hidrogel untuk mengembang [13]. Ruang yang terhadap ini secara langsung telah menghalang monomer AAm ataupun kanji untuk mengikat molekul air melalui ikatan hidrogen [15].

Hidrogel 1:4 pula mempunyai nisbah pembengkakan yang lebih rendah berbanding hidrogel 1:3. Hal ini berkaitan rapat dengan jumlah kepekatan komposisi campur-adun. Membandingkan hidrogel 1:3 dan 1:4, hidrogel 1:4 mempunyai kepekatan bahan campur-adun (kepekatanagen taut-silang, MBA dan monomer, AAm) yang lebih tinggi. Secara umumnya, agen taut-silang akan berada di antara rantai monomer untuk mentaut-silangkan rantai – rantai monomer tersebut. Maka, bilangan kumpulan hidrofilik yang tersedia untuk membentuk ikatan hidrogen dengan molekul air telah berkurang dan ini menyebabkan pembengkakan hidrogel 1:4 menjadi lebih rendah [16]. Selain itu, kepekatan monomer (AAm) yang lebih tinggi dalam hidrogel 1:4 memadatkan rangkaian polimer hidrogel dan air menjadi lebih sukar untuk meresap ke dalamnya [16]. Oleh itu, hidrogel 1:3 dengan jumlah kepekatan komposisi campur-adunyang lebih rendah mempunyai rangkaian yang tidak begitu padat. Rangkaian dengan ruang antaranya yang besar memudahkan pengikatan dengan molekul air berlaku dan peresapan air ke dalam rangkaian polimernya juga lebih mudah lalu nisbah pengembangan meningkat.

Analisis Spektrometer Inframerah Transformasi *Fourier*-Jumlah Pantulan Teratenuat (ATR-FTIR)

Rajah 6 menunjukkan spektrum ATR-FTIR bagi hidrogel yang disintesis dengan menggunakan nisbah kanji terhadap akrilamida yang berbeza. Puncak di antara 3400 – 3200 cm^{-1} terdapat pada ketiga – tiga spektrum yang mewakili kumpulan hidroksi pada kanji. Pempolimeran taut silang dikenal pasti telah berlaku berdasarkan kepada pembentukan ikatan C-O-C yang ditunjukkan pada frekuensi 1150 – 1100 cm^{-1}[17]. Puncak pada julat frekuensi

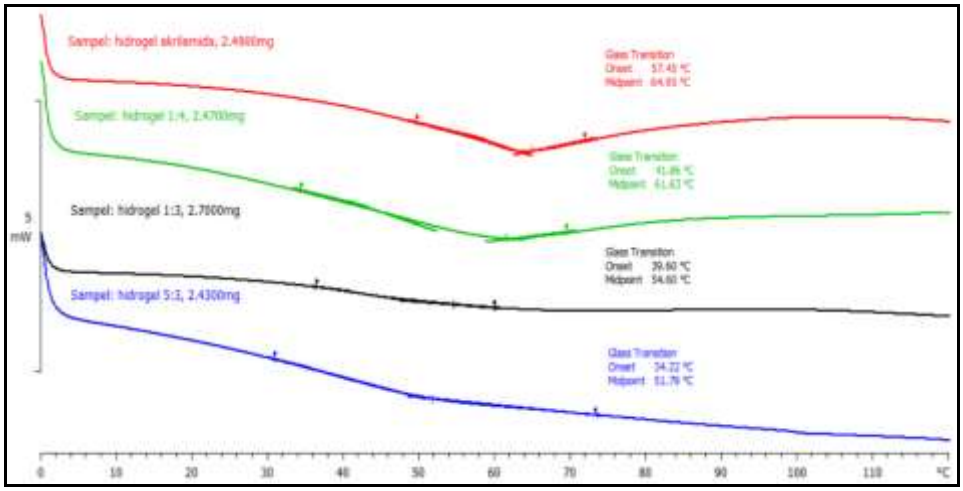


1000 – 800cm^{-1} juga telah hilang. Ini menandakan bahawa tindak balas pempolimeran antara kumpulan vinil pada monomer telah berlaku. [18].

Rajah 6. Perbandingan spektrum inframerah bagi hidrogel 1:4, hidrogel 1:3 dan hidrogel 5:3

Difraktometri Sinar-X (XRD)

Rajah 7 di bawah menunjukkan difraktogram pembelauan sinar-X bagi sampel kanji Ubi *Stemona curtisii*, hidrogel akrilamida dan hidrogel berkanji yang dihasil.



Rajah 7. Difraktogram pembelauan sinar-X sampel kanji, hidrogel akrilamida dan hidrogel berkanji yang dihasil

Berdasarkan Rajah 7, kanji Ubi *Stemona curtisi* menunjukkan sifat penghabluran dengan beberapa puncak keamatan yang tinggi pada belauan dengan skala 2θ 15˚, 17˚, 18˚ dan 23˚. Hal ini berlaku kerana disebabkan oleh kehadiran molekul berganda amilopektin di dalam struktur kanji yang boleh menghasilkan satu kawasan kristal jika molekul-molekul tersebut berada pada susunan selari antara satu sama lain manakala molekul amilosa hanya akan membentuk kelompok dan mewujudkan satu rantau tak berhablur yang membawa kepada sifat keamorfusan kanji [19, 20].

Berdasarkan kepada difraktogram pada Rajah 7, keempat-empat hidrogel menunjukkan sifat amorfus. Ini menunjukkan morfologi kanji telah berubah setelah proses pempolimeran/taut-silang untuk menghasilkan hidrogel berkanji. Puncak kanji yang tinggi pada belauan berskala 2θ 15˚, 17˚, 18˚ dan 23˚ tidak lagi wujud dalam difraktogram hidrogel. Menurut Bhattachary [21], hidrogel bersifat amorfus kerana taut silang dalam polimer hidrogel menghalang rangkaian daripada bersusun padat dalam orientasi berkala, rangkaian tidak dapat menggelongsor antara satu sama lain lalu tidak mempunyai sifat hablur tetapi menjana kekenyalan dalam hidrogel amorfus.

Kalorimeter Pengimbas Kebedaan (DSC)

Berdasarkan kepada Rajah 8 didapati bahawa setiap termogram sampel hanya terdapat nilai tunggal suhu peralihan kaca. Ini telah jelas menunjukkan bahawa semua bahan campur-adun yang digunakan untuk sintesis hidrogel adalah pada tahap kebolehcampuran yang baik. Menurut Diab [22] sistem polimer hidrogel yang terlarut campur dengan baik menunjukkan suhu peralihan kaca yang tunggal manakala jika suatu sistem itu tidak serasi akan mempunyai beberapa suhu peralihan kaca secara terasing yang mewakili setiap komponen dalam polimer hidrogel.

Rajah 8. Gabungan termogram DSC bagi hidrogel 0:3, hidrogel 1:4, hidrogel 1:3 dan hidrogel 5:3.

Jadual 3 menunjukkan suhu peralihan kaca bagi keempat-empat jenis hidrogel yang telah disintesis. Keputusan menunjukkan hidrogel kosong (0:3) mempunyai nilai T_g yang paling tinggi dan diikuti oleh hidrogel 1:4 (mempunyai kandungan kanji yang paling rendah), 1:3 (mempunyai kandungan kanji yang sederhana) dan 5:3 (mempunyai kandungan kanji yang paling tinggi). Ini telah menunjukkan bahawa kepekatan kandungan kanji mempengaruhi nilai T_g hidrogel yang dihasil. Semakin banyak kanji yang ditambahkan ke dalam sintesis hidrogel, semakin rendah nilai T_g hidrogel itu. Penurunan nilai T_g hidrogel ini berlaku disebabkan molekul air cenderung untuk mengikat pada molekul kanji dan menyebabkannya berfungsi sebagai pemplastik, maka hidrogel dengan kandungan kanji yang lebih tinggi akan mengalami penurunan nilai T_g akibat peningkatan sifat pemplastikan [17]. Hidrogel kosong pula mempunyai nilai T_g yang paling tinggi kerana ia tidak mempunyai kanji. Ketidakhadiran kanji menyebabkannya kurang sifat plastik dan mempamerkan nilai T_g yang lebih tinggi.

Kajian turut mencatatkan peningkatan penambahan monomer akrilamida dalam sintesis hidrogel meningkatkan nilai T_g hidrogel. Ini jelas dilihat daripada nilai T_g hidrogel 1:4 yang dihasil daripada paling banyak monomer adalah paling tinggi iaitu pada 65.0 ˚C. Peningkatan penambahan monomer (akrilamida) dapat meningkatkan nilai suhu T_g polimer hidrogel kerana ia menguatkan ikatan hidrogen antara rangkaian polimer lalu dapat menstabilkan polimer hidrogel [23]. Keputusan yang sama telah diperolehi oleh Painter [24] di mana mereka turut mencadangkan sifat ini sering dijumpai dalam adunan hidrogel kerana interaksi ikatan hidrogen.

Jadual 3. Suhu peralihan kaca bagi hidrogel yang berbeza komposisi bahan mula

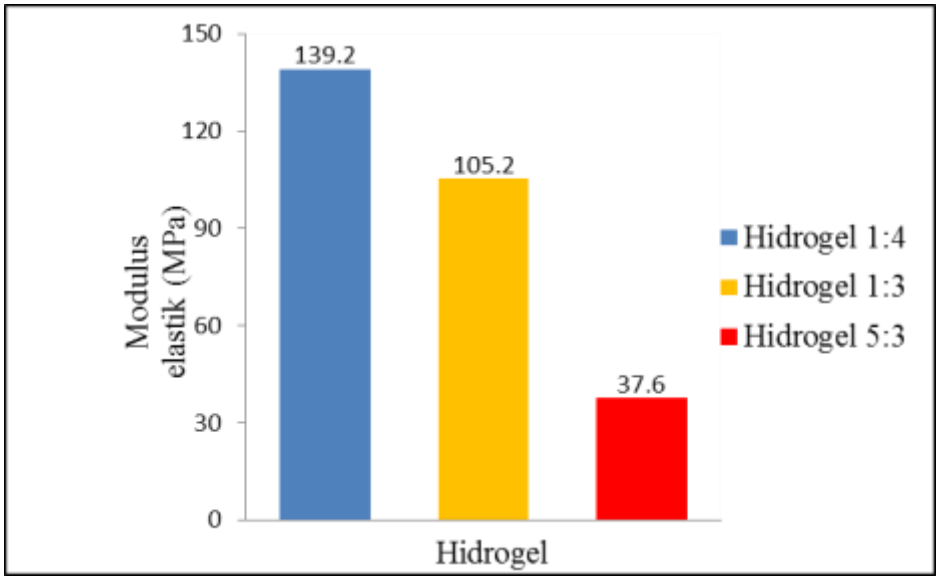
Warna Termogram DSC	**Sampel**	**Suhu peralihan kaca hidrogel (˚C)**
Merah	Hidrogel 0 : 3	65.0
Hijau	Hidrogel 1 : 4	61.6
Hitam	Hidrogel 1 : 3	54.6
Biru	Hidrogel 5 : 3	51.8

Analisis Termogravimetrik (TGA)

Dalam kajian ini, analisis TGA dijalankan untuk mengetahui kestabilan/ketahanan hidrogel berasaskan kanji daripada Ubi *Stemona curtisii* terhadap haba. Data berkaitan dengan nilai peratus kehilangan jisim pada setiap peringkat, jumlah peratus kehilangan jisim dan peratus jisim yang masih ada pada suhu 600 ˚C dalam kanji Ubi *Stemona curtisii* dan setiap hidrogel yang disintesis telah disenaraikan dalam Jadual 4.

Jadual 4. Nilai peratus kehilangan jisim pada setiap peringkat, peratus kehilangan jisim maksima dan peratus jisim baki dalam kanji Ubi *Stemona curtisii* dan setiap hidrogel yang disintesis.

Sampel	**Peratus Kehilangan Jisim (%)**			**Peratus Kehilangan Jisim Maksima (%)**	**Peratus Jisim Baki (%)**
	Peringkat pertama (0 - 250 ˚C)	**Peringkat kedua (280 - 450 ˚C)**	**Peringkat ketiga (450 - 600 ˚C)**		
Kanji	10	76	-	-	-
Hidrogel 0: 3	9	59	11	79	21
Hidrogel 1: 4	7	44	23	74	26
Hidrogel 1: 3	7	47	18	72	28
Hidrogel 5: 3	12	38	19	69	31



Peringkat pertama kehilangan jisim yang berlaku pada sekitar 0 – 250 ˚C boleh dikaitkan dengan penyejatan air yang terjerap secara fizikal atau kimia dalam semua sampel manakala peringkat penguraian yang lain adalah disebabkan oleh penguraian terma sampel [13, 25]. Secara keseluruhannya, semua hidrogel dengan kehadiran kanji mengalami peratus kehilangan jisim yang lebih rendah berbanding dengan hidrogel kosong. Hal ini kerana dalam hidrogel berkanji,atom hidrogen daripada kumpulan hidroksi primer dalam molekul kanji telah digantikan oleh monomer semasa perpautan-silang.Taut-silang antara monomer dan molekul kanji Ubi *Stemona curtisii* menghasilkan ikatan baru dan ikatan inilah yang menyebabkan hidrogel berkanji lebih stabil terhadap haba [17, 26].

Daripada keputusan kajian juga boleh dilihat hidrogel yang mempunyai lebih banyak kanji adalah lebih tahan haba dan mengalami peratus kehilangan jisim maksima yang lebih rendah. Hidrogel 5:3 (kandungan kanji paling tinggi) mempunyai jisim sampel yang paling tinggi pada suhu 600 ˚C diikuti oleh hidrogel 1:3 (kandungan kanji yang sederhana) dan hidrogel 1:4 (kandungan kanji paling rendah).Peratus jisim baki sampel-sampel tersebut pada suhu 600 ˚C adalah masing-masing 31, 28 dan 26 %. Kandungan kanji yang tinggi dalam hidrogel 5:3 menyebabkan rangkaiannya menjadi sangat padat dan mempunyai lebih banyak amilopektin (struktur rantai bercabang). Kandungan amilopektin mendorong kepada ketahanan sampel hidrogel terhadap haba kerana penguraiannya memerlukan suhu yang lebih tinggi berbanding rantai linear (amilosa) [17, 27].

Selain itu, tahap kestabilan/ketahanan sesuatu sampel terhadap haba juga berkait rapat dengan tahap penghabluran sampel itu. Peningkatan kandungan kanji dalam suatu sampel meningkatkan tahap penghabluran sampel dan meningkatkan tahap ketahanan sampel tersebut terhadap haba [28]. Oleh itu,semua hidrogel yang mempunyai kanji akan menunjukkan tahap ketahanan terhadap haba yang lebih tinggi berbanding hidrogel kosong [26].

Ujian tegangan hidrogel

Rajah 9 di bawah menunjukkan graf bar modulus elastik bagi setiap nisbah hydrogel yang telah disintesis. Berdasarkan Rajah 4.9, hidrogel 1:4 yang mempunyai kandungan kanji paling rendah telah menunjukkan nilai modulus elastik yang paling tinggi dan dikuti oleh hidrogel 1:3. Hidrogel 5:3 yang mengandungi berat kanji paling tinggi pula menunjukkan nilai modulus elastik dan tegasan tegangan yang paling rendah. Keputusan kajian menunjukkan tahap kekenyalan hidrogel menurun akibat peningkatan kandungan kanji (bahan asas) yang ditambah dalam sintesis hidrogel. Hal ini kerana penambahan kanji dalam hidrogel akrilamida menyebabkan sampel hidrogel itu menjadi lebih tegar. Hidrogel yang tegar menjejaskan kestabilan proses pemanjangannya kerana hidrogel yang tegar ini tidak akan terus memanjang untuk satu tempoh yang lama tetapi ia mudah putus. Maka, hidrogel yang mudah putus ini tidak bersifat elastik dan akan mempunyai nilai *Young's* modulus yang rendah [12]. Keputusan yang sama telah dilaporkan oleh [27]

Rajah 9. Graf bar modulus elastik bagi hidrogel dengan nisbah kanji : akrilamida 1 : 4, 1 : 3, 5 : 3.

Walau bagaimanapun, hidrogel berasaskan kanji daripada Ubi *Stemona curtisii* ini mempunyai potensi untuk diaplikasikan sebagai pembalut luka. Menurut laporan Gallagherdan [30] nilai kegagalan tegangan kulit adalah 34 MPa. Semua nilai modulus elastik hidrogel yang dihasilkan dalam kajian ini adalah lebih tinggi daripada nilai

kegagalan tegangan kulit. Oleh itu, hidrogel yang dihasilkan ini boleh digunakan untuk meliputi luka kerana tahap kekenyalannya yang tinggi boleh menahan tegasan geseran yang dan dapat menyerap tenaga tanpa pecah dan memberi kesan perlindungan terhadap luka [31].

Kesimpulan

Kajian yang dilakukan ini telah berjaya menghasilkan hidrogel berasaskan-kanji Ubi *Stemona curtisii* dengan menggunakan gelombang mikro. Penggunaan gelombang mikro membolehkan tindak balas berlaku pada kehadiran kepekatan bahan pemula yang lebih rendah dan lebih menjimatkan masa sintesis. Justeru, penghasilan hidrogel menggunakan kaedah gelombang mikro ini dilihat dapat dikomersilkan terutamanya di dalama bidang biobahan.

Penghargaan

Penulis ingin mengucapkan setinggi – tinggi penghargaan dan terima kasih kepada kakitangan makmal di Jabatan Kimia, Fakulti Sains dan Teknologi serta Universiti Kebangsaan Malaysia (FRGS/1/2014/ST01/UKM/03/1 dan PRGS/1/2014/TK04/UKM/03/1) di atas sokongan, bantuan dan bimbingan sepanjang tempoh kerja makmal dijalankan.

Abstract

2,4-dichlorophenoxyacetic acid (2,4-D) is a common herbicide that has been used widely. Due to its excessive usage, the 2,4-D herbicides can cause contamination over agricultural land and water bodies. In the present work, a simple impregnation method was used to modify the commercial titanium dioxide (P25 TiO_2) nanoparticles with the copper oxide. The prepared samples were characterized by X-ray Diffraction (XRD), reflectance UV-visible and fluorescence spectroscopies. It was observed that the incorporation of copper oxide did not significantly affect the crystal structure of P25 TiO_2. On the other hand, the presence of copper oxide was confirmed by reflectance UV-visible and fluorescence spectroscopies. The activity of the prepared sample was evaluated for photocatalytic removal of the 2,4-D. The photocatalytic activity of the TiO_2 increased with the increase of copper oxide loading up to 0.5 mol%. Unfortunately, the higher loading amount of copper oxide resulted in the lower photocatalytic activity. This study suggested that the higher photocatalytic activities obtained on the low loading samples were due to the lower electron-hole recombination.

Keywords: P25 TiO_2, copper oxide, impregnation, photocatalyst, 2,4-D herbicide

Abstrak

Asid 2,4-diklorofenoksiasetik (2,4-D) adalah herbisid biasa yang telah digunakan secara meluas. Oleh kerana penggunaan yang berlebihan, herbisid 2,4-D boleh menyebabkan pencemaran di kawasan pertanian dan sistem air. Dalam kajian ini, satu kaedah pengisitepuan yang mudah telah digunakan untuk mengubahsuai nanozarah titanium dioksida komersial (P25 TiO_2) dengan kuprum oksida. Sampel yang disediakan telah dicirikan dengan XRD, spektroskopi pantulan serakan ultra lembayung-cahaya nampak, dan spektroskopi pendarfluor. Didapati pengubahsuaian P25 TiO_2 dengan kuprum oksida tidak memberi kesan yang signifikan kepada struktur kristal P25 TiO_2. Sebaliknya, kehadiran kuprum oksida telah disahkan oleh spektroskopi pantulan serakan ultra lembayung-cahaya nampak. Aktiviti sampel telah diuji untuk penyingkiran 2,4-D. Aktiviti fotomangkin TiO_2 meningkat dengan peningkatan jumlah kuprum oksida kepada 0.5 mol%. Malangnya, jumlah kuprum oksida yang lebih tinggi menghasilkan aktiviti fotomangkin yang lebih rendah. Kajian ini mencadangkan bahawa aktiviti fotomangkin yang tinggi diperolehi pada sampel loading rendah adalah disebabkan oleh penggabungan elektron-lubang yang lebih rendah

Kata kunci: P25 TiO_2, kuprum oksida, pengisitepuan, fotomangkin, 2,4-D herbisid

Introduction

The 2,4-dichlorophenoxyacetic acid (2,4-D) is one of the most used herbicides in the world and has been used since the 1940s. The 2,4-D is used widely to control broadleaf weeds in a variety of settings from crops, rights-of-way, lawns, forests to aquatic settings. In 1986, the International Agency for Cancer Research (IARC) classified the chlorophenoxy herbicides as a Group 2B (possible) carcinogen. Since then, various studies have been done on the toxicity and carcinogenicity of the 2,4-D. Recently, the 2,4-D epidemiology literature has been qualitatively reviewed [1]. Even though no convincing evidence for any chronic adverse effect of 2,4-D in human, studies in the removals of the 2,4-D in order to prevent the negative effects of the 2,4-D towards human and environment are still in progress.

One of the simple methods to remove the 2,4-D from water is by adsorption process. Some adsorbents have been reported to give good performance to adsorb the 2,4-D, such as the layered double hydroxides (LDH) [2 –5] and mesoporous materials [6] due to the large surface area, high anion capacity, and good thermal stability. However, rather than removing the 2,4-D by an adsorption process, degradation of the 2,4-D would be a great advantage to solve the environment problems. Degradation of the 2,4-D could be achieved by introducing the electrochemical assistance to a micobiological reduction system [7], and photooxidation via Fenton reaction and in the presence of strong oxidant such as hydrogen peroxide [8]. However, from the point of view of sustainability and environmentally safe process, photocatalytic reaction would be the promising method to degrade the 2,4-D herbicide [9 – 13]. Some studies also reported the combined method to degrade 2,4-D by the photocatalytic reactions with the use of strong oxidants and microwave [9, 10].

In general, photocatalytic removal of environmental pollutants has been a topic of great interest over the years [14]. One of the most widely used materials for photocatalytic degradation of environmental pollutants is titanium dioxide (TiO_2). As a photocatalyst, TiO_2 has a range of useful features, including high photocatalytic activity, stability, low toxicity, ready availability and low cost [15]. While TiO_2 is one of the most active catalysts for the degradation of a wide range of organic compounds, its catalytic activity should be further improved. Hence, there have been a great number of studies to modify the TiO_2 based photocatalysts. It has been reported that the TiO_2 bound with TiO_2 sol with the help of polymeric bonds showed better photocatalytic activity for degradation of 2,4-D than the unmodified TiO_2, owing to the better distributions of photons [11]. Another study reported that the addition of reduced graphene oxide and $CuInS_2$ on the TiO_2 improved its activity for degradation of the 2,4-D [12]. The addition of Ag/reduced graphene oxide was also reported increasing the activity of TiO_2 for the 2,4-D degradation [13]. The improved activity was closely related to the effective carriers separation and large adsorption capacity for the 2,4-D [12, 13].

While several studies have been reported to modify TiO_2 with noble metals, transition metal oxides and non-metal ions [15-18], in particular, it has been shown that transition metal oxides such as copper oxide have the potential of enhancing the photocatalytic activity of TiO_2 [19 – 21]. When applied to TiO_2 on the optimal composition, phase and size, these transition metal oxide nanoparticles can act as effective co-catalysts that improve the efficiency of TiO_2 photocatalysis. In the present work, a simple impregnation method was used to grow copper oxide nanoparticles on the surface of commercial P25 TiO_2 particles. The amount of copper incorporated on the surface of the P25 TiO_2 particles was varied in the range of 0.1 to 5 mol%. The effect of Cu loading on the photocatalytic activity of TiO_2 to degrade the 2,4-D was investigated.

Materials and Methods

Preparation of photocatalysts

P25 TiO_2 (Evonik) and copper(II) nitrate trihydrate (Aldrich, 99 – 104%) were used as received without any treatments. The required amount of copper(II) nitrate trihydrate was dissolved into 20 ml of distilled water. Then, the P25 TiO_2 (1 g) was dispersed in the copper nitrate solution by sonicating the mixture for 10 minutes. Under vigorous stirring, the resultant mixture was heated at 80 °C until the solvent was removed. The dried mixture was ground to a fine powder and calcined at 500 °C for 4 hours. The resultant powder was ground and stored under ambient conditions. The samples were labeled as *x* mol% Cu/P25 TiO_2, with *x* showed the ratio of Cu to Ti (mol%) and varied in the range of 0.1 – 5 mol%. For comparison, the P25 TiO_2 was also treated in the same manner to the samples, except for the addition of the copper(II) nitrate trihydrate.

Characterizations

X-ray Diffraction (XRD, Bruker AXS Diffrac plus release 2000) was used to identify the structure of the prepared photocatalysts. The optical properties of the samples were analyzed by an Avantes spectrophotometer AvaSpec-ULS2048 using a reflection probe holder with angle of 45° and PTFE-coated white material as the reference sample. The emission spectra were measured at room temperature on a Fluorescence Spectroscopy JASCO FP-8500. The spectra were monitored at excitation wavelength of 218 nm. The morphology and particle size of the samples were investigated by a transmission electron microscopy (TEM, JEM-2100) at an accelerating voltage of 200 kV. The sample was dispersed well in ethanol and then, put on a carbon-coated copper grid.

Photocatalytic activity test

The prepared samples were evaluated for removal of 2,4-D at room temperature under UV light irradiation. Prior to the irradiation, the sample (50 mg) was dispersed in 2,4-D solution (50 mL, 0.5 mM) and stirred in the dark condition for 1 hour to achieve the adsorption-desorption equilibrium. The reaction was carried out for 1 hour under irradiation by a 200 W Xe-Hg lamp, which light intensity was 15 mW cm^{-2} and it was equipped with an IR cut off filter. The remaining amount of 2,4-D after each reaction was determined by UV-Visible spectrophotometer using a Thermo Scientific Genesys 10S. The monitored wavelength was 283 nm. The percentage of 2,4-D removal was then calculated from the ratio of concentrations between the reacted and the initial 2,4-D.

Results and Discussion

Properties of Cu/P25 TiO_2 samples

Figure 1 shows the XRD patterns of P25 TiO_2 and the prepared Cu/P25 TiO_2 samples. All samples showed the diffraction peaks at 2θ of 25.30 and 27.43°, corresponding to the (101) plane of anatase TiO_2 and (110) plane of rutile TiO_2, respectively. These XRD patterns clearly suggested the presence of both anatase and rutile phases in the samples. However, no appreciable diffraction peak of copper oxide phase was observed on all of the Cu/P25 TiO_2 samples. This was mostly likely due to the small amount of copper oxide present in the sample. In addition, a high degree of dispersion of copper oxide on the TiO_2 support would result in the small particle size of the metal oxide, which would be beyond the detection limit of XRD.

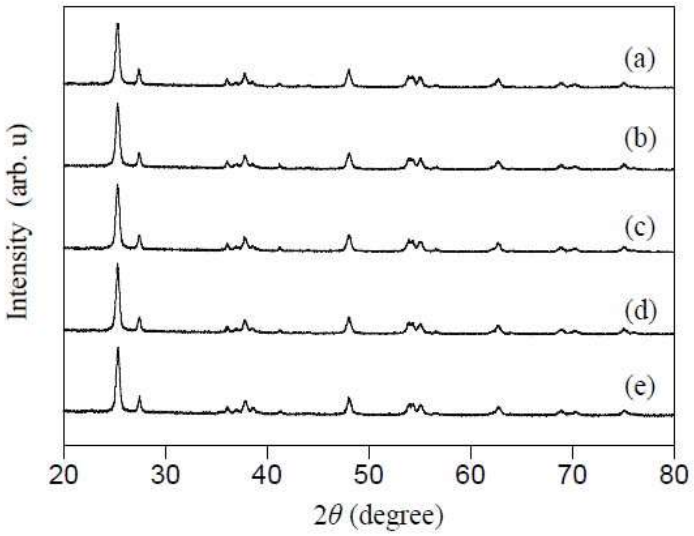

Figure 1. XRD patterns of (a) P25 TiO_2, (b) *0.1* mol% Cu/P25 TiO_2, (c) *0.5* mol% Cu/P25 TiO_2, (d) *1* mol% Cu/P25 TiO_2, and (e) *5* mol% Cu/P25 TiO_2 samples.

As shown in Figure 1, the XRD patterns of the Cu/P25 TiO_2 samples were very similar to that of the P25 TiO_2 sample. This result showed that the incorporation of copper oxide did not affect significantly the crystal structure of P25 TiO_2. Table 1 shows the crystallite size of anatase and the anatase to rutile ratio of the P25 TiO_2 and the prepared Cu/P25 TiO_2 samples. The crystallite size for anatase and rutile phase was determined by a Scherrer equation as shown in Equation 1, using the most intense peak of anatase (101) around 2θ of 25.3° and rutile (110) around 2θ of 27.4°, respectively.

$$t = \frac{K\lambda}{\beta\cos\theta} \tag{1}$$

where t is the average crystallite size in nm, while K is dimensionless shapes factor generally taken as 0.89, λ is the wavelength of the X-ray equals to 1.542 Å, β is full width at half maximum (FWHM) at 2θ of 25.3 or 27.4° and θ is Bragg's angle. The anatase to rutile ratio was also calculated based on the intensity of the most intense peaks at around 2θ of 25.3 and 27.4° for anatase (101) and rutile (110), respectively, as shown in Equation 2.

$$A(\%) = \frac{100 \times I_A}{I_A + 1.265 \times I_R} \tag{2}$$

where *A(%)* is the percentage of anatase, I_A and I_R correspond to the intensity of the anatase (101) and rutile (110) reflections, respectively.

As listed in Table 1, the crystallite size of P25 TiO_2 for both anatase and rutile phase was only slightly increased upon the addition of copper oxide. The average crystallite size for anatase phase was in the range of 17-21 nm, while for rutile phase was in the range of 60-72 nm. In addition, the anatase to rutile phase ratio of P25 TiO_2 likewise was not much affected by the incorporation of copper oxide. In order to support the crystallite size data, TEM images for the P25 TiO_2 and 0.5 mol% Cu/P25 TiO_2 are shown in Figure 2. The P25 TiO_2 showed irregular polyhedral shape nanoparticles (Fig. 2(a)). Most of the particles have size in the range of 15-25 nm due to the presence of anatase phase, while larger particles in the range of 50-70 nm were due to the presence of rutile phase. On the other hand, Figure 2(b) showed that no remarkable change in morphology and particle size could be observed on the 0.5 mol% Cu/P25 TiO_2. These results are in good agreement with the calculated average crystallite size from the XRD patterns shown in Table 1.

Table 1. Crystallite size and anatase to rutile ratio for P25 TiO_2 and Cu/P25 TiO_2 samples

Entry	Sample	Crystallite size (nm)[a]		Anatase to rutile ratio (%)[b]
		Anatase	Rutile	
1	P25 TiO_2	17.1	60.2	72:28
2	*0.1* mol% Cu/P25 TiO_2	18.1	67.8	74:26
3	0.5 mol% Cu/P25 TiO_2	18.5	71.9	74:26
4	*1* mol% Cu/P25 TiO_2	18.7	59.9	76:24
5	*5* mol% Cu/P25 TiO_2	20.3	62.0	74:26

[a]Estimated by the Scherrer equation shown in the Eq. 1.
[b]Estimated by the formula shown in the Eq. 2.

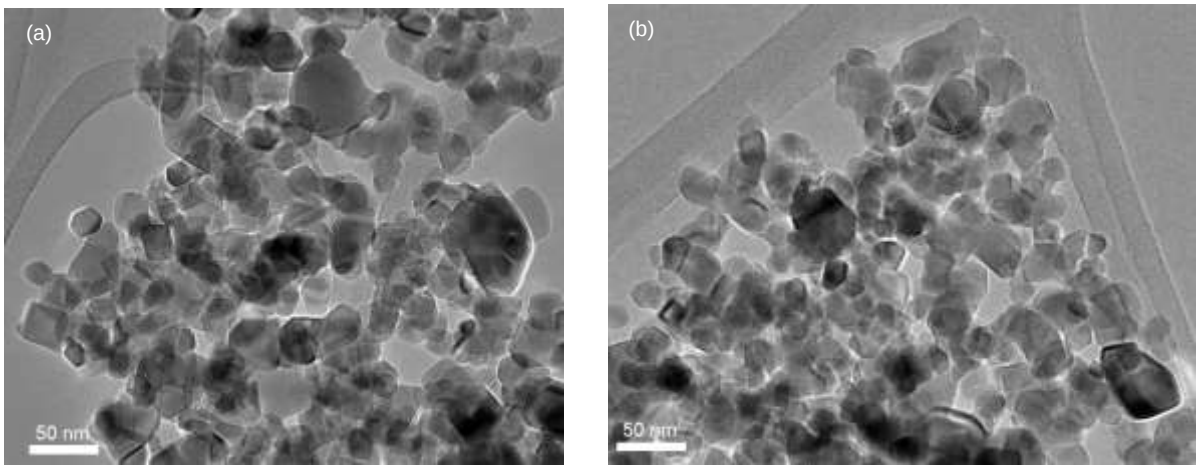

Figure 2. TEM images of (a) P25 TiO_2 and (b) *0.5* mol% Cu/P25 TiO_2 samples.

Figure 3 shows the reflectance UV-Vis absorption spectra of the P25 TiO_2 and Cu/P25 TiO_2 samples. The unmodified P25 TiO_2 sample has white colour as can be reflected in its UV-Vis absorption spectrum that displayed very low absorption intensity in the visible region of the spectrum (Fig. 3(a)). The addition of copper oxide resulted in the colour change from white to green. The colour became darker with the increase of the copper oxide loading. These changes could be observed in Figure 2, in which the Cu/P25 TiO_2 samples gave additional absorption in the visible light region and the absorbance increased with the increase of the copper oxide loading amount. The absorbance in the visible light region would be originated from the d-d transitions of the Cu^{2+} system [19], which were present on the surface of copper oxide modified TiO_2. While the Cu/P25 TiO_2 samples with low loadings of copper oxide did not much influence the band gap of the TiO_2, sample with high loading 5 mol% Cu/P25 TiO_2 slightly shifted the band edge absorption of P25 TiO_2 to longer wavelength. The shift indicated that some copper metal ions might alter the band gap of TiO_2 [16, 17].

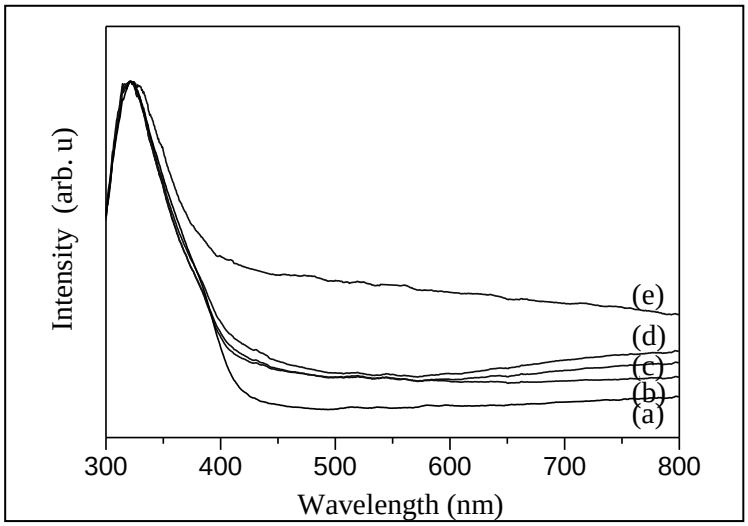

Figure 3. Normalized reflectance UV-Visible spectra of (a) P25 TiO_2, (b) *0.1* mol% Cu/P25 TiO_2, (c) *0.5* mol% Cu/P25 TiO_2, (d) *1* mol% Cu/P25 TiO_2, and (e) 5 mol% Cu/P25 TiO_2 samples

In order to study the interaction between the P25 TiO_2 and the copper oxide, the emission spectra of the samples were measured at the excitation of P25 TiO_2, which was at 218 nm. Figure 4 shows the emission spectra of P25 TiO_2 and the Cu/P25 TiO_2 samples. It was obvious that the emission intensity of P25 TiO_2 was reduced with the addition of copper oxide. The emission intensity was further reduced with the further increase of the copper oxide loading. This result clearly showed that there were interactions between P25 TiO_2 and the added copper oxide. Since emission intensity can be corresponded to the electron-hole recombination, the decreased emission intensity can be assigned to the suppression of electron-hole recombination.

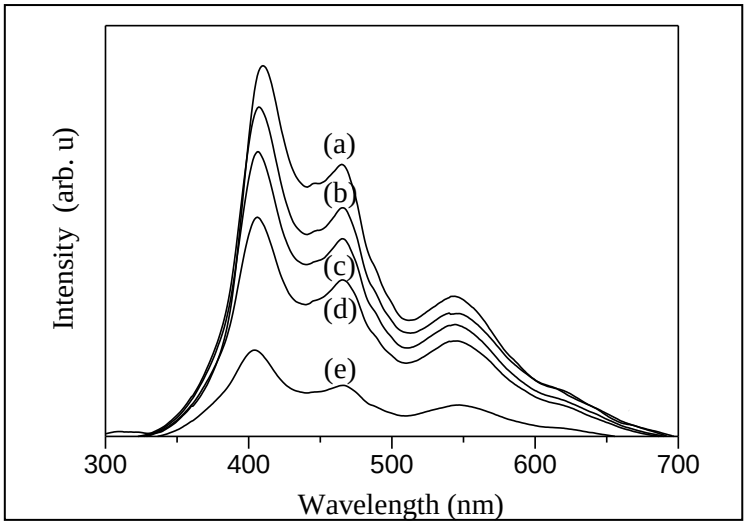

Figure 4. Emission spectra of (a) P25 TiO_2, (b) *0.1* mol% Cu/P25 TiO_2, (c) *0.5* mol% Cu/P25 TiO_2, (d) *1* mol% Cu/P25 TiO_2, and (e) *5* mol% Cu/P25 TiO_2 samples, monitored at excitation wavelength of 218 nm

As discussed previously, copper ions might alter the band gap energy of P25 TiO_2. Therefore, copper oxide might act as the co-catalyst to trap electron, thus enhancing the charge separation in the P25 TiO_2 that would lead to the enhanced activity. However, if the amount of copper oxide was too high, it would reduce the electrons in the conduction band of the P25 TiO_2 that might reduce the efficiency. Moreover, the large amount of copper oxide might also block the active sites of the P25 TiO_2 and reduce the photocatalytic activity. In other words, there would be an optimum amount of copper oxide that would give the optimum activity, which would be explained in the following part.

Photocatalytic activities of Cu/P25 TiO_2 samples

Figure 5 shows the photocatalytic removal of 2,4-D on the P25 TiO_2 and Cu/P25 TiO_2. It can be clearly shown that after 1 hour reaction, the photocatalytic activity of TiO_2 increased from 48.3 to 59.4 % with the increase of copper oxide loading up to 0.5 mol%. Unfortunately, the higher loading amount of copper oxide resulted in the lower photocatalytic activity. When the loading amount was 5 mol%, the activity decreased to 25.8 %. This result clearly suggested that the small amount of copper oxide, which was 0.5 mol%, was the optimum amount in this study to give the highest activity for the Cu/P25 TiO_2. The higher photocatalytic activity would be originated from the lower electron-hole recombination. On the other hand, the high loading amount of copper oxide might reduce the electrons in the conduction band of P25 TiO_2 or might block the active surface of P25 TiO_2, thus reduced the photocatalytic activity. Therefore, the optimum amount of copper oxide that would result in the optimum activity would be related to the optimum electron-hole separation, without reducing electrons in the conduction band of P25 TiO_2 and/or blocking active sites of the TiO_2. Similar results have been reported elsewhere [19 – 21]. The high amount of copper oxide may give masking effect on the P25 TiO_2, which prevented the UV light source to reach the active sites of TiO_2.

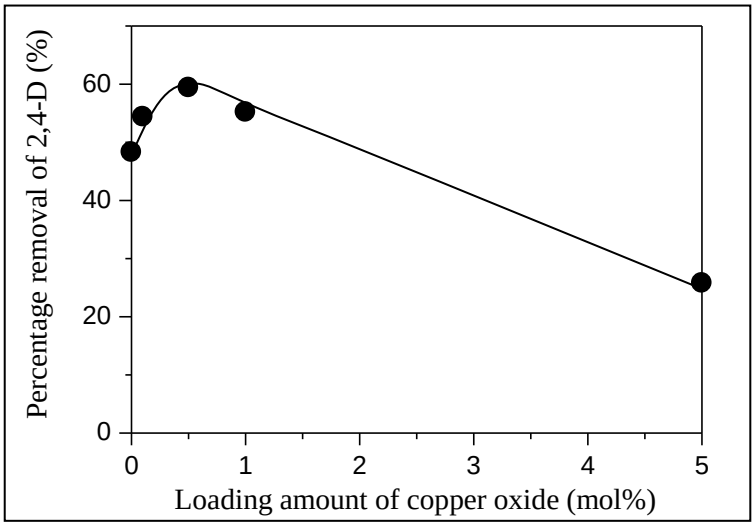

Figure 5. Photocatalytic removal of 2,4-D herbicide on the P25 TiO_2 and Cu/P25 TiO_2 samples.

Conclusion

The Cu/P25 TiO_2 samples were prepared successfully by an impregnation method. The addition of copper oxide did not much affect the crystallite size and the crystal phase of the P25 TiO_2. On the other hand, the addition of copper oxide increased the visible light absorption and slightly altered the band edge absorption of P25 TiO_2. Copper oxide also reduced the emission intensity, suggesting that optimum amount of copper oxide might act as good co-catalyst to trap electros, thus suppress the electron-hole recombination. The 0.5 mol% was found to be the optimum amount of copper oxide that enhance the activity of P25 TiO_2 for the photocatalytic removal of 2,4-D herbicide.

Abstract

The levels of metsulfuron methyl (methyl 2-(4-methoxy-6-methyl-1,3,5-trazine-2-ylcarbamoylsulfamoyl) benzoate (IUPAC) (MSM) and its metabolite IN-A4098 (4-methoxy-6-methyl-1,3,5-triazin-2-amine (AMMT) were determined from surface water samples of six rivers located at Tasik Chini, Pahang, Malaysia. The optimization analytical method was developed for the determination of the MSM herbicide and its metabolite, AMMT in surface water up to 0.05 ng/ml with good linearity in the calibration range 0.1 – 10 ng/ml. The procedure involves a clean-up process using the IST ISOLUTE ENV$^+$ solid phase extraction (SPE) method and the pesticide level are determined using the HPLC with variable wavelength detector (VWD) and 81 – 105 % recovery. The MSM compound represents one of main herbicides used in the Tasik Chini oil palm plantation. The method enables study to be made of the herbicide and its transformation products through simultaneous detection and quantification. In the field study levels of MSM in the surface water ranged from undetectable to 0.1378 ng/ml from the first season to forth season, while levels of the metabolite, AMMT ranged from undetectable to 1.473 ng/ml. The variation of the MSM and AMMT levels depended directly on the time of the pesticide application and the season.

Keywords: metsulfuron methyl, metabolite, solid phase extraction, Tasik Chini

Abstrak

Tahap pencemaran metsulfuron metil (metil 2-(4-metoksi-6-metil-1,3,5-triazin-2-ilkarbamoilsulfamoil) benzoat (IUPAC) (MSM) dan metabolit IN-A4098 (4-metoksi-6-metil-1,3,5-triazin-2-amina (AMMT) telah ditentukan daripada sampel air permukaan daripada enam batang sungai yang terletak di Tasik Chini, Pahang, Malaysia. Pengoptimuman kaedah analisis telah dibuat untuk menentukan kandungan herbisid MSM dan metabolitnya, AMMT dalam air permukaan dengan kepekatan minimum adalah 0.05 ng/ml dan julat kalibrasi adalah 0.1 – 10 ng/ml. Prosedur ini melibatkan satu proses pengekstrakkan menggunakan IST ISOLUTE ENV$^+$ kaedah pengekstrakan fasa pepejal (SPE) dan tahap herbisid ditentukan menggunakan HPLC dengan pengesan gelombang pelbagai (VWD) pada tahap perolehan semula adalah 81 – 105 %. Sebatian MSM merupakan salah satu daripada herbisid utama yang digunakan dalam ladang kelapa sawit Tasik Chini. Kaedah ini membolehkan herbisid dan metabolitnya dikesan dan dianalisis serentak. Di peringkat kajian lapangan, julat bacaan MSM dalam air permukaan adalah dari tidak dapat dikesan sehingga 0.1378 ng/ml dari musim pertama hingga musim keempat, manakala tahap pencemaran AMMT, yakni metabolitnya adalah dalam julat yang tidak dapat dikesan hingga 1.473 ng/ml. Tahap pencemaran MSM dan AMMT bergantung secara langsung kepada masa penyemburan herbisid dan musim kawasan tersebut.

Introduction

Sulfonylurea herbicides are widely used in agriculture by reason of their low application rates, good crop selectivity and very low animal toxicity [1]. One of the common sulfonylurea herbicides used in oil palm plantations is metsulfuron methyl (MSM) which is often sprayed with glyphosate. MSM is particularly effective on some annual and perennial broad-leaved species and can be degraded by microbes into 4-methoxy-6-methyl-1,3,5-triazin-2-amine (AMMT). It is a selective, translocated herbicide that is mainly absorbed through leaves. Its main uses are for broad-leaved weed control in oil palm plantations in Malaysia, as a tank mix with glyphosate for pre-plant weed control and for the control of perennial weeds. Metsulfuron methyl acts on the plants, ALS enzyme (not present in animals) and this is the main reason for its low toxicity to mammals, birds and fish [2].

Pollution of surface water with metsulfuron methyl can occur when the pesticide is sprayed during the rainy season, at hilly areas, consisting of impermeable soil such as clay soil, or soil with low organic content and high pH [3, 4]. The indigenous tribes in Tasik Chini are still consuming the surface water of the lake for bathing and fishing, and some of the populations are using groundwater for their daily needs. Thus, it is important to monitor the level of pesticide in the lake (Tasik Chini) before it endangers human and aquatic lives. Contamination of groundwater can occur if the soil is sandy loam type because MSM is highly soluble in water, with log K_{ow} at 1.8 and 0.018 for pH5 and pH7 respectively (water solubility of MSM pesticide is pH dependent) [5]. It is not hazardous to the environment as its usage rate is low, it has low toxicity and degradation in the field is rapid. However, there are studies that contradict its low toxicity effects, whereby concerns arise with regard to the possibility of environmental contamination, mainly regarding the leaching potential into the ground water system [6, 7]. Besides, due to its high solubility in water there is a need to monitor and compare the level of metsulfuron methyl sprayed in the oil palm plantation area at different seasons (rainy and dry). No specific maximum residue limit (MRL) has been established; therefore a default MRL of 0.1mg/L applies to food [3]. Conversion of the sulphonylurea herbicide group has been studied [8] and initial cleavage of the sulphonylurea bridge has been identified as the main transformation reaction. The primary degradation occurs with DT_{50} in 81-148 days [8], whereby, the products subsequent from the cleavage (of metsulfuron-methyl) is include, 4-methoxy-6-methyl-1,3,5-triazin-2-amine (AMMT).

Recent years, many alternative techniques have been explored and established, these include using capillary electrophoresis, gas chromatography and liquid chromatography [10, 11, 12, 13] to extract metsulfuron methyl and its metabolite. Solid phase extraction (SPE) is the preferred method for environmental samples instead of liquid-liquid extraction due to its simple operation. A few studies on SPE type comparison have been conducted to select the SPE type that is suitable for sulfonylurea herbicide extraction. For the present study IST ISOLUTE ENV$^+$ cartridge was used. The quantification of extracted MSM and AMMT was detected by a high performance liquid chromatograph (HPLC) equipped with a variable wavelength detector. Liquid chromatography procedure used as the routine method in the laboratory was adapted from previous research [15].

Materials and Methods

Study Area

Tasik Chini is located at the south eastern region of the state of Pahang, Malaysia and approximately 100 km from Kuantan, the capital of Pahang. The Tasik Chini lake system lies between 3°22´30" to 3°28´00" N and 102°52´40" to 102°58´10" E and comprises 12 open water bodies that are referred to as "laut" by the local people. There are a few groups of the indigenous Jakun tribe that live around the lake. Tasik Chini is the second largest natural fresh-water lake in Malaysia (after Tasik Bera). It covers 202 hectares of open water and 700 hectares of riparian, peat, hill and lowland Dipterocarp forests. There are three hilly areas surrounding the lake, namely Bukit Ketaya (209 m) in the southeast, Bukit Tebakang (210 m) at the north and Bukit Chini (641 m) located southwest. The study area has a humid tropical climate with two monsoon seasons, characterized by the following bimodal pattern: southwest and northeast monsoons bringing rainfall which varies from 1488 to 3071 mm annually. The mean annual rainfall is 2500 mm and the temperature range is from 21 to 32 °C. The lake drains northeasterly into the Pahang River through the Chini River, which flows for 4.8 km before it reaches the Pahang River. Sampling sites were selected according to land use and are shown in Figure 2.

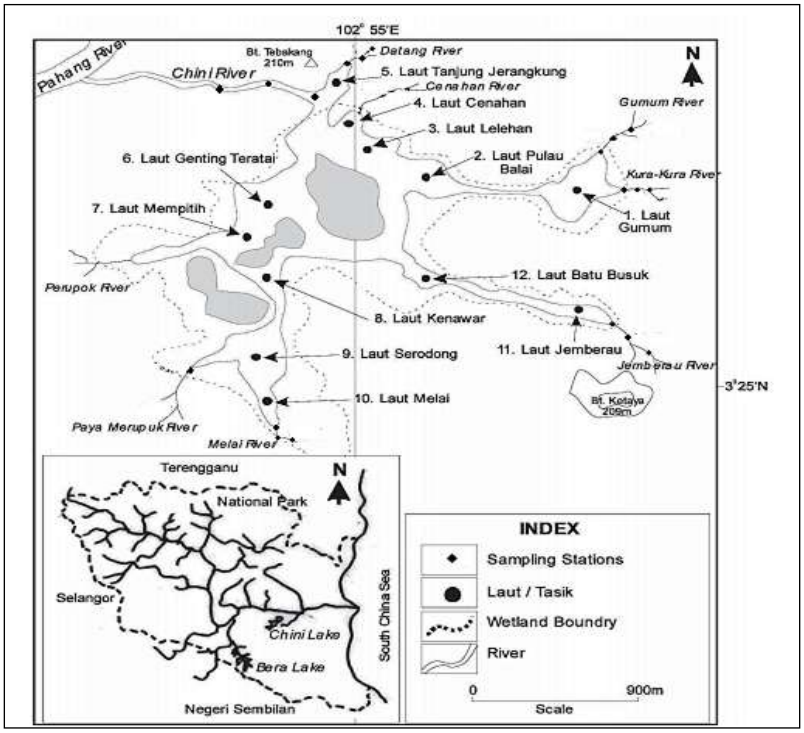

Figure 2. Map of the region: studied area and sampling sites

Sampling

Application of 150 gram/hectare MSM was applied on 15/12/2011, 14/03/2012, 13/06/2012 and 12/09/2012 to an individual oil palm plantation area near (20 meters) Sungai Jemberau (with the permission of the oil palm plantation owner and other pesticide applications were controlled). Herbicide application dates were decided by the researcher. The method of application involved spraying of the formulation using a backpack sprayer. Samples were taken one day after the MSM spraying and sampling details are as shown in Table 1 and Table 2 respectively. Water samples were taken from each sampling sites in accordance to standard methodology [12]. Samples were stored at glass containers in pH 5 – 6 (adjusted) for not more than one week at -4°C prior to analyses.

Reagents

All reagents and solvents used in the study were of HPLC grade. The MSM was purchased from Sigma Aldrich and the AMMT was purchased from Dr. Ehrenstorfer GmbH. The ultra-pure water was produced using of a sartorius water purification system (Sartorius, Germany). All calibration stock solutions of MSM and AMMT (500 mg/L) were prepared in methanol and stored at 4 ^{o}C for not more than six months. Working standards were prepared in methanol and used by the addition of the standard to samples for the recovery test and stored at 4 ^{o}C for less than one week. Each sample was analysed three times. Good linearity was obtained for the every signal for MSM and AMMT if no interfering pollutant was present.

Table 1. Identification of sampling time

Sampling Season	Sampling date	Description
M1	16/12/2011	Rainy season
M2	15/03/2012	Rainy season
M3	14/06/2012	Regular raining
M4	13/09/2012	Dry season

Instrumentation and chromatographic conditions

Liquid chromatographic analysis was performed with an Agilent 1220 Infinity LC System (Agilent, US) equipped with a dual plunger in series pump with proprietary servo-controlled variable stroke drive, an automatic injector,

and a variable wavelength detector (VWD). The Agilent 1220 instrument was controlled by computer (OpenLab Chemstation Edition software); data from the VWD was collected and evaluated by use of the same station after transfer via an analog-to-digital converter.

Separations were performed on a 150 mm, 4.6 x 150, 3.5 µm, Zorbax Eclipse XDB-C18 column (Agilent, USA), 3.5 µm internal diameter packed with high purity silica; The mobile phase was (A) methanol: acetonitrile: acetic acid = 50:50:0.01% and (B) 0.005 M phosphate buffers: acetic acid = 100:0.01% with adjusted pH to 2.5. Separation compound was achieved in a gradient condition, 15% B linear for 1.5minutes, increased to 60% B in 5.5 minutes, linear 60% B for 8 minutes, then returned to 15% B in 3 minutes. The column temperature was controlled at 40°C (sharpness of the compound peaks are better compared to uncontrolled temperature) and the volume of the sample injected was 20 µL. Variable wavelength detection, 200 nm, was used to monitor the products. A post-run period of 5 minutes was used for stabilisation. A total of 25 minutes of analysis was needed.

Sample Preparation and Clean-up Process

Water samples (1 liter) were collected in amber glass bottles and stored at -4ºC for a short term storage. After thawing, samples were filtered through a 0.45-µm nylon membrane filter and the filtrate was adjusted to pH 5 – 6 by addition of dilute hydrochloric acid (0.136 M). Samples were placed in ultrasonic bath for 15 minutes before the clean-up process. The targeted herbicide and its metabolite (MSM AND AMMT) were extracted by pulling the sample through a reverse-phase solid phase extraction (SPE) cartridge (ENV^{+} cartridge). Before pulling the sample through the cartridge, the cartridge was rinsed with 3ml of acetonitrile and 3 ml of water to reduce residual acidity within the cartridge, and then dried to remove any residual water. The analytes were eluted off the SPE cartridge using 8 ml of methanol. The resulting elute was evaporated near to dryness exactly at 1 ml. This final extract was filtered through a 0.20 µm membrane filter, and submitted for analysis.

Results and Discussion

The method optimised for detection of MSM and AMMT in water samples showed the following parameters: level of detection for water sample was 5µg/L for MSM and 1µg/L for AMMT with a good linearity in the standard addition calibration range 1 – 50 µg/L (r^2 = 0.998 – 0.999). Retention time for MSM was 3.176 minutes and for AMMT 10.721 minutes (Figure 3). Recovery rates of 83-110% were obtained for MSM and AMMT in water of pH 5.26. Figure 6 shows the recovery of 3 mg/L obtained for the pH range of 2.38 – 10.27. Using the gradient method, it was possible to perform simultaneous analysis for the herbicide (MSM) and its metabolites (AMMT). Thus, using the methods presented, it was possible to screen both MSM and AMMT simultaneously.

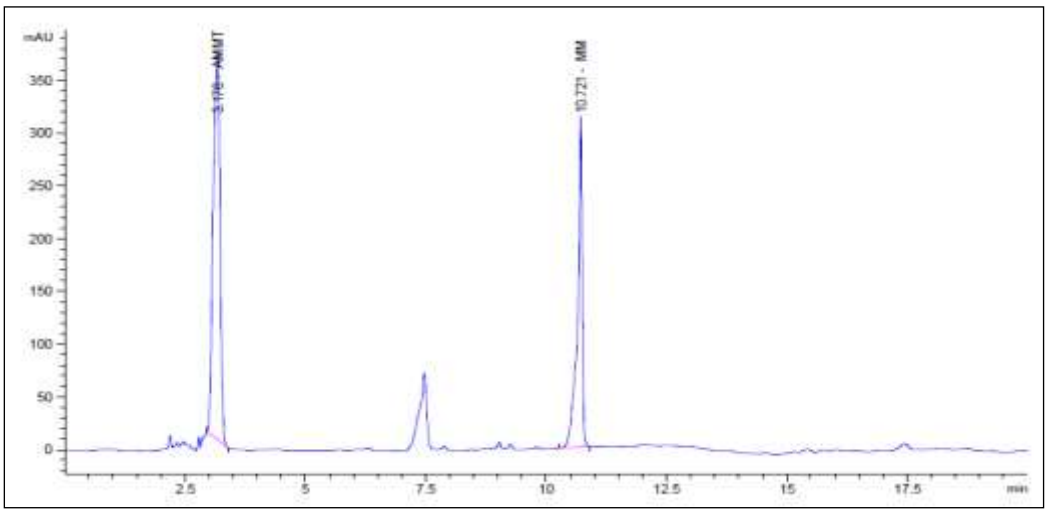

Figure 3. Gradient method: HPLC profile of spiked MSM and AMMT. Chromatogram has been corrected for baseline drift (overlay sample chromatogram on blank chromatogram)

In the present study, samples were collected four times from each of the 18 stations at six selected rivers during the wet and dry seasons. M1 and M2 represented the rainy season, with monthly average rainfall of 300 mm to 400 mm, meanwhile M4 represented the dry season, with a monthly average rainfall of 50 mm to 150 mm, and M3 the regular season, with a monthly average rainfall of 150 mm to 300 mm. The result obtained from water monitoring for MSM and AMMT from the sampling is provided in Figure 4 and Table 3. MSM concentration in the water ranged from undetectable to 604.4 µg/L (Figure 5). The amount of AMMT prevent in several stations and seasons shown in Table 3. A significant increase of the MSM concentration in the water was observed in the vary season (M1 and M2) in most of the rivers. The release of MSM can be associated with surface runoff from the oil palm plantation area and with soil exposure to MSM. These results showed the drift of MSM due to precipitation and related leaching in relation to its high solubility in water and its binding ability to the soil particles which drifted by the runoff [9]. In the present study, rain events played an important role transporting the MSM present in the soil towards the water stream through the mechanisms of dilution or drift of surface material by runoff. For Sungai Jemberau (J1, J2 and J3) the concentration increased from downstream to upstream possibly due to the location of the oil palm plantation area. A different patent occurred for Sungai Gumum (G1, G2 and G3) where the concentration decreased from downstream to upstream, perhaps due to the reduction of oil palm plantation area at the upstream area. Referring to the amount of AMMT in the water, there was no trend observed in the water bodies during the monitoring period and AMMT was found mainly during the dry season at low concentrations < 0.15mg/L.

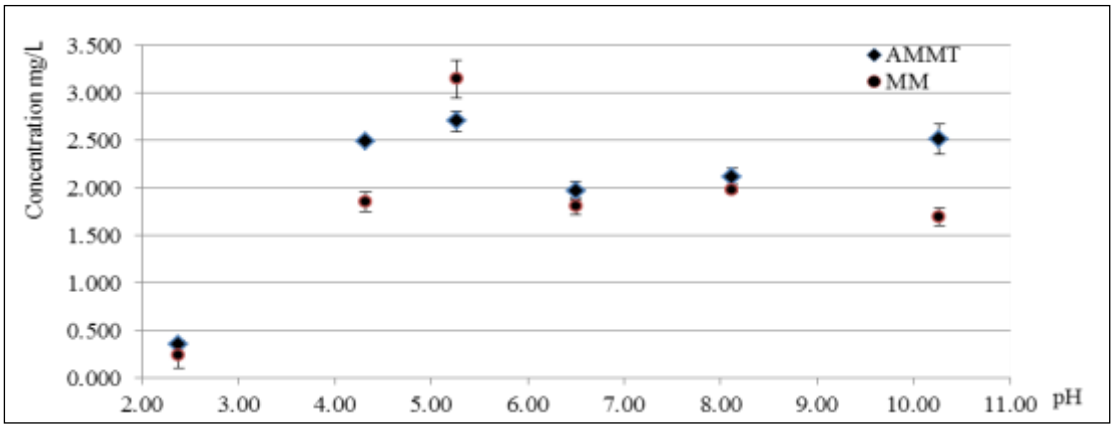

Figure 4. Recovery result of 3 mg/L for the pH range of 2.38 – 10.27

Table 3. AMMT concentration

Sampling	Sampling place	Concentration (mg/L)
Season 1	K3	0.0191
Season 2	D1	0.0510
Season 3	Every sampling point is not detected	
Season 4	CH2	0.0220
	D1	0.1390
	D2	0.0575
	K1	0.0472
	K2	0.1238
	K3	0.0381

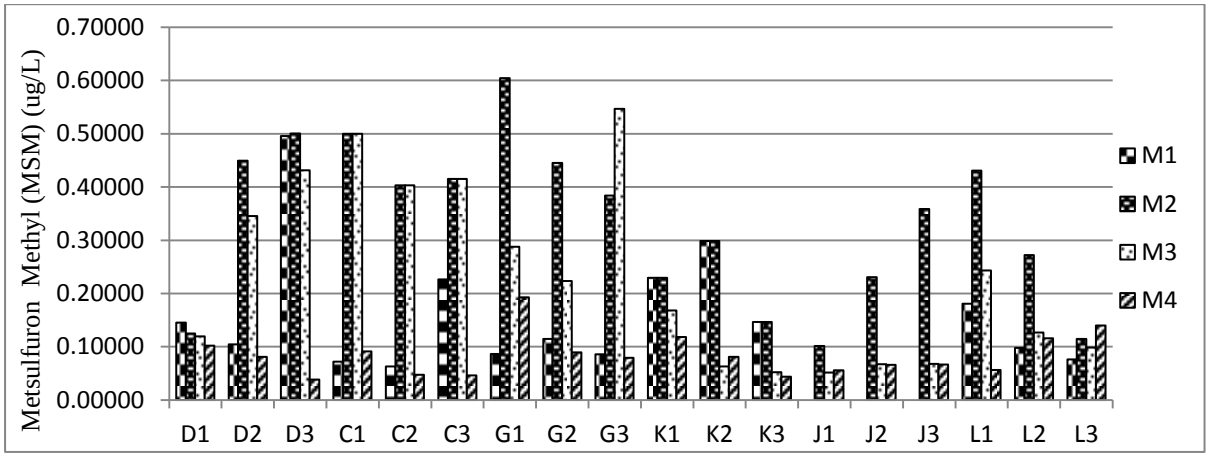

Figure 5. MSM concentration in water

Conclusion

The inclusion of the study of metabolites in monitoring programs and in experimental studies is mandatory. The optimized method used showed an adequate sensitivity for the detection of MSM and AMMT in water samples by a simple procedure. Concerning the levels of MSM detected in the water samples, there was no direct relationship observed between MSM application time and its detection in water. However, the rain events cause a rise in MSM concentration in the water. Finally, the contribution of this preliminary study is disclosed because there is little unpublished information in this region regarding pesticides application. Further studies for pesticide modeling on a monthly basis will be a useful tool for estimation of application rates.

Abstract

The purpose of this study is to investigate the effectiveness of banana trunk as an adsorbent in removal of heavy metals in aqueous solution. Functional groups of adsorbent were determined using Fourier Transform Infrared spectroscopy (FTIR). Batch experiments were conducted to determine the adsorption percentage of heavy metals (Cu, As, Pb and Zn). The optimum adsorption using banana trunk was based on pH difference, contact time and dosage. Adsorption percentage was found to be proportional to pH, contact time and dosage. Maximum adsorption percentage of Cu, As, Pb and Zn at pH 6, 100 minutes and 8 gram of dosage are 95.80 %, 75.40 %, 99.36 % and 97.24 %, respectively. Langmuir and Freundlich isotherms were used to determine the equilibrium state for heavy metals ion adsorption experiments. All equilibrium heavy metals were well explained by the Freundlich isotherm model with R^2 = 0.9441, R^2 = 0.8671, R^2 = 0.9489 and R^2 = 0.9375 for Cu, As, Pb and Zn respectively. It is concluded that banana trunk has considerable potential for the removal of heavy metals from aqueous solution.

Keywords: adsorption, heavy metals, banana trunk, pH, contact time

Abstrak

Kajian ini bertujuan untuk menyiasat keberkesanan batang pisang sebagai penjerap dalam penyingkiran logam berat di dalam larutan akueus. Kumpulan berfungsi penjerap ditentukan menggunakan Spektrospkopi Infra Merah Transformasi Fourier (FTIR). Eksperimen kelompok dilakukan untuk menentukan peratusan penjerapan logam berat (Cu, As, Pb dan Zn). Penjerapan optimum menggunakan batang pisang berdasarkan pH yang berbeza, masa sentuhan dan dos penjerap dianalisis dalam eksperimen kelompok. Peratus penjerapan didapati berkadar terus dengan pH, masa sentuhan dan dos penjerap. Peratus penjerapan maksimum Cu, As, Pb dan Zn pada pH 6, 10 minit masa sentuhan dan 8 gram dos penjerap masing-masing ialah 95.80 %, 75.40 %, 99.36 % dan 97.24 %. Isoterma Langmuir dan Freundlich telah digunakan untuk menentukan keadaan keseimbangan bagi eksperimen penjerapan logam berat. Semua keseimbangan logam berat dijelaskan dengan baik oleh model isoterma Freundlich dengan R^2 = 0.9441 , R^2 = 0.8671 , R^2 = 0.9489 dan R^2 = 0.9375 masing – masing untuk logam Cu, As, Pb dan Zn. Dapat disimpulkan bahawa batang pisang mempunyai potensi besar untuk penyingkiran logam berat daripada larutan akues.

Kata kunci: penjerapan, logam berat, batang pisang, pH, masa sentuhan

Introduction

The presence of heavy metals in the water bodies has caused severe health effects to people. Too much ingestion of copper (Cu) may bring about serious toxicological concerns, such as convulsions, vomiting, cramps or even death [1] while its deficiency may cause excessive accumulation of zinc (Zn) in human and animals which can reduce the immune system function. Among other effects include anemia, death of fetuses, liver, pancreas and kidney damage

[2]. Arsenic (As) is known as a poisonous element and very toxic to human. It can cause cancer and skin disorder besides non-cancerous diseases such as cardiovascular, pulmonary and neurological problems. Meanwhile, exposure to lead (Pb) resulted in a wide range of biological effects depending on the level and duration of the exposure.

Heavy metal sources can be natural or anthropogenic in origin. They existed naturally in a small amount on the Earth's crust and could not be degraded or eliminated. Higher concentration of heavy metals in the environment usually comes from anthropogenic activities such as copper (Cu) from electricity conductor, building materials and various alloys constituents. Zinc (Zn) is one of the transition elements possibly from refining and extraction industry while arsenic is contributed by human activities such as sewage and toxic chemicals disposals, industrial activities, vehicular emissions and erosion [3]. Finally, lead (Pb) is possibly coming from several other sources such as petrol, industrial processing, painting and soldering industries, water pathways and piping [4].

There are several conventional methods in removing heavy metals from water, which include precipitation, ion exchange, reverse osmosis, electrocoagulation and nanofiltration [5 – 7]. However, these methods are limited for the use of large industries since the operational cost is high [8]. Thus, using waste materials as an absorbent over activated carbon in removing heavy metals is wisely suggested since they are cheaper and effective.

The major aim of this study is to determine the potential of banana trunk as an adsorbent in removal of heavy metals in aqueous solution. Banana trunk is an agricultural waste generated from agricultural activities. It is chosen due to the waste generated is rising dramatically which can risk both human and ecosystem [9]. This waste can be converted into useful products through recycle which subsequently minimize the level of pollution caused by agricultural burning activities. From previous studies, agricultural wastes are potentially low cost adsorbent as they are unexploited resources, widely available, environmental friendly and also natural materials that exist in large quantities [10]. Many research had been conducted such as the study of the removal of Pb (II) by citrus pectin [11] and adsorption of Fe (II) using tamarind bark (*Tamarindus indica*) and potato peel waste (*Solanum tuberosum*) [12]. The optimum adsorption process was identified as a function of pH, contact time and dosage.

Materials and Methods

Chemical and stock preparation

5 ppm of each heavy metal solution was prepared from 100 ppm stock solution through dilution. The metal solutions were adjusted to pH 5 using 0.1 M of hydrochloric acid (HCl) [13]. It is recommended to shake the stock solution thoroughly prior to use and must not pipette directly from the bottle.

Sample preparation and analysis

The samples of banana trunk were obtained from banana plantation in Kuang, Selangor. The trunks were sliced into small pieces and washed thoroughly using distilled water. The trunks were air-dried for 4 – 5 hours before keeping them in the oven for 24 hours at 50 ºC. Then, the dried trunks were grounded and sieved and ready for FTIR-analysis [14]. This analysis is to determine the functional groups in banana trunk by scanning the sample from 4000 to 400 cm^{-1} at a 400 cm^{-1} resolution [15].

Batch analysis

50 mL of 5 ppm metal solution was mixed with 2 g of adsorbent in 250 mL flasks and agitated at 100 rpm for 60 min using an orbital shaker. The experiment was continued to identify the adsorption equilibrium dosage through mixing the solution with 4 – 10 g of dosage. The suspension was then separated by decantation. Determination of the rate of adsorption and adsorption equilibrium time was performed by determining the residual metal solution in the supernatant by allowing metal support-banana trunk fibers sorbent to equilibrate at different pH values of 2-10 for 60 min. Then, at the optimum pH and dosage, metal support-banana trunks were allowed to contact at different period between 5 – 150 min. The residual metal ion concentration was analyzed using Inductively Coupled Plasma-Optical Emission Spectrometer (ICP-OES). The percentage removal of heavy metal was calculated as equation 1 below:

$$\text{Adsorption (\%)} = \frac{(C_i - C_f)}{C_i} \times 100 \quad (1)$$

where, C_i and C_f are the initial and final concentrations of heavy metals present in the adsorption studies.

Adsorption isotherm

Analysis of adsorption under constant temperature was studied by using Langmuir and Freundlich equations. Langmuir isotherm assumes that there is an infinite number of binding sites having the same affinity for adsorption of mono layer and there is no interaction between the adsorbed molecules [16]. Based on the assumption, Langmuir isotherm represents the following equation 2:

$$q_e = \frac{q_m K_L C_e}{1 + K_L C_e} \quad (2)$$

The Langmuir equation is transformed into linear form to determine Langmuir adsorption parameters as expressed in Equation 3 below;

$$1/q_e = (1/q_m) + (1/q_m K_L)(1/C_e) \quad (3)$$

where q_e (mg/g) and q_m (mg/g) are the amount of adsorbed metal ions per unit mass of adsorbent and adsorption capacity, respectively. K_L is a constant related to the affinity of the binding sites (L/mg) and C_e is a un-adsorbed metal ion concentration in solution at equilibrium (mg/L).

The assumption of Freundlich isotherm is the adsorption energy of a metal binding to a site on an adsorbent depends on the vacancies of the adjacent sites and it is expressed by the following equation 4 [17]:

$$q_e = K_F C_e^{1/n} \quad (4)$$

In linear form, the Freundlich equation is expressed as follows:

$$\log q_e = \log K_F + 1/n \log C_e \quad (5)$$

where q_e the amount of metals adsorbed per unit mass of adsorbent (mg/g); C_e is the equilibrium concentration of metal ions (mg/L) while K_F (mg/g (L/mg)$^{1/n}$) and *n* (dimensionless) signify the adsorption capacity and adsorption intensity respectively. It can be defined as the adsorption or distribution coefficient and represents the quantity of dye adsorbed onto adsorbent for unit equilibrium concentration. 1/n is the heterogeneity factor and n is a measurement of the deviation from linearity of adsorption. The values indicate the degree of non-linearity between solution concentration and adsorption. The interpretations are as follow: If the value of *n* is equal to unity, the adsorption is linear; if the value is below unity, this implies that adsorption process is chemical, if the value is above unity adsorption is a favorable physical process.

Results and Discussion

Characterization of adsorbent

Based on the FTIR spectrum of banana trunk biomass shown in Figure 1, three different absorption peaks were detected. The peak at 3400.84 cm^{-1} represents the O-H functional group. The absorption band at 1624.01 cm^{-1} occurred for primary amine N-H functional group while the carboxylic acid (-COOH) group were detected at 1054.52 cm^{-1} wavelength. Previous study had stated that hydroxyl and carboxylic acid groups played a major role in the adsorption process [18]. According to [19], the hydroxyl group is highly effective towards adsorption rate and efficient through the exchange with metal ions. Meanwhile, the carboxylic acid group is relatively high adsorption rate due to the presence of more negatively charged groups on its surface [20].

Effect of adsorbent dosage

The effect of adsorbent dosage on the removal of selected heavy metals was investigated and shown in Figure 2. At the initial stage of batch experiment, the adsorption percentage of heavy metals increased with increasing of adsorbent dosage. This is probably due to the fact that by increasing the adsorbent dosage there will be numbers of active sites available for the adsorption of metal ions. However, further expansion of adsorbent dosage (> 8 g) did not significantly affect the percentage removal of heavy metals due to overcrowding of adsorbent particles [21].

Hence, the optimum dosage of banana trunk biomass for removing metal ions from liquid phase was 8 gram.

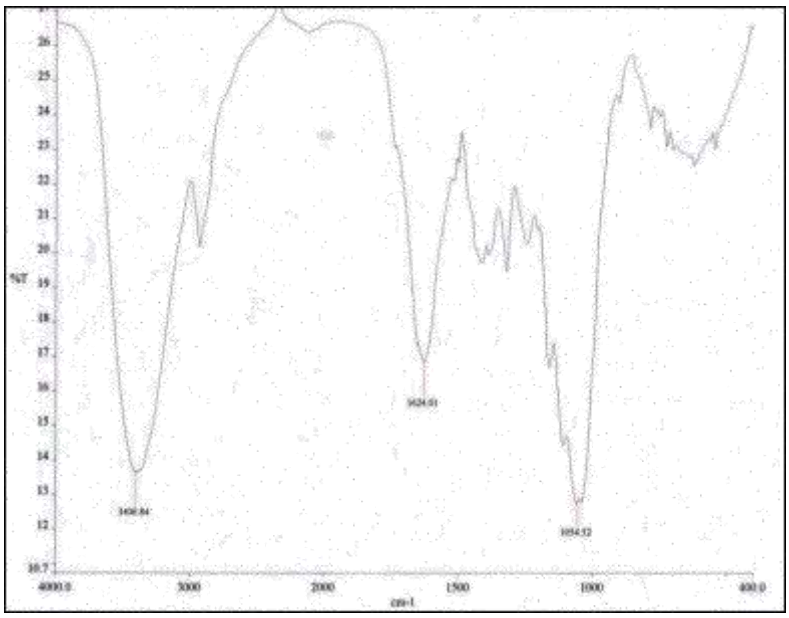

Figure 1. FTIR spectrum of banana trunk biomass (4000 cm^{-1} – 400 cm^{-1})

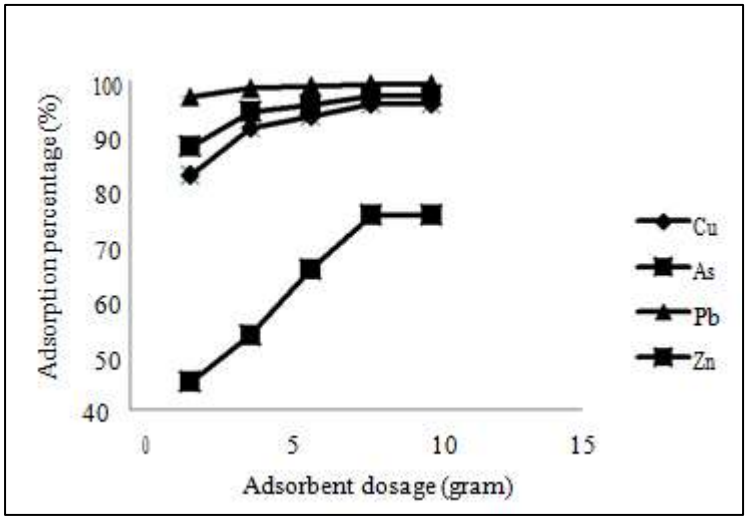

Figure 2. Graph of adsorbent dosage versus adsorption percentage

Effect of pH

Figure 3 shows the relationship between the adsorption percentages with pH for all the four heavy metals. The results obtained showing that there was a rapid removal of metal ions followed by slower adsorption process until the optimum pH was reached pH 6. It was noticed that the adsorption percentages for all four metals remained

constant as the pH increased beyond the optimum level. The tremendous metals removal as the pH increased is due to the reduction of competition between protons and metal cations for the same functional groups and by decreasing in the positive surface charge resulting in a lower electrostatic repulsion between the surface and metal ions [13]. It was recorded that the adsorption was at the least at the initial pH 2. The low adsorption percentage at the pH 3 and below is because of the H^+ ion competing with the metal cations for the adsorption site available whereas at the higher pH, the adsorption site is not active.

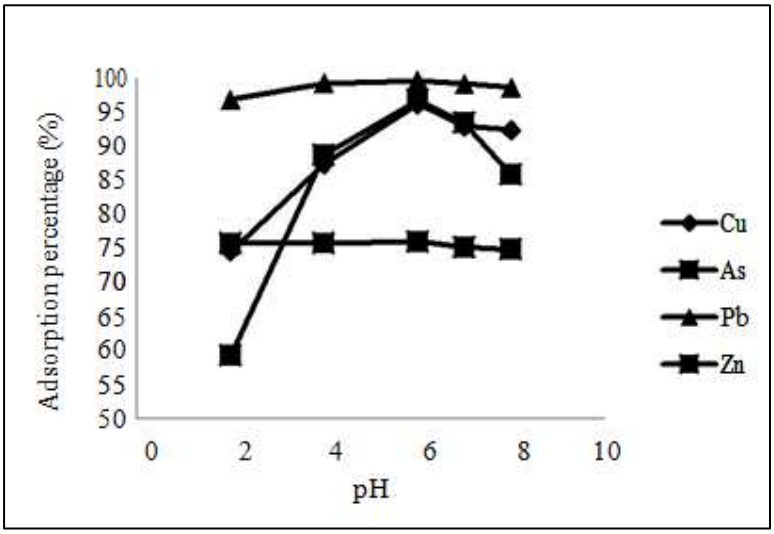

Figure 3. Graph of pH versus adsorption percentage

Effect of contact time

Optimum pH solutions were used for the determination of adsorption equilibrium time. Investigation of the effect of contact time in removal of heavy metals using banana trunk is explained in Figure 4. The removal of all four types heavy metal is increased with contact time until the optimum state is reached which was at 100 min. By extending the contact time beyond the optimum state, the process of removal of heavy metals was not significantly effective. On the other hand, the adsorption percentage was decreased due to the accumulation of metal ion species [22].

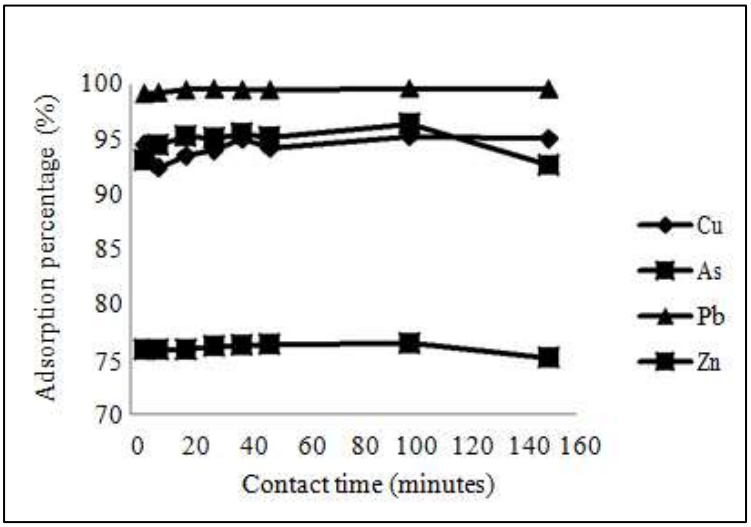

Figure 4. Graph of contact time versus adsorption percentage

Equilibrium studies

Langmuir and Freundlich isotherms were used to describe the equilibrium state of metal ions adsorption. The uptakes occur on a homogenous surface by monolayer sorption without any interaction between adsorbent molecules is described by Langmuir isotherm. This isotherm assumes there are no transmigration of metal ions in the plane of the surface and uniform energies of adsorption onto the surface. Langmuir isotherm constants were obtained from the plot of $1/q_e$ against $1/C_e$. Heavy metals (Cu, As, Pb and Zn) adsorptions that follow the Langmuir isotherm model are shown in Figure 5 whereas $1/q_e$ was plotted against $1/C_e$ and straight line was obtained for all studied heavy metals. The Langmuir parameters, q_m and K_L were calculated from the slope and interception of the isotherm as recorded in Table 1. From the Langmuir parameter, the adsorption capacities, (q_m), were identified in the sequence of Cu > Pb > As > Zn.

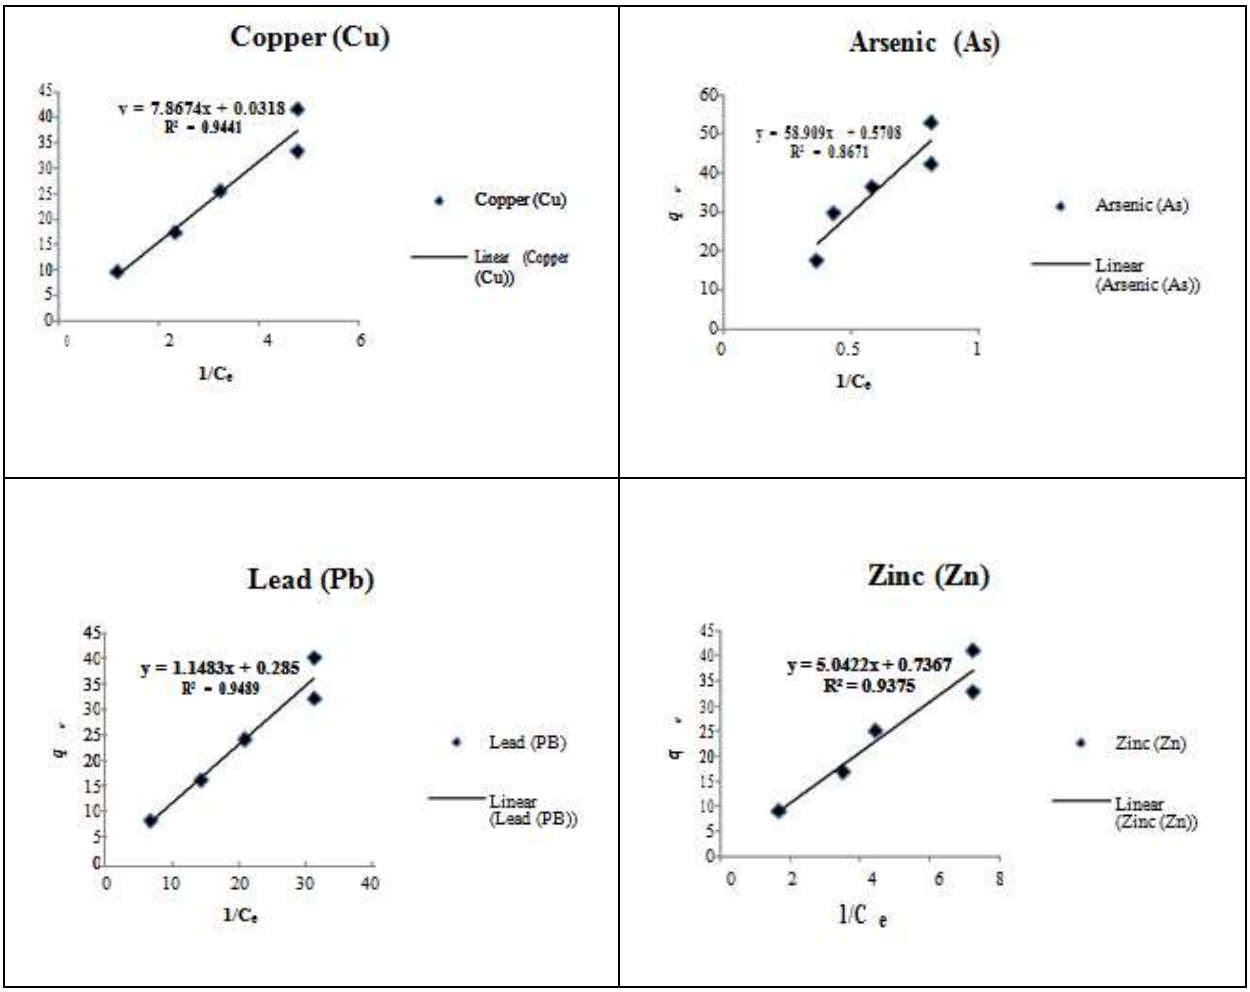

Figure 5. Plots of Langmiur isotherm for all heavy metals examined

The Freundlich isotherm describes the adsorption onto a heterogeneous surface. In Figure 6, when log C_e was plotted against log q_e, straight line was obtained representing that metal ions adsorption has followed the Freundlich isotherm model. Freundlich parameters which include *n* values and K_F values were computed from the slope and interception of the isotherm.

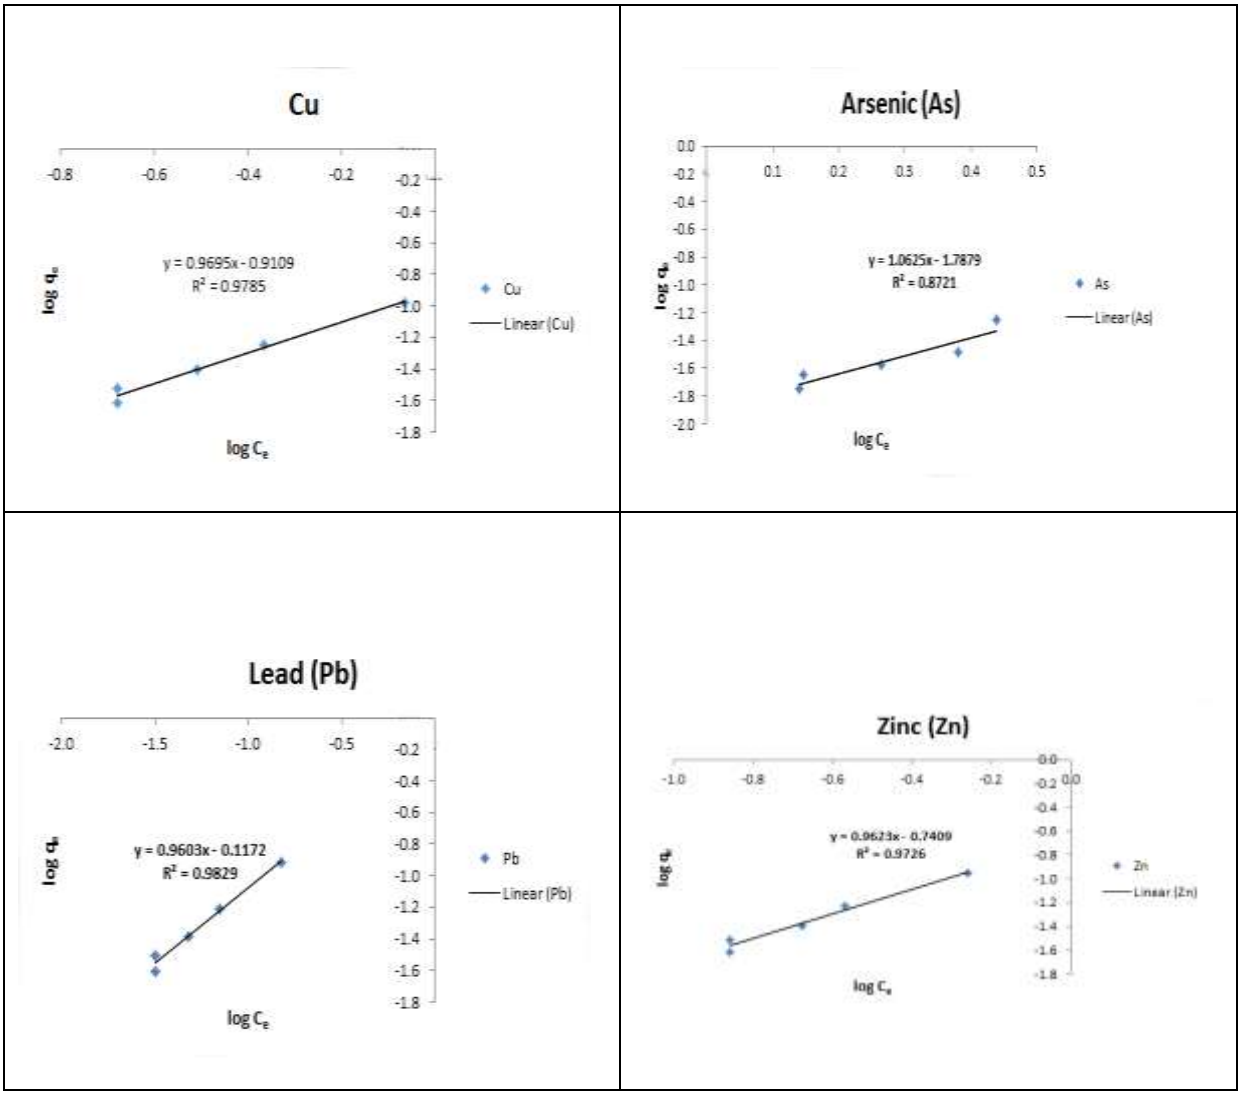

Figure 6. Plots of Freundlich isotherm for all heavy metals examined

Metal ions of Cu, Pb and Zn were favorably adsorbed by adsorbent since the n values are greater than 1. *N* values less than one indicate that the metal ions were not favorably adsorbed by adsorbent as shown in As adsorption. Table 2 shows the comparative evaluation of heterogeneous adsorption capacities onto various adsorbents.

The linear coefficient (R^2) was calculated to examine the fitness of the two isotherm models in the linear form. It is noted that Freundlich model describes the adsorption more successfully than Langmuir model where R^2 values of Langmuir model for all investigated heavy metals is higher and closer to unity compared to Freundlich model. According to Nady and Iman [23], if R^2 and $K_L < 1$, it is shown that metal ions are highly favorable adsorbed by prepared adsorbent. Thus, in this study, it is confirmed that banana trunk is effective in removal of heavy metals from aqueous solution.

Table 1. Langmuir and Freundlich parameters and correlation coefficient for the metals examined

Heavy Metals	Langmuir Isotherm			Freundlich Isotherm		
	q_m	K_L	R^2	n	K_L	R^2
Cu	31.45	4.04×10^{-3}	0.9441	1.03	0.12	0.9785
As	1.75	9.70×10^{-3}	0.8671	0.94	1.63×10^{-2}	0.8721
Pb	3.51	0.25	0.9489	1.04	0.76	0.9829
Zn	1.36	0.15	0.9375	1.04	0.18	0.9726

Table 2. Comparative evaluation of heterogeneous adsorption capacities onto various adsorbents

Metal	Adsorbent	Heterogeneous adsorption capacity (mg/g)	References
Cu	Banana trunk	1.03	Present study
	Banana peel	1.31	[24]

Conclusion

In the present study it is proven that banana trunk has potential to be an effective and economically feasible adsorbent in removal of heavy metals. Three (Cu, Pb and Zn) out of four heavy metals achieved more than 90 % removals whereas As removal was only 75.40 %. In the batch experiment, it has been shown that the percentage removal is highly dependent on pH, contact time and dosage. The highest percentage removal for all investigated heavy metals was found at optimum pH 6, 100 min of contact time and 8 g dosage. The effectiveness of banana trunk as adsorbent in removal of heavy metals is confirmed by FTIR result that has detected three functional groups

including hydroxyl groups, carboxylic group and amine groups which played a major role in adsorption. The equilibrium adsorption data is best represented by Freundlich isotherm model compared to the Langmuir isotherm.

Abstract

Dithizone-PVC membrane was constructed and utilized as an ionophore reagent material for chemically modified silver (Ag) electrode. The modified electrode was characterized using cyclic voltammetry where the electrochemical behaviour of dithizone modified Ag electrode surface was investigated in the range of -0.6 to +0.6 V with 0.1 M KCl as supporting electrolyte. Comparative studies towards metal ions Cu^{2+}, Fe^{2+} and Pb^{2+} exhibited good responses for redox reactions with linear relationship between peak currents and concentrations. The correlation coefficients obtained were 0.9800, 0.9944 and 0.9949 while the evaluated limits of detection were 8.3 x 10^{-7} M, 4.7 x 10^{-7} M and 7.6 x 10^{-7} M respectively.

Keywords: PVC membrane, dithizone (1,5-diphenylthiocarbazone), cyclic voltammetry, redox reactions

Abstrak

Membran PVC-Ditizon telah dibina dan digunakan sebagai bahan reagen ionofora bagi elektrod perak (Ag) yang diubahsuai secara kimia. Elektrod yang diubahsuai telah dicirikan menggunakan voltametri berkitar di mana sifat elektrokimia bagi ditizon yang diubahsuai pada permukaan elektrod Ag telah dikaji di dalam julat -0.6 ke +0.6 V dengan 0.1 M KCl sebagai elektrolit sokongan. Kajian perbandingan terhadap ion-ion logam Cu^{2+}, Fe^{2+} dan Pb^{2+} mempamerkan respon yang baik bagi tindak balas redoks dengan hubungan linear antara arus-arus puncak dan kepekatan. Pekali korelasi yang diperolehi adalah 0.9800, 0.9944 dan 0.9949 manakala had pengesanan yang diukur adalah 8.3 x 10^{-7} M, 4.7 x 10^{-7} M dan 7.6 x 10^{-7} M masing-masing.

Kata kunci: membran PVC, ditizon (1,5-difeniltiokarbazon), voltametri berkitar, tindakbalas redoks

Introduction

Heavy metals pollution in environment is a global issue that has been discussed over the years. Heavy metals can enter the environment by both natural and anthropogenic sources including mining, agrochemicals, sewage and sludge applications and also industrial activity. Copper (Cu^{2+}), iron (Fe^{2+}) and lead (Pb^{2+}) are the most common existence of toxic metal ions in aqueous environmental solution. Although metal ions such as Cu^{2+} and Fe^{2+} are categorized as micronutrients at low concentrations, however, in excess contamination, these metals can be highly toxic [1].

Since the last few decades, the need to determine these heavy metal ions in aqueous environments has been highly focused especially in the field of environmental, pharmaceutical and biomedical studies [2, 3]. Electrochemical techniques in particular, chemically modified electrodes have received a great deal of attentions for determination of heavy metal ions [4]. These modified electrodes were prepared in varieties of specific modification processes in

order to improve the sensitivity and specification of the sensing purposes. Different modification processes such as physisorption [5], chemisorption [6], covalent attachment [7], modified polymers [8] and bulk modification of carbon composite materials [9] have been reported. In this study, surface modification of the electrode via polymerized chemisorption coating was applied using the specific and selective dithizone reagent. This method provides a particular function on the electrode surface such as a medium for metal ion bonding and unique properties of metal complexes [10].

Dithizone or 1,5-diphenylthiocarbazone (H_2D_Z) is an organic chelating reagent that was initially used for calorimetric determination of trace metal ions [11]. It was discovered by Helmuth Fischer, and the vast potential of dithizone has been reveiled in 1925 [12]. Through the years, applications of dithizone become widely used and continue to be expended in many analytical researches. Due to its capability in exhibit ions interesting redox chemistry, the electrochemical behaviour of dithizone has been studied [13]. With the presence of azo and sulfhydryl groups, the oxidation and reduction of dithizone can be characterized. Previous studies shown that dithizone has been exploited in chemically modified electrode as a modifier for determination of metal ions [14-15].

In this study, the immobilization of dithizone as a polymerized polyvinyl chloride (PVC) membrane was carried out in order to improve the stability and sensitivity of the reagent. PVC act as a polymer matrix that can be easily incorporated with an ionophore, and was commonly used in many electrochemical studies [16 – 17]. It was first investigated by Heineman and coworkers in 1980, which demonstrated the application of polymer film in chemically modified electrode [18]. A platinum (Pt) disk composed of PVC film impregnated with valinomycin can offer high selectivity and electrochemical activity on the PPy/PPS layer [19]. The modified electrode showed a stable standard potential of potassium ion. Recently, studies of PVC film coated in Pt electrode for the determination of chromium showed good detection limit of 6.8×10^{-8} M with linear concentration range of 8.4×10^{-8} M - 1.0×10^{-2} M. The sensor was successfully developed with the fast response time in 10 s [20]. Therefor, a new modified Ag electrode coated with polymerized chemisorption dithizone-PVC membrane as an electroactive reagent has been investigated. The electrochemical behaviour of the modified Ag electrode was described using cyclic voltammetric technique with several parameters studied.

Materials and Methods

Chemicals and reagent

All chemicals and reagent were of analytical grade and were used without further purification. Dithizone was obtained from Merck, Darmstadt, Germany. All metal salts, Copper (II) Sulphate, Iron (II) Chloride and Lead (II) Sulphate were of analytical grade from R & M Marketing, Essex, U.K. Other chemicals were polyvinyl chloride (PVC) from Sigma-Aldrich, tributyl phosphate (TBP), tetrahydrofuran (THF), sodium tetraphenylborate $NaB(C_6H_5)_4$ and hydrochloric acid (HCl) from Merck Darmstadt, Germany. Deionized water was used throughout the preparation of the samples.

Instrumentation

Electrochemical measurements were performed using Autolab model PGSTAT30 from Metrohm Ltd, Herisau, Switzerland.

Preparation of modified Ag electrode

Initially, dithizone-PVC membrane was prepared by mixing 120 mg of PVC powder, 10 mg of dithizone as ionophore and 1.5 mg of $NaB(C_6H_5)_4$ as a lipophilic additive with 240 mg of TBP. The mixture was dissolved in 6 ml of THF and was stirred for 3 hours. At the mean time, Ag electrode was polished repeatedly with sandpaper and was then thoroughly rinsed with acetone and followed by distilled water. Then, the Ag electrode was dipped into the dithizone-PVC membrane cocktail prepared, for 10 s. Finally, the modified Ag electrode was dried at room temperature for 1 hour before use.

Characterization of modified Ag electrode using cyclic voltammetry

All measurements were done using a conventional three electrode system. A Ag electrode modified with a dithizone-PVC membrane coating was used as a working electrode with a surface area of 0.60 cm^2. The Pt electrode and Ag/AgCl electrode were used as auxiliarly and reference electrodes, respectively. All electrochemical

experiments were carried out at room temperature and the potential was scanned in the range of -0.6 to +0.6 V at 0.1 Vs^{-1}.

Results and Discussion

Electrochemical characterization

The modified Ag electrode with dithizone-PVC membrane was characterized using cyclic voltammetry (CV) with and without the presence of metal ions containing 0.1 M KCl as supporting electrolyte. The CV was performed using a potential range between -0.6 to +0.6 V (vs. Ag/AgCl) with the scan rate of 0.1V s^{-1}. The voltammogram is represented in Figure 1. Line (a) shows the response of dithizone modified Ag electrode without metal ion, line (b), (c) and (d) show the responses of dithizone modified Ag electrode with $1x10^{-3}$ M Cu^{2+}, Pb^{2+} and Fe^{2+}, respectively. For modification of Ag electrode with Cu^{2+}, two reduction peaks can be observed from -0.1 to -0.3 V, corresponds to the two-electron reduction of Cu(II) to Cu(I) and Cu(0) (eq. 1 and Eq. 2). However, only one oxidation peak was observed at +0.2 V corresponding to the deposition of Cu(0) to Cu(I)/Cu(II) [21]. The proposed mechanism is illustrated as below:

$$Cu^{2+} + e^- \longrightarrow Cu^+ \quad (1)$$

$$Cu^+ + e^- \longrightarrow Cu^0 \quad (2)$$

The same reduction peaks also can be seen in modified Ag electrode with Pb^{2+} and Fe^{2+} from the range of -0.14 to -0.35 V and -0.15 to -0.36 V respectively. The reduction process for each metal ion showed that the dithizone-PVC membrane incorporates well with metal ions on the electrode surface, thus improved the electrode's performance. Meanwhile, the oxidation peak for modified Ag electrode with Pb^{2+} and Fe^{2+} was observed at +0.30 V and +0.20 V, respectively.

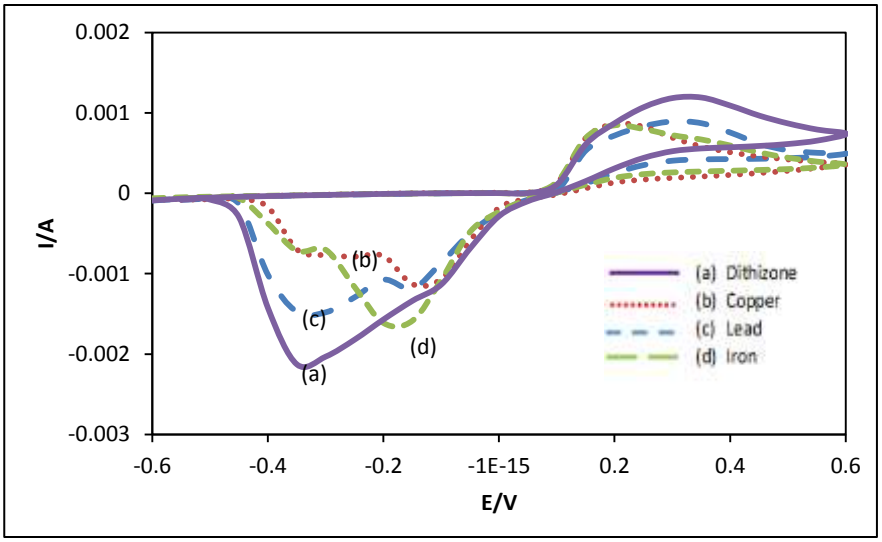

Figure 1. Cyclic voltammograms of (a) dithizone modified Ag electrode without metal (b) dithizone modified Ag electrode in Cu^{2+}, (c) dithizone modified Ag electrode in Pb^{2+}, and (d) dithizone modified Ag electrode in Fe^{2+}.

Effect of scan rates

In cyclic voltammetry, scan rate was used to determine the electrochemical behavior of a species generated at the modified electrode [22]. In this research, scan rate were optimized in order to characterized the redox reaction. Figure 2 (a), (b) and (c) show the effect of scan rates on the voltammogram of modified Ag electrode in the

potential range of 0.1 to 0.3 Vs^{-1} for Cu^{2+}, Pb^{2+} and Fe^{2+}. Increasing the potential scan rate influenced the change of peak current in both redox reactions. As it can be seen, the change of peak current in cathodic reaction shifted to more negative value with the increasing of scan rates for all metal ions.

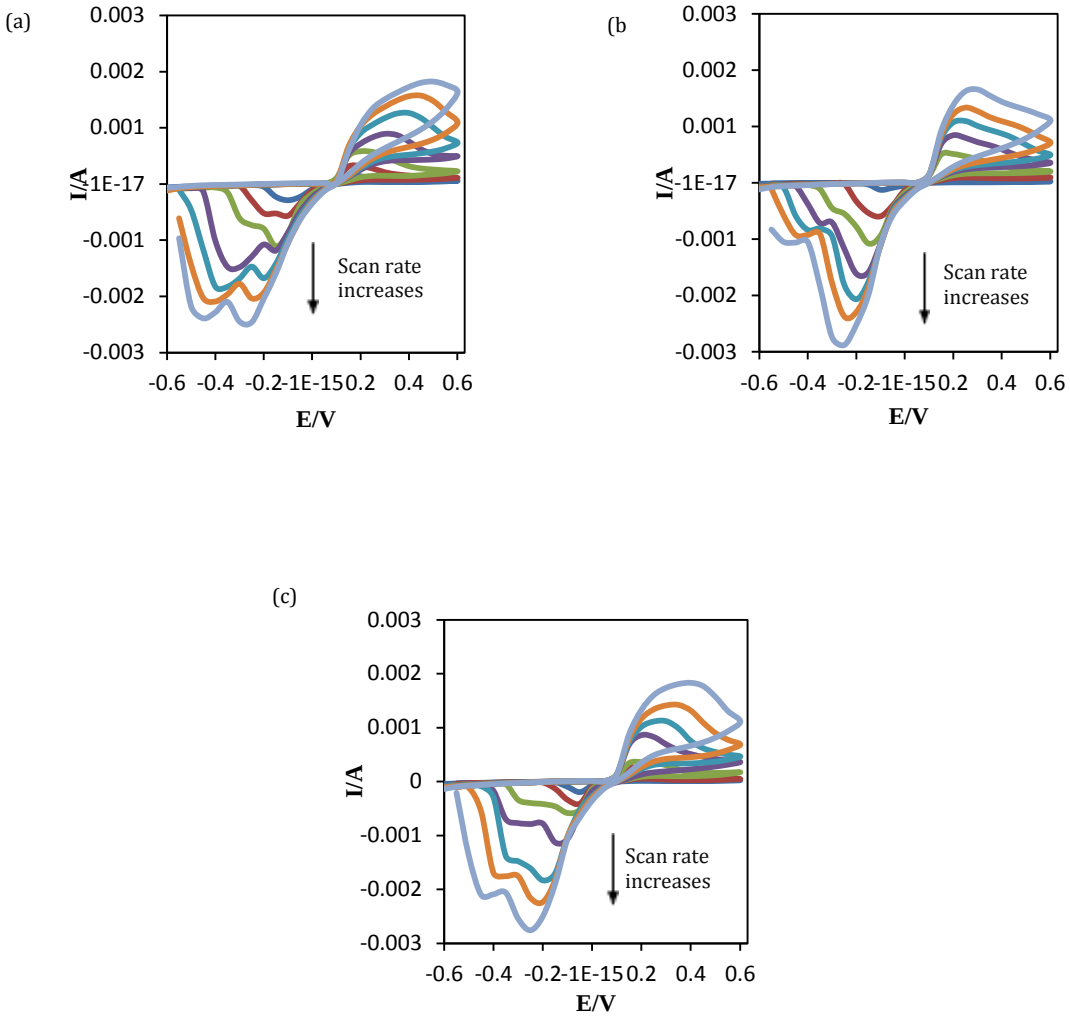

Figure 2. Optimization of scan rates on cyclic voltammograms of dithizone modified Ag electrode in $1x10^{-3}$ M of (a) Pb^{2+}, (b) Fe^{2+} and (c) Cu^{2+} with 0.1 M KCl as supporting electrolyte. (0.01 V, 0.025 V, 0.05 V, 0.1 V, 0.15 V, 0.2 V and 0.3 V).

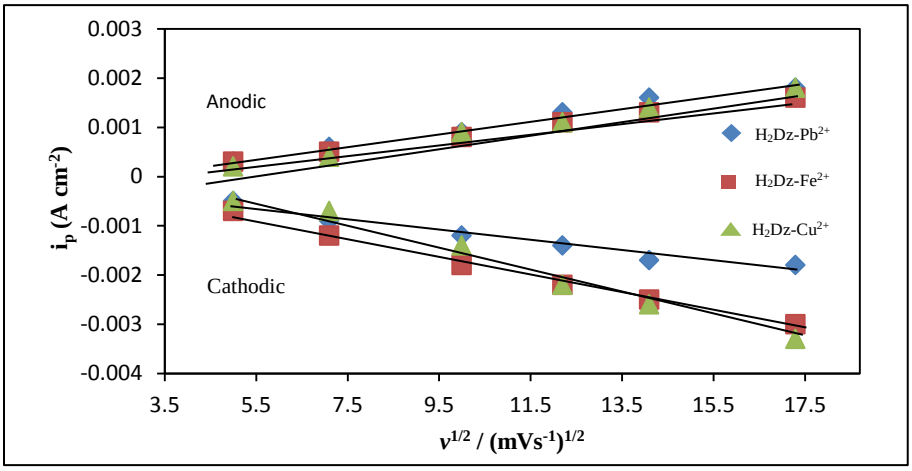
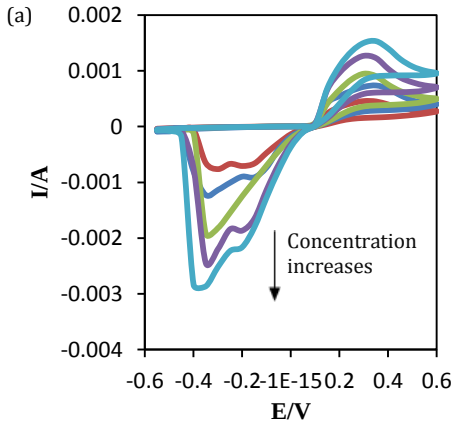
The relationship between peak current densities, i_p, and peak on the square root of scan rate ($v^{1/2}$), can be determined using the Randles-Sevcik equation (Eq. 3) [23].

$$i_p = (2.69 \times 10^5) n^{3/2} A D^{1/2} v^{1/2} C \quad (3)$$

where n is the number of electrons passed per molecule, A is the electrode area (in cm^2), D is the diffusion coefficient of analytes (in $cm^2\ s^{-1}$) and C represents the concentration of analytes (in mol cm^{-3}). A graph on peak current densities (i_p) vs. square root of scan rate ($v^{1/2}$) was illustrated in Figure 3. The results show that the linear

relationships were obtained with the i_p is proportional to $v^{1/2}$ which indicates that the mechanism of mass transfer occurs from the bulk of the metal ion solution to the electrode surface by diffusion process. This behavior indicates that the electrochemical process was diffusion controlled [24-25].





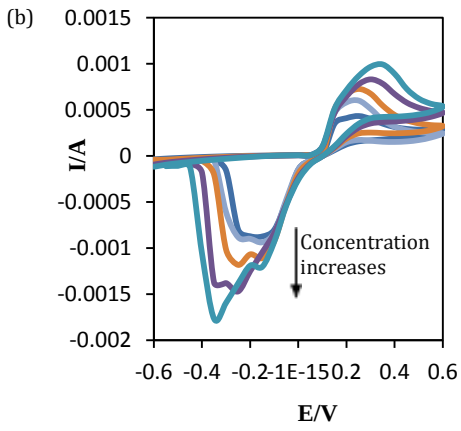


Figure 3. The relationship between peak current densities (i_p) on the $v^{1/2}$ for the H_2Dz modified Ag electrode in $1x10^{-3}$ M of Pb^{2+}, Fe^{2+} and Cu^{2+}.

Effect of different concentration

In order to investigate the influence of metal ions concentration on the cyclic voltammogram, study on different concentrations of metal ions Pb^{2+}, Fe^{2+} and Cu^{2+} were carried out. Figure 4 (a), (b) and (c) show the cyclic voltammogram for concentration of metal ions from 2 x 10^{-5} M to 10 x 10^{-5} M in 0.1 KCl at the scan rate of 0.1 Vs^{-1}. As can be seen from the figure, the anodic and cathodic peak current increase with the increasing of concentration. This indicates the concentration of metal ion Pb^{2+}, Fe^{2+} and Cu^{2+} are proportional to the electrochemical peak current.

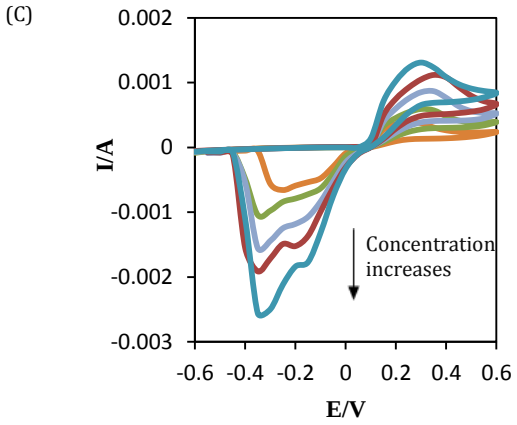

Figure 4. Cyclic voltammograms of different concentration of metal ions (a) Pb^{2+}, (b) Fe^{2+} and (c) Cu^{2+} deposited on the dithizone modified Ag electrode. (2 x 10^{-5} M, 4 x 10^{-5} M, 6 x 10^{-5} M, 8 x 10^{-5} M and 10 x 10^{-5} M).

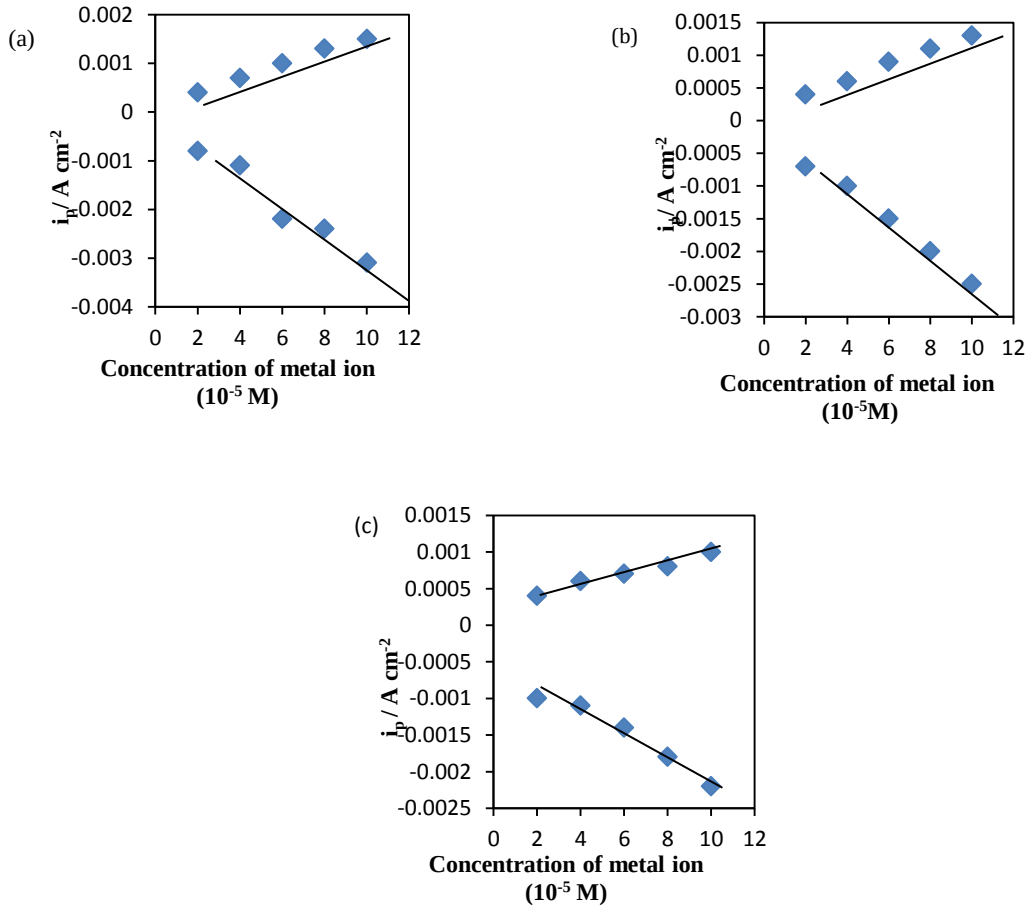

Figure 5. The relationship between peak current densities (i_p) on concentration of metal ions (a) Pb^{2+}, (b) Fe^{2+} and (c) Cu^{2+} at dithizone modified Ag electrode.

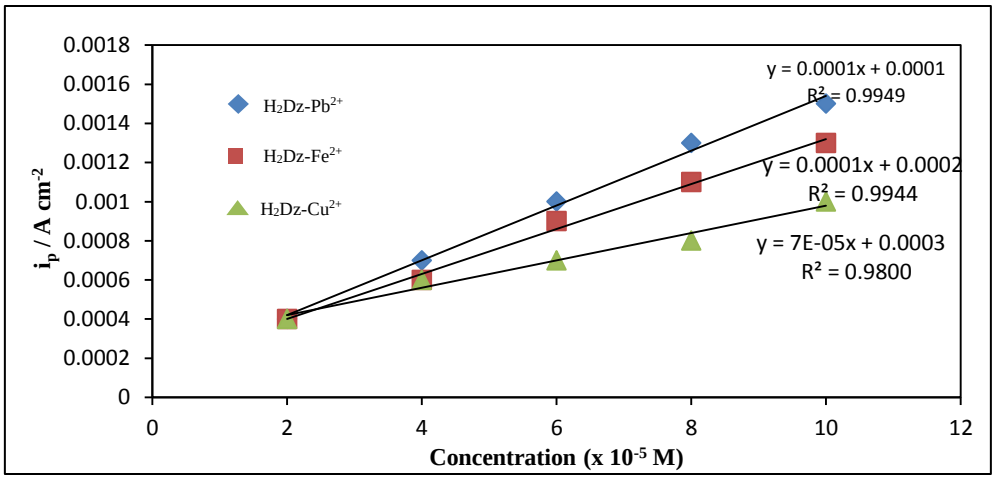

Figure 6. Calibration graph of peak current, i_p versus the concentration of metal ions using H_2Dz modified Ag electrode in 0.1 M KCl as supporting electrolyte.

Limit of Detection (LOD)

A calibration graph for the response of dithizone modified Ag electrode towards the metal ion Cu^{2+}, Fe^{2+} and Pb^{2+} has been plotted in Figure 6 to determine the sensitivity of the system. Within the potential range of -0.6 to +0.6 V, the correlation coefficient observed for Cu^{2+}, Fe^{2+} and Pb^{2+} were 0.9800, 0.9944 and 0.9949. From the results obtained, the evaluated values for LOD were 8.3 x 10^{-7} M, 4.7 x 10^{-7} M and 7.6 x 10^{-7} M, respectively.

Conclusion

The modification of Ag electrode based on dithizone as an ionophore reagent has been successfully developed to determine the concentration of Pb^{2+}, Fe^{2+} and Cu^{2+} in aqueous solutions. The modification using immobilized dithizone in PVC membrane via chemisorptions on the surface of Ag electrode exhibited irreversible process in a wide potential range from -0.6 to +0.6 V. The system showed excellent electrochemical characteristics with a good limit of detection in the range of 4.7 x 10^{-7} M to 8.3 x 10^{-7} M for those three metal ions studied. Hence, a new chemically modified electrode for detection of Pb^{2+}, Fe^{2+} and Cu^{2+} based on dithizone modified Ag electrode has been developed.

Abstract

The determinations of toluene and their metabolites in biological samples such as urine and blood allow the estimation of the degree of exposure to this chemical. Chromatographic methods and preliminary methods are now universally employed for this purpose. Preliminary color test methods are well established for qualitative determination of toluene and its metabolites. Mobile test kits using color test methods are a vast tool for screening urine samples but chromatographic methods are still needed for confirmation and quantitative analysis. Gas chromatography (GC) methods are well-adapted for the determination of toluene metabolite in urine, but these methods often require several pretreatment steps. Meanwhile, high performance liquid chromatography (HPLC) is becoming a powerful tool for the accurate and easy determination of toluene metabolites considering its decisive advantages for routine monitoring. Furthermore, recent development in HPLC could widen the usefulness of this method to solve the most complex analytical problems that could be encountered during the measurement.

Keywords: toluene, toluene metabolites, preliminary test, gas chromatography, high performance liquid chromatography

Abstrak

Penentuan toluena dan metabolitnya dalam sampel biologi seperti urin dan darah membolehkan anggaran tahap pendedahan terhadap bahan kimia ini. Kaedah kromatografi dan kaedah awalan merupakan kaedah yang sering digunakan untuk tujuan ini pada masa kini. Kaedah awalan menggunakan ujian warna telah dibangunkan untuk penentuan kualitatif toluena dan metabolit. Kit ujian mudah alih menggunakan ujian warna meluas digunakan bagi pemeriksaan sampel urin tetapi kaedah kromatografi masih diperlukan untuk pengesahan analisis kuantitatif. Kaedah kromatografi gas adalah kaedah yang kerap digunakan bagi menentukan metabolit toluena dalam urin namun kaedah ini sering memerlukan beberapa langkah rawatan awal. Sementara itu, kromatografi cecair berprestasi tinggi (HPLC) menjadi alat yang berkuasa untuk penentuan tepat dan mudah metabolit toluena memandangkan kelebihannya yang jelas untuk pemantauan rutin. Tambahan pula, perkembangan terkini dalam HPLC boleh memperluaskan kegunaan kaedah ini bagi menyelesaikan masalah analisis rumit yang boleh dihadapi semasa pengukuran.

Kata kunci: toluena, metabolit toluena, ujian awalan, kromatografi gas, kromatografi cecair berprestasi tinggi

Introduction

Volatile organic compounds (VOCs) are used as a component in a variety of domestic or industrial consumer products. This statement illustrates that humans always use and are frequently in contact with VOCs. Consumer products such as cleaning products, paints or thinner, glues, lighter, aerosols, cosmetics, fuels and others contain VOCs. Despite these, prolonged exposure to VOCs may lead to poisoning and sudden death [1, 2].

One of the major current issues among adolescents is misuse of the consumer products. In most of the cases, organic compounds contained in the consumer products are inhaled by them using different methods such as huffing, bagging and sniffing. Such conducts will deliver the desired effect such as feeling of pleasure, disinhibition, euphoria and hallucination [3, 4]. Unfortunately, the most difficult facet of the inhalant problem to confront is the fact that inhalants are everywhere.

Even though, there are many VOCs in consumer products, the concern is largely on toluene. This is because toluene has been the most widely used organic solvent in the industries since the second half of the last century [5-7].Such exposure to high concentrations of toluene has been reported by Watson [8]. Toluene biotransformation consists of several steps [9] involving side-chain oxidation where toluene is metabolized into benzoic acid and further conjugated with glycine to form hippuric acid [10]. Meanwhile, small amounts of absorbed toluene are oxidized at the aromatic ring and excreted in urine as *o*- and *p*-cresol.

This review aims to present a summary of the toluene exposure pertaining to toluene metabolites and its potential biomarker, preliminary tests for toluene metabolites, sample pretreatment and determination of toluene metabolites using various instrumentations. From this review, researchers in this area are expected to gain a good idea of analytical procedures, analytical techniques and analytical instrumentations involved. It is our hope that this review will facilitate researchers to plan their own research on toluene exposure and to develop fast method and new separation technique using green technology, electrochemical sensors with mobile instrumentation and other related techniques. The discussion begins with a general topic about toluene exposure and its effects on humans. The metabolism of toluene in human body from its inhalation until excretion in urine is then described. The selection of potential biomarkers and indicators of exposure to toluene are also described in a considerable detail.

Toluene exposure effects and analysis

The preliminary test has become a vast tool for on-site screening of urine sample as many drugs and other poisons give characteristic colors with appropriate reagents if present in sufficient amounts and in the absence of interfering compounds. A few of these tests are only for practical purposes but usually compounds containing similar functional groups will also react and thus interferences from other poisons, metabolites or contaminants are to be expected. Color tests for toluene metabolites have been described including for hippuric acid [11] and *o*-cresol [12].

Methods for toluene analysis and the identification of a reliable indicator in toluene exposure have been described by many researchers. High Performance Liquid Chromatography (HPLC) represents a valuable tool for the routine monitoring of workers exposed to toluene. The determination of urinary metabolites of toluene using HPLC has been extensively studied including those focusing on hippuric acid [13-17], cresol [18] and S-benzyl mercapturic acid [19-20]. For the urinary determination of solvent metabolites, especially for monitoring purposes, HPLC is becoming a method of choice. This method offers decisive advantages in this area as it permits the simultaneous determination of several metabolites whether it is run in isocratic mode or by gradient analysis. This method provides a complete metabolic profile, detection of isomer compound, it is easily automated, and does not require extraction, derivatization steps or pre-treatment of samples.

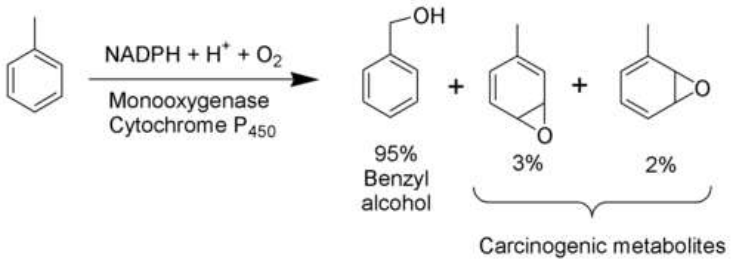
Determination of toluene metabolites in complex mixtures such as biological fluids is well-known and established. The separation of toluene metabolites from biological fluid can easily be achieved by gas chromatography (GC) with headspace method [21, 22]. However, gas chromatography-mass spectrometry (GC-MS) appears very suitable for the identification of toluene and their metabolites [23-27]. Unfortunately, not all target compounds are amenable to GC due to their poor thermal stability or volatility. Polar compounds are an example of analytes that need the pretreatment of sample using derivatization processes and these together rendered GC less widely-employed compared to HPLC in the analysis of toluene and its metabolites.

Metabolism and potential biomarker of toluene: Historical background

Hippuric acid has been a historical biomarker for toluene exposure but the validity of hippuric acid as an exposure marker is questionable as non-exposed subjects (background levels) were found to contain higher levels of hippuric acid compared to exposed subjects [28-31]. The value of the hippuric acid as a biomarker of occupational toluene exposure was further challenged by the presence of benzoate in some preservatives [32, 33] as benzoate is metabolized and excreted as a hippuric acid in urine [32, 34, 35].

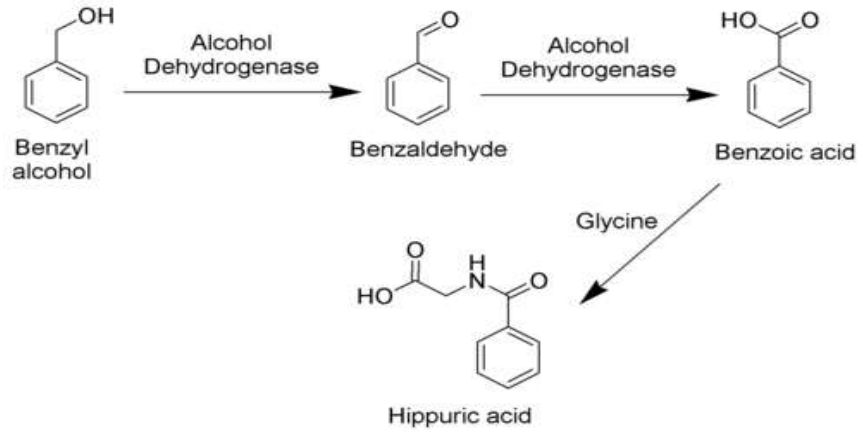
Several researchers have considered a few other possible biomarkers for toluene exposure namely *o*-cresol [27, 36, 37], benzylmercapturic acid [19, 20, 38] and toluylmercapturic acid [39]. Although hippuric acid has attracted considerable attention as an indicator of exposure to toluene, the fact that it can deliver false results of toluene exposure has prompted a number of researchers to suggest *o*-cresol be used as a biomarker, especially for the determination of low-level exposures to toluene. However, it was found that urinary *o*-cresol demonstrated false results too when it involved smoking and drinking counterpart [40] where it can reduce the amount of this chemical particularly at low levels of toluene exposure.

More recently, researchers found a new specific biological marker for toluene metabolites namely S-benzylmercapturic acid (SBMA) [19, 20, 41]. SBMA was found to be a more specific biomarker compared to hippuric acid and *o*-cresol. It was found that SBMA was dependent only on airborne toluene and not effected by food preservative, smoking and drinking habit even at low level of exposure to toluene [42].



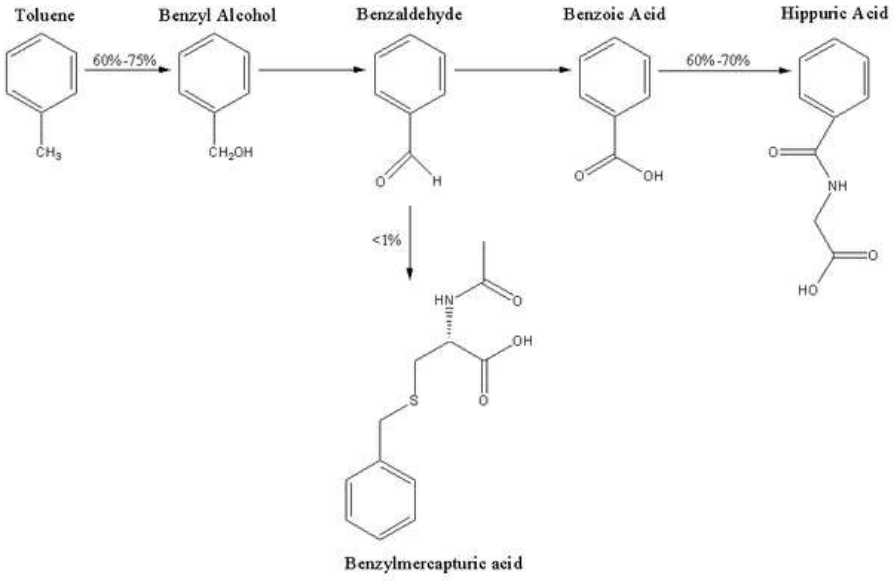
Toluene metabolism

According to Park et al. [43], toluene is the major solvent with the most documentation of abuse, possibly because of its relative low risk of sudden death and the ease of detection in blood. When many aromatic compounds such as toluene and benzoic acid are taken internally, they are converted to hippuric acid by reaction with the amino acid glycine [43]. In another paper, Anderson et al. [44] explained in detail that the principal metabolite of toluene is benzoic acid (approximately 80% of dose) which is conjugated with the glycine to form hippuric acid and directly excreted in urine (half-life of 2-3 hours).



Toluene can be absorbed into the blood stream from the lung and the gastrointestinal tract and through the skin and mucosa. In late 1980s, Ameno et al. described that the brain and liver serve as reservoir for toluene [45]. A few years later, Yamazaki et al., in their work explained that more than 80% of absorbed toluene is metabolized by mix-oxidase enzyme system to benzoic acid and hippuric acid in the liver and kidney before excretion into the urine. Meanwhile, some absorbed toluene (0.4 – 1.1 %) is hydroxylated and excreted as a mixture of *ortho*-, *para*-, and *meta*-cresol. A schematic diagram for toluene metabolism in humans is shown in Scheme 1 [46].

Later on, Zuppi et al. [47] stated that the hippuric acid is biosynthesized from glycine, benzoic acid and CoA by enzymes located in the mitochondrial matrix of liver and kidney cells. This metabolic pathway provides an alternative flux of nitrogen from the usual urea precursors (ammonia, alanine and glutamate) to glycine and it is utilized for the detoxification of aromatic compounds such as toluene. Toluene is very hazardous to our health, with the potential of inflicting considerable pain and suffering until death to the sniffer.



Following inhalation or oral exposure to toluene, approximately 60 – 75 % of absorbed toluene is metabolized to benzoic acid. The initial step involves side chain oxidation to benzyl alcohol by cytochrome P450 enzymes (Scheme 2). Benzyl alcohol is further oxidized to benzoic acid by alcohol dehydrogenase and aldehyde dehydrogenase. Benzoic acid is subsequently conjugated with glycine to form hippuric acid. Benzoic acid may also be conjugated with glucuronic acid to form benzoyl glucuronide in the urine. Less than 1% of absorbed toluene undergoes ring hydroxylation to form *o*-, and *p*-cresol, which are excreted in the urine as glucuronide or sulphate conjugates as reported by Amorim et al. [48].

Scheme 1. First step of toluene metabolism [46]

Scheme 2. Second step of toluene metabolism [46]

Scheme 3. Complete toluene metabolism in urine [47]

According to the World Health Organization (WHO), following inhalation, toluene is predominantly excreted in the urine as the metabolite, hippuric acid. Approximately 7 – 20 % of absorbed toluene is eliminated in air unchanged. Following a single acute exposure, toluene and its metabolites are almost completely eliminated within 24 hours [49].

Scheme 3 illustrates a full steps of toluene metabolism in urine. Approximately 60 to 75 % toluene is converted to benzyl alcohol before further oxidized to benzaldehyde. Less than 1 % benzaldehyde is converted to benzyl mercapturic acid while the rest is converted to benzoic acid. About 60 to 70 % hippuric acid is produced from conjugating benzoic acid with glycine.

Analytical methods: Sample collection and storage

It is a good practice that biological specimens should be stored at 4 ºC before transported to the laboratory. Exceptions to this include hair and nail, which are stable at room temperature and filter paper with adsorbed dried blood, which is a convenient way of storing and transporting blood samples for specified analyses whenever refrigerated transport and storage is not feasible [50].

Each specimen bottle should be securely sealed to prevent leakage and individually packaged in a separate plastic bag. Particular attention should be given to the packaging of the samples to be transported by post or courier in order to comply with current health and safety regulations. Sample volumes or amounts smaller than those indicated in Table 1 are often sufficient to complete the analyses required. However submission of very small sample may result in reduced sensitivity and scope of the analyses undertaken but nevertheless such samples should always be forwarded to the laboratory. Any residual specimen should be kept at -20 ºC or below until investigation of the incident has been concluded.

Table 1. Sample requirements for general analytical toxicology

Sample	Notes
Whole Blood	10 mL (lithium heparin or EDTA tube - use fluoride/oxalate/citrate if ethanol is suspected; plastic tube if paraquat is suspected; glass or plastic tube with minimal headspace if carbon monoxide or other volatile is suspected)
Plasma/Serum	5 mL (send whole blood if volatiles, metals and some other compounds are suspected)
Urine	20 - 50 mL (plain bottle, sodium fluoride)
Gastric contents	25 - 50 mL (plain bottle, no preservative)
Other samples	Vitreous humor (maximum available collect separately from both eyes), bile (2 mL) or liver (about 5g) can be a substitute for urine postmortem work. Other tissues (brain, liver, kidney, lung, and subcutaneous fat – 5g) may also be valuable, especially if organic solvents or other volatile poison is suspected.

Preliminary Test

Color tests are useful in minimizing the use of equipment and expertise required. However, the reagent has to be easily available and stable. Sensitivity is limited and the tests are usually applicable only to urine. It is possible to extract the metabolite and apply the color test to the residue, though this is rarely done for biological fluids. False negatives are a risk even when a test is used for its intended purposes in appropriate samples. Positive results with poison, metabolite or others serve to indicate the need for quantitative measurement. Urine samples are commonly used for preliminary test. This is because of urine is easy to collect and it can be useful to provide qualitative information about exposure to a particular substance (Table 2).

Researches in toluene exposure are extensive whether they involve quantitative or qualitative analyses. One of the most varied tools for qualitative analysis is a color test method. Many years ago, only a few of researchers

employed color test method to determine toluene metabolites [51]. Among the metabolites of toluene, hippuric acid is a traditional biomarker for the biological monitoring of toluene exposure but both *o*-cresol and hippuric acid are used by the endogenous and dietary sources [52].

Table 2. Color test methods for determination of toluene metabolites in urine

Sample Pre-treatment	Procedure[a]	Analysis Method	Color Changes	Detection Limit	Ref.
Extracted three times with methanol	Detection of hippuric acid based upon azlactone formation resulting from the reaction of an aldehyde with hippuric acid.Hippuric acid was converted to a deep orange-colored azlactone, 2-phenyl 4- (p-dimethylamino)benzal 5-oxazolone, by treatment of hippuric acid with acetic anhydride and p-dimethylamino-benzaldehyde.	Colorimetry method. λ_{max} = 410 nm	Yellow to deep orange color.	N.R	[52]
Acid extraction of urine sample	0.5 mL hippuric acid of pyridine (Pyr) solution mixed to 0.2 mL of benzenesulphonyl chloride (BSC). The solution was allowed to stand >20 min. It is then diluted to 5 mL with chloroform and recorded at 380 nm.	Colorimetry method. λ_{max} = 420 (red color) and 360 nm (orange color).	Yellow to orange red color within 40 min.	0.135 mg/mL	[53]
No extraction	0.5 mL of urine and 0.5 mL of Pyr were mixed and added with 0.2 mL of BSC and mixed for 5 s with a vibration mixer. The colored solution was allowed to stand for 30 min at room temperature, diluted to 5 mL with ethanol and mixed. The solution was centrifuged for 5 min to remove a little turbidity. The absorbance was determined at 410 nm in ethanol.	Colorimetry method. λ_{max} = 410 nm	Yellow to deep red color within 20 min.	0.20 mg/mL	[54]
No extraction	Urine sample (0.1 or 0.2 mL) was mixed with 0.25 mL Pyr, and subsequently with 0.1 mL BSC. Then, 0.125, 0.25, 0.5. 1.0 or 1.5 mL ultra-pure water was added.	Colorimetry method. λ_{max} = 410 nm	Yellow to deep red	0.125 mg/ml	[55]
No extraction	0.1 mL of urine added with 0.25 mL Pyr and 0.1 mL BSC and 1.0 mL distilled water.	Spectrophotomety UV at λ_{max} = 417 nm	Yellow to deep red within 1 min.	0.125 mg/ml	[11]

[a] Pyr, Pyridine; BSC, Benzenesulphonyl Chloride. N.R; Not reported.

Color test methods for hippuric acid have been developed since 1950s and further investigated by researchers in early 1980s. The founders of color reaction for hippuric acid, Gaffney et al. employed the formation of azlactone resulting from the reaction of an aldehyde with hippuric acid [51]. In this reaction, hippuric acid was converted to a deep orange colored azlactone, 2-phenyl-4-(p-dimethylamino) benzal-5-oxazolone by treatment of hippuric acid with acetic anhydride and p-dimethylaminobenzaldehyde. Urine sample was extracted three times with methanol for sample pre-treatment. The absorption was recorded with colorimetry method at λ_{max} = 410 nm.

A few years later, Umberger and Fiorese found a new method using pyridine and benzenesulfonyl chloride to develop deep red color in the presence of hippuric acid. Urine sample was extracted using ethyl acetate before recording using colorimetric method at λ_{max} = 420 nm (red) and 360 nm (orange) with detection limit of 0.135 mg/mL [53]. An investigation using colorimetric method was also reported by Tomokuni and Ogata [54]. The procedure employed 0.5 mL of urine, 0.5 mL of pyridine and 0.2 mL of BSC that were mixed for about 5 s with a vibration mixer and the colored solution was allowed to stand for 30 min at room temperature and then diluted with 5 mL of ethanol. Then the solution was centrifuged for 5 min to remove a little turbidity and the absorbance was determined at 410 nm in ethanol. This spectrophotometer method was simple but the yellow coloration obtained was indistinguishable from the yellowish color of urine because of the ethanol dilution.

In 2005, Yoshida et al. [55] modified the color test method that was established by Umberger and Fiorese, [53]. It involves a new color test method where the addition of pyridine and benzenesulfonyl chloride with existing distilled water develops a deep red color in the presence of hippuric acid. The colorimetric method for urine hippuric acid investigated in this study is based on the color reaction (reddening) of the specimen, which can be judged more clearly than the method of Tomokuni and Ogata [54] which involves a change to yellowish color. This method required only several minutes and used only commercially-available reagents without any pre-treatment. This work demonstrated the color changed but they it did not illustrate the color changes with different concentrations of hippuric acid. Besides that, the work was only focused on samples of people exposed to toluene and did not provide the equation and reaction of the color test method [55].

More recently, Yacob and Zinalibdin, developed a simple mobile test kit for screening and detecting glue sniffers based on the color test method [11]. The results obtained using the kit is are similar to those using UV–Vis result but it technique is faster with the results obtained within only 5 min and is also comparable to the dip strip urine drug testing kits. Thus, this kit can be a fast and in situ tool to help the National Anti-Drug agency for in the screening and detecting glue abusers among school students and teenagers [11].

Sample pre-treatment: Hippuric acid sample pre-treatment prior to HPLC

Liquid-liquid extraction (LLE) has been used for sample pretreatment of toluene metabolites. Poggi et al. illustrated the extraction procedure was performed on acidified urine, after addition of 4-hydroxybenzoic acid as internal standard using a butylchloride/isopropanol mixture and 0.5 mL of the organic layer was dried under nitrogen flow. The residue obtained was dissolved in 0.1 mL water/acetonitrile and 5 µL was injected into a HPLC [15]. Matsui et al. in his research used ethyl acetate for partial clean-up of biological samples [56]. Bevine et al. conducted a sample pretreatment which is made alkaline and extracted stepwise with methylene chloride and ethyl acetate and the addition of internal standard (3-methoxysalicylic acid) in plasma samples [57]. Meanwhile, several works have demonstrated sample pretreatments that do not require extraction step but effected only by dilution with distilled water followed by centrifugation [14, 58, 59].

Liquid-liquid-liquid microextraction (LLLME) method was developed for the determination of hippuric acid in urine and serum sample [60]. The analyte was extracted from an acidic aqueous sample solution (pH 3) through a thin layer of organic solvent membrane and back-extracted to a basic acceptor drop (pH 11) suspended on the tip of a 10-µL HPLC syringe in organic layer. Green technology was adapted in this method that offers the advantages of being simple, sensitive and inexpensive.

A simple molecularly imprinted polymer coated with modifed polysulfone membrane was introduced by Moein et al. [61]. The membrane was utilized for online extraction of hippuric acid in biological matrices. This method provided fast, sensitive, selective and robust sample preparation method for hippuric acid in biological fluids.

Hippuric acid sample pre-treatment and derivatization procedure prior to gas chromatography

Methods for the determination of hippuric acid based on GC usually require a derivatization procedure in the sample pretreatment step. A number of researchers have established the derivatization procedure for the analysis of toluene metabolites. Some researchers used diazomethane but it is an explosive, carcinogenic and highly toxic reagent [62-64].Other researchers used expensive substances as reagents to obtain methylsilyl derivatives which

require frequent cleaning of the GC detector [65, 66] and these derivatives are moisture-sensitive. In 1991, De Carvalho et al. [23] proposed the derivatization of hippuric acid using methanol in acid medium (HCl), a low-cost and low toxicity reagent. About ten years later, Kongtip et al. modified the method using a GC equipped with a DB-1 capillary column and a flame ionization detector [25]. The method successfully separated and eluted methyl esters of hippuric acid, *o*-, *m*- and *p*-methylhippuric acid within 11 min.

Extraction step is often the first step for the detection of toluene metabolites using GC. Before this century, many researcher used LLE as extraction step where the sample was acidified with acid and then the analyte was extracted using ethyl acetate [23, 25, 62-64]. The organic layer was collected for the derivatization step.

A novel approach of the extraction of hippuric acid using solid phase extraction [67] has been introduced. In the approach, an online automatic method for extraction of hippuric acid from urine sample using µ-solid phase extraction with polypyrrole adsorbent system was established [68]. However, post derivatization of hippuric acid by conversion to its methyl ester with methanol in hydrochloric acid was still needed for monitoring the toluene metabolites using GC.

Cresol pre-treatment prior to gas chromatography

The urinary cresol is present in urine sample usually as sulphate or glucuronic acid conjugates. For this reason, hydrolysis and neutralization steps are required to determine the urinary cresol. Truchon et al. in 1996 described a sensitive and reproducible gas chromatographic procedure for the determination of urinary *o*-cresol as follows. Acid hydrolysis was the first step encountered to produce unconjugated *o*-cresol. After extraction with methylene chloride at pH 2, the organic layer was concentrated by evaporation and the sample was analyzed by GC-flame ionization detection [27].

Solid phase microextraction (SPME) was established for determination of urinary *o*-cresol. Acid-hydrolyzed step is still required for the sample and a CW/DVB fiber was directly immersed in the sample solution for 20 min under magnetic stirring for the extraction. This SPME device was then introduced into chromatography injector port where the analyte is thermally desorbed from the fiber [26].

Analysis by High Performance Liquid Chromatography

Numerous sample pretreatment and HPLC methods have been proposed for the separation of toluene metabolites in biological samples, some of which are listed in Table 3. Several researchers have worked on the determination of hippuric acid in urine and blood samples. A few of them studied on the determination of hippuric acid in urine and blood for exposure of toluene, xylene and other chemicals for occupational and safety health. Ogata and his co-workers [59] determined hippuric acid as indicator of toluene exposure by HPLC. They used mixed solution of methanol-water-acetic acid (20: 80: 0.2) as the mobile phase and UV detection at 254 nm and without solvent extraction and pretreatment. Their results showed a low detection limit of 0.2 µg and analysis time of < 30 min.

HPLC method for simultaneous quantitative determination of the urinary metabolites of toluene, m-xylene and styrene (hippuric acid, *m*- methyl hippuric acid, phenylglyoxylic acid, mandelic acid) was described by Poggi et al. [15]. In the method, the residue obtained was dissolved in 0.1 mL of water/acetonitrile and 5 µL of the solution was injected into a HPLC system for analysis. Absorbance measurement was performed at 225 nm using UV detector. All metabolites were clearly separated within 12 min [15].

The direct determination of hippuric acid (HA) and *o*-, *m*- and *p*-methylhippuric acids (MHA) in the urine, metabolites of toluene and *o*-, *m*- and *p*-xylenes by HPLC have been described and established. A mixed solution of methanol-water-acetic acid (80: 20: 0.2) containing tetra-*n*-butylammonium bromide (0.2 % w/v) as mobile phase was used. Concentrations of HA and MHAs were estimated from their peak height at a wave length of 225 nm. Urine can be analyzed directly without solvent extraction or pretreatment to obtain complete separation of HA and *o*-, *m*- and *p*-MHAs. Authentic samples of glycine conjugates, HA and *o*-, *m*- and *p*-MHAs, in water and urine were well separated from each other and eluted within 25 min [69].

An automated HPLC method for the direct determination of urinary concentrations of hippuric acid (HA), and *o*-, *m*- and *p*-methyl hippuric acids (MH As), metabolites of toluene and *o*-, *m*- and *p*-xylenes, and of urinary phenyl glyoxylic acid (PGA) and mandelic acid (MA), metabolites of styrene or ethylbenzene have been described. Methanol was added to urine, the mixture was centrifuged and the supernatant was injected into HPLC A stainless-steel column packed with octadecyl silanized silicate was used and the mobile phase was a mixture solution of 5 mM potassium phosphate monobasic-acetonitrile (90:10) The method is simple and specific. Urine can be analyzed without solvent extraction. Analysis can be performed satisfactorily within 45 min for samples containing HA, MHAs, PGA and MA, and within 15 min for those containing HA, PGA and MA [70].

Matsui et al. [56] used HPLC for the determination of hippuric acid in urine sample. The separation was carried out on a reversed-phase column using 20 % methanol in 0.01 M potassium phosphate containing 0.5 % acetic acid as the mobile phase. The column effluent was monitored using UV detection at 254 nm. Hipuric acid was separated from other normal urine constituents in less than 10 min.

Kubota et al. [58] described the monitoring of hippuric acid and benzoic acid simultaneously in human biological fluids and considered it to be clinically important. They developed a simple and accurate HPLC method for the simultaneously determination of hippuric acid and benzoic acid in human urine and plasma. This research required no extraction step. Aliquots of urine and plasma were added to a solution of internal standard (*o*-chlorobenzoic acid) in acetonitrile and directly injected into a HPLC system using an acidic (pH 2.7) eluent and UV detection at 235 nm.

A method has been developed for the isocratic HPLC analysis of hippuric acid in human blood plasma. After the addition of internal standard (3-methoxysalicylic acid), plasma samples were made alkaline and extracted stepwise using methylene chloride and ethyl acetate. The detection limit was 50 pmol of hippuric acid per mL plasma. This work was conducted on samples from human occupationally exposed to organic solvent as described by Bevine et al. [57].

A simple HPLC procedure was described as a method for simultaneous determination of the six metabolites in urine namely hippuric acid , *o*-, *m*- and *p*-methylhippuric acid, phenylglyoxylic acid and mandelic acid. Urine analysis was selected in the study because of its non-invasive nature in sampling with minimal burden on exposed workers. A mobile phase of methanol-acetic acid-water (200: 8: 792) by volume was allowed to flow at a rate of 0.85 mL/min and monitored at a wavelength of 257 nm [13].

Yang [14] described a simple method for the simultaneous determination of creatine, uric acid, creatinine and hippuric acid in urine using HPLC. Chromatography was performed with a 0.02 M KH_2PO_4 as a mobile phase and UV detection at 220 nm without any extraction method. This method was applied for biomedical application to analyze urine samples from normal subjects and some patients. A HPLC method for determination of hippuric acid in urine was described by Yoshida et al. [55]. The mobile phase was 30% methanol containing 0.1% acetic acid and UV detection at 225 nm. No extraction method was used in this work. Urine samples were centrifuged (12 000 rpm, 10 min) and 5 µL supernatant was injected for analysis. This method was applied to the analysis of glue sniffer's urine [55].

A simple method for the simultaneous determination of hippuric acid and benzoic acid in urine using reversed-phase HPLC was described by Yacob and Zinalibdin [71]. Chromatography was performed with a mobile phase of mixed solution methanol-water-acetic acid (20: 80: 0.2) and UV detection at 254 nm in < 10 min. The detection limit of this method was 0.01 mg/L for hippuric acid and 0.06 mg/L for benzoic acid. This method was applied to the analysis of urine samples from the suspected of toluene abuser or glue sniffer among secondary school students. Meanwhile, Lee et al. [18] developed a simple and rapid HPLC-UV method for the simultaneous determination of eight urinary metabolites which is hippuric acid, mandelic acid, *o*-, *m*- and *p*-methylhippuric acid and *o*-, *m*- and *p*-cresols. All eight metabolites were successfully resolved within 5 min in 10 % aqueous ethanol containing 0.3 % acetic acid and 1.6 % β-cyclodextrin, using a gradient flow rate 1.0 - 5.0 mL/min [18].

Analysis of VOCs by gas chromatography

Gas chromatography (GC) offers some advantages for determination of volatile substances such as toluene due to its easy procedure. Selected examples of conditions for sample pretreatment and GC separation of toluene metabolite in biological sample are listed in Table 4. Head space method can achieve good separation of volatile solvents from the biological matrix [22]. In addition, the determination of toluene and its metabolites was not a problem as the GC peaks were well separated [21].

De Carvalho in his work [23] described the determination of hippuric acid by GC-flame ionization detection. This research proposed the derivatization of hippuric acid using methanol in acid medium which is a low cost reagent with a low level of toxicity. After the extraction procedure, hippuric acid and internal standard were converted to the methyl esters using methanol in acid medium. All methyl ester were detected in < 45 min [23]. Besides that, a sensitive and reproducible GC procedure for the quantitative determination of urinary o-cresol was also described [27]. The first step involves acid hydrolysis (2 N HCl, 100 ºC, 10 min) which yields unconjugated *o*-cresol. After extraction (methylene chloride, pH 2), the organic layer is concentrated by evaporation and samples are analyzed by GC-flame ionization detection with a DB-5 column. The detection limit of the method is 0.36 µmol/L [27].

Determination of hippuric acid and *o*-, *m*- and *p*-methylhippuric acid in urine was described by Kongtip et al. [25]. These metabolites were extracted using ethyl acetate and then derivatized it to methyl ester derivatives and quantitated using a gas chromatography flame ionization detector and DB-1 capillary column. The derivative of hippuric acid and *o*-, *m*- and *p*-methylhippuric acid were well separated within 11 min [25].

Simultaneous determination of hippuric acid, *o*-, *m*- and *p*-methylhippuric acids, mandelic acid and phenyl glyoxylic acid was developed and described by Ohashi et al. and it proved to be a fast and sensitive technique [72]. These metabolites were converted to methyl esters derivatives using methanol in hydrochloric acid and then quantitated by gas chromatography-mass spectrometry (GC-MS) with selected ion monitoring using a DB-1 capillary column. The target analytes were quantitatively analyzed and resolved within 19 min with low detection limit.

Table 4. Conditions for sample pretreatment and GC separation of toluene metabolites in biological sample

Sample Pre-treatment[a]	**GC Procedure**[b]	**Target Analyte**[c]	**Derivatization Reagent**[d]	**GC Temperature**[e]	**Detection Limit**[f]	**Ref.**
Urine was acidified with 0.5 N HCl and extracted with ethyl acetate 20 min in horizontal shaker. Sample was centrifuged at 4000 rpm for 4 min and organic phase was collected.	SE-30 in Chromosorb W-Silanized glass column using GC-FID	PGHA, OA, *o*-mHA, *p*-mHA, BA, SA, MA, *m*-cresol	MeOH in HCl medium.	Carrier N_2 : 40 mL/min- TPGC Oven : 200 ºC Injector: 240 ºC Detector: 240 ºC	N.R	[23]
Hydrolyzed (2N HCl, 100ºC, 10 min) and extracted with methylene chloride, pH 2. Organic layer evaporated and collected	DB 5-column using GC-FID	o-cresol	Hydrolyzed using HCl and incubated in oven at 100 ºC for 10 min.	Carrier N_2 : 40 mL/min TPGC 30 ºC for 12 min and then increased 2ºC/min to 93 ºC	o-cresol: 0.36 µmol/L	[27]
1 mL of urine mix with 1 mL distilled water and acidified with 0.5M HCl then extracted with 3 mL ethyl acetate. Sample was evaporated to dryness and the residue reconstituted with derivatizing reagent and left in oven at 60ºC for 45 min. Solution was extracted with 1 mL chloroform and add 2 mL distilled water.	DB 1-column using GC-FID	HA, *o,m,p*-mHA	MeOH in HCl medium.	Carrier He: 10 mL/min Isothermal programmed Oven : 200 ºC Injector: 250 ºC Detector:250 ºC	HA: 0.05 mg/mL o,m,p-HA: 0.015 mg/mL	[25]
Acidified and extracted with diethyl ether. Sample was centrifuged at 2500 rpm for 10 min and dry incubated at 70ºC for 15 min. Next derivatize step was take part.	DB1-column using GC-MS. MA-mz:107 PHGA-mz: 105 HA-mz: 105 *o,p,m*-mHA-mz: 119	HA, o,m,p-mHA, MA, PHGA .	MeOH in HCl medium.	Carrier He: 1.8 mL/min TPGC 150 ºC for 3 min at 10 ºC/min and then increased 250 ºC for 7 min at 10º C/min Injector: 260 ºC Detector:260 ºC	HA, o,m,p-mHA, MA, PHGA : 8-27 pg/L	[72]

Table 4 (cont'd). Conditions for sample pretreatment and GC separation of toluene metabolites in biological sample

Sample Pre-treatment[a]	GC Procedure[b]	Target Analyte[c]	Derivatization Reagent[d]	GC Temperature[e]	Detection Limit[f]	Ref.
Acidified using HCl and kept in oven at 100ºC for 1 h. Hydrolyzed and adjusted pH 7 with NaOH & Na_2SO_4. Immersed with CW/DVB for 20 min under magnetic stirrer.	ZB-35 column using GC-FID	o-cresol	Hydrolyzed using HCl and kept in oven at 100ºC for 1 hour.	Carrier N_2: 8.0 mL/min Isothermal GC Oven: 190 ºC Injector: 210 ºC Detector:220 ºC	o-cresol: 0.1 mg/L	[26]
DI-SPME directly immersed in 10 mL vial for 20 min at 60ºC and under agitation for 20 min.	SLB-5 MS using GC-MS	FA, HA, m-mHA, MA, PGHA, SA trans muconic acid	Terimethyl-oxonium tetrafluoro-borate	Carrier He:1.2 mL/min TPGC 50 ºC (1min); increased at 10 ºC/min to 300 ºC (3 min).	FA: 0.9µg/mL, SA: 8.1 µg/mL, t,t-MA: 0.9 µg/mL.	[24]
Centrifuge urine at 4500 rpm for 10 min. µ-SPE system condition with 2.0 mL MeOH and 3.0 mL of Britton-Robinson buffer (3.0×10^{-3}mol/L, pH2). 0.1 mL aliquot sample dilute with Britton Robinson buffer at 10 mL volumetric flask. Preconditioned catridge 20 mg polypyrrole and washed with Britton Robinson buffer.	CP Sil 8 CB using GC-FID	HA in urine and water	MeOH in HCl medium.	Carrier He:10 psi. TPGC. 80 ºC (1 min) at 20 ºC/min to 140 ºC hold for 1 min at 20ºC/min then increased 280ºC (10 min). Injector: 280ºC Detector:280ºC	HA: Urine: 16.5 ng/mL Water: 12.1 ng/mL	[68]

[a]HCl, Hydrochloric acid; NaOH, Sodium hydroxide; Na_2SO_4, Sodium sulfate, CW/DVB, Carbowax-divinylbenzene; Direct immersion-solid phase microextraction, DI-SPME; MeOH, Methanol.

De Paiva et al. [26] developed a method for the determination of urinary *ortho*-cresol using solid-phase microextraction (SPME), followed by capillary GC-flame ionization detection (GC/FID). After optimization of the SPME variables and validation of the method, it was applied to analysis of *o*-cresol in urine collected from 27 workers exposed to solvents in automotive repair shops. The maximum extraction efficiency was obtained using a carbowax-divinylbenzene (CW/DVB) fiber (70 µm), immersed 20 min in acid hydrolyzed urine added with 3 g

Na_2SO_4 at pH 7.0 and under magnetic stirring. The SPME-GC/FID method –proved to be fast, simple and can be applied to the occupational toluene biomonitoring.

A method for the determination of the organic acids directly in the urine employing derivatization with trimethyloxonium tetrafluoroborate as a methylating agent and sequential extraction by head space and direct immersion-solid phase microextraction is reported. Furoic acid, hippuric acid, methylhippuric acid, mandelic acid, phenylglyoxylic acid and *trans*-muconic acid contained in urine and determined by GC-ion trap-mass spectrometry/tandem mass spectrometry analysis within 20 min [24].

Meanwhile, Ahmadi et al. [68] described a rapid, simple and high sensitive method for extraction of hippuric acid from human urine samples by using an automated micro solid phase extraction system (µ-SPE). However in order to increase sensitivity of gas chromatography with flame ionization detector, a post derivatization procedure was developed. In this work, a polypyrrole was synthesized by chemical oxidation of the pyrrole monomer in non-aqueous solution and applied as an excellent and efficient sorbent for µ-SPE. This method was successfully used to analyze trace amounts of HA in human urine samples without any interference from coexisting.

Conclusion

Biological monitoring of toluene exposure is a growing field of interest in toxicological and occupational laboratories. Chemical and biomedical analysts should be aware and have a broad knowledge to choose the most appropriate analytical method because it can remain a major problem. They are no ideal method *per se* but the best method selected should be able to deliver good results and compromise between several conflicting requirements.

Preliminary test is one of the indicators for screening purposes. It could be used on site for qualitative analysis with fast results using the mobile kit. The color test has proved a powerful method for preliminary test since early this decade. However, this method is not sensitive for low concentrations of toluene exposure and it can give a false results. Thus, quantitative instrumental analysis is still required for enforcement and research purposes such as using GC-MS and HPLC. Indeed, in these situations, cost, length, complexity and workload problems generated by the analytical method are not necessarily major concerns. In contrast, for the routine monitoring of toluene exposure and forensic cases in industrial environment and enforcement agency, the cost per determination, simplicity and automation will be important considerations.

HPLC appears to be the primary choice for the determination of toluene metabolites. The apparatus is relatively economical, automatable and sufficiently versatile to be used for other determination in related areas such as drug monitoring or clinical toxicology that are currently of interest in the same laboratory. As previously indicated, the analyst now has a choice between several methods, well adapted to routine and simultaneous determination of urinary metabolites of some common volatile solvents that require biological monitoring. Moreover, HPLC is also becoming an attractive tool in the growing field of more elaborate approaches with new urinary markers such as specific conjugates or isomers.

Abstract

Ultra-performance liquid chromatography (UPLC) is more effective than high performance liquid chromatography in terms of analysis speed and sensitivity. This paper presents a feasibility study on forensic red pen inks analysis using UPLC. A total of 12 varieties of red ballpoint pen inks were purchased from selected stationary shop. For each variety, four different individual pens were sampled to provide intra-variability within a particular variety of pen. The proposed approach is very simple that it only involved limited analysis step and chemicals. A total of 144 chromatograms were obtained from red ink entries extracted with 1.5 mL 80 % (v/v) acetonitrile. Peaks originated from pen inks were determined by comparing the chromatograms of both blank paper and blank solvent against that of ink samples. Subsequently, one-way ANOVA was conducted to discriminate all 66 possible pairs for red pen inks. Results showed that the proposed approach giving discriminating power of 95.45 %. The outcome of the study indicates that UPLC could be a fast and simple approach to red ballpoint inks analysis.

Keywords: forensic ink analysis, ballpoint pen inks, ultra-performance liquid chromatography

Abstrak

Kromatografi cecair berprestasi Ultra (UPLC) adalah lebih berkesan dari kromatografi cecair berprestasi tinggi dari segi kelajuan analisis dan kepekaan. Kertas ini mempersembahkan kajian kebolehlaksanaan pada analisis dakwat pen merah menggunakan UPLC. Sebanyak 12 jenis dakwat pen mata bulat merah dibeli dari kedai alat tulis yang terpilih. Untuk setiap jenis, empat batang pen telah disampel untuk memberi maklumat tentang intra-variasi bagi suatu jenis pen. Pendekatan yang dicadangkan adalah mudah kerana ia hanya melibatkan langkah analisis dan bahan kimia yang terhad. Sejumlah 144 kromatogram telah diperolehi dari dakwat tulisan merah yang diekstrak dengan 1.5 mL 80 % (v/v) asetonitril. Puncak yang berasal dari dakwat pen ditentukan melalui perbandingan antara kromatogram kertas kosong dan pelarut kosong dengan yang diperolehi dari sampel dakwat. Seterusnya, ujian ANOVA sehala telah dijalankan untuk membezalayan kesemua 66 pasangan dakwat pen merah yang terbentuk. Keputusan menunjukkan pendekatan yang dicadangkan memberi 95.45 % kuasa pembezalayan. Hasil kajian ini menunjukkan UPLC dapat dijadikan satu pendekatan yang cepat dan mudah untuk analisis dakwat pen mata bulat merah.

Kata kunci: analisis dakwat forensik, dakwat pen mata bulat, kromatografi cecair prestasi ultra

Introduction

Over recent years, forensic document examination is an important area of forensic science and its contribution towards solving crimes is significant. On one hand, the invention of computer has resulted in reducing usage of writing instruments and paper as a form of proof, agreement and communication. Nevertheless, writing instruments

like ballpoint pen and gel pen are still widely used in documentation [1]. Around 80 % of the questioned documents contain ballpoint pen ink [2]. On the other hand, the forensic analysis of ballpoint pen inks is a frequently encountered at questioned documents examination and its contribution towards solving crimes is significant. For that reason, it is vital to have a fast and simple ink analysis method capable of providing high differentiation power.

Ballpoint pen ink is a complex mixture of different types of chemicals. Inks produced by writing instrument manufacturers are specially formulated depending on their applications. Different kinds of writing instruments have their own writing mechanisms. In addition, characteristics such as color, flow capacity, viscosity and drying time are also taken into account [3]. Therefore, the final composition of inks can be quite complicated. In general, ballpoint pen ink comprises of 50 % solvent, 25 % dyes as well as 25 % resins and other additives [4]. In most cases, ink analysis always focuses on dye components because of their ability to absorb light of different wavelength [5].

Ink analysis aimed at determining the age of a questioned document and identifying the kind of writing instrument/inks used to produce the questioned document. Methods of ink analysis can be divided into destructive and non-destructive. Zieba-Palus and Kunicki reported that 95 % of ballpoint pen can be classified according their varieties via Fourier-transform infrared (FTIR) and Raman spectroscopy [6]. Recently, Lee et al. have proposed a new and non-destructive method for systematic analysis black ballpoint pen inks using micro-ATR-FTIR spectroscopy [7-9]. Nevertheless, non-destructive methods seldom provide satisfactory results. Most of the time, chromatographic techniques such as thin layer chromatography (TLC) and high performance liquid chromatography (HPLC) could assist in further identification of pen ink's source. For example, Djozan et al. successfully differentiate 41 blue ballpoint pens via TLC coupled with image analysis [10]. Feasibility of HPLC for blue ballpoint pen ink classification has been studied as well [11, 12]. While Neumann and Margot have investigated the feasibility of high performance thin layer chromatography (HPTLC) for blue ballpoint pen inks [13, 14].

This study was aimed at exploring advantages of ultra-performance chromatography (UPLC) for forensic ink analysis purpose in terms of simplicity. There were two differences between this paper against two other similar papers published recently [15, 16]. Firstly, this paper present analysis of red ballpoint pen inks that is still very rare being studied. Secondly, the approach proposed here give emphasis on simplicity that we only use chemicals that are readily available in any analytical laboratory and do not apply any advanced statistical techniques such as Principal Component Analysis. In addition, UPLC is well known for its high resolution and faster separation speed [17].

Materials and Methods

Sample preparation

A total of 12 different varieties of red ballpoint pens were selected to be studied. Four different individual pens were sampled for each variety of pens. Table 1 shows the details and identification number of the pen samples. White paper template (Double A premium copy paper, A4 size, 80 gsm, Thailand) was prepared as well. Both pens and paper were brought from a selected stationary shop. Sample pen was prepared using similar methods as described in [16]. Every individual pen was used to write "HUNDRED THOUSAND ONLY" (measured approx. 50 mm x 5 mm) three times on piece of white copy papers. Ink was extracted right after 2 hours of its preparation in the same day to avoid variations introduced by ink ageing process.

UPLC analysis

Ink entry prepared with the red ballpoint pen inks were cut out and eluted with acetonitrile (HPLC grade, Fisher Scientific UK Ltd) and distilled water. All analysis was carried out on Waters® ACQUITY UPLCTM system that consisted of the ACQUITY UPLC Binary Solvent Manager, the ACQUITY UPLC Sample Manager and the Waters 2996 Photodiode Array Detector (PDA) with a low volume flow cell. The ACQUITY UPLC column BEH C18 (2.1 x 50 mm) with 1.7 mm particle size was used to separate the ink components. Injection volumes for all samples were set to 7.5 uL. Two types of mobile phases used were acetonitrile (HPLC grade, Fisher Scientific UK Ltd) and distilled water (solvent B). After several times of trial and error, the time-dependent, gradient elution protocol was established. The mobile phases were run with a flow rate of 0.20 mL/min for a period of eight minutes. Details of gradient elution system were listed in Table 2. To collect as much information as possible, the chromatogram of red

inks were recorded at 205 and 279 nm. All data were acquired and processed using Waters® Empower™ chromatography data software. Chromatograms of the blank paper and blank solvent were also prepared in the same manner as the pen ink samples.

Table 1. Details and identification numbers of each selected varieties of red ballpoint pens. Each variety of pens was assigned with an identification numbers (id no.)

ID No.	Model/Brand	No. of Sample

4.50	0.20	50.0	50.00
8.00	0.20	50.0	50.00

Data analysis

As this paper aimed to propose simple analysis protocol to discriminate pen inks, no statistical technique is introduced to the data except one-way ANOVA was applied to determine the discrimination status of pen pairs based on *p*-value. Later, discriminating power (DP) was calculated using the following Equation 1 [9]:

$$DP = 1 - \frac{2M}{n(n-1)} \quad (1)$$

where *M* is the number of non-discriminated pairs of samples and *n* denotes the total number of samples. The DP is a measurement of the selectivity of the method to differentiate the pen inks analyzed [18].

Results and Discussion

Previous studies used to discriminate ballpoint pen inks based on profiling of dye components by chromatographic techniques [13, 14, 19]. Most of the dye components of red ballpoint pen inks have maximum UV-absorption above 500 nm, i.e. rhodamine 6G at 524 nm [20]. However, this study intended to investigate the possibility of discriminating red ballpoint pen inks using information obtained from components other than dyes. Therefore, all of the chromatogram of inks was only scanned between 200 and 500 nm.

Prior to discrimination analysis, all of the chromatograms of ink sample were compared against the chromatogram of blank solvent and blank paper (Figure 1) in order to identify peaks originated from pen inks only. The representative chromatograms for two red pens inks are as shown in Figure 2. A total of 39 peaks obtained from chromatogram scanned at 205 and 279 nm were determined as coming from red ballpoint pen inks. Those identified peaks were most likely due to ink components other than dyes, such as additives that included driers, plasticizers and detergents which are present at very minute amount [16].

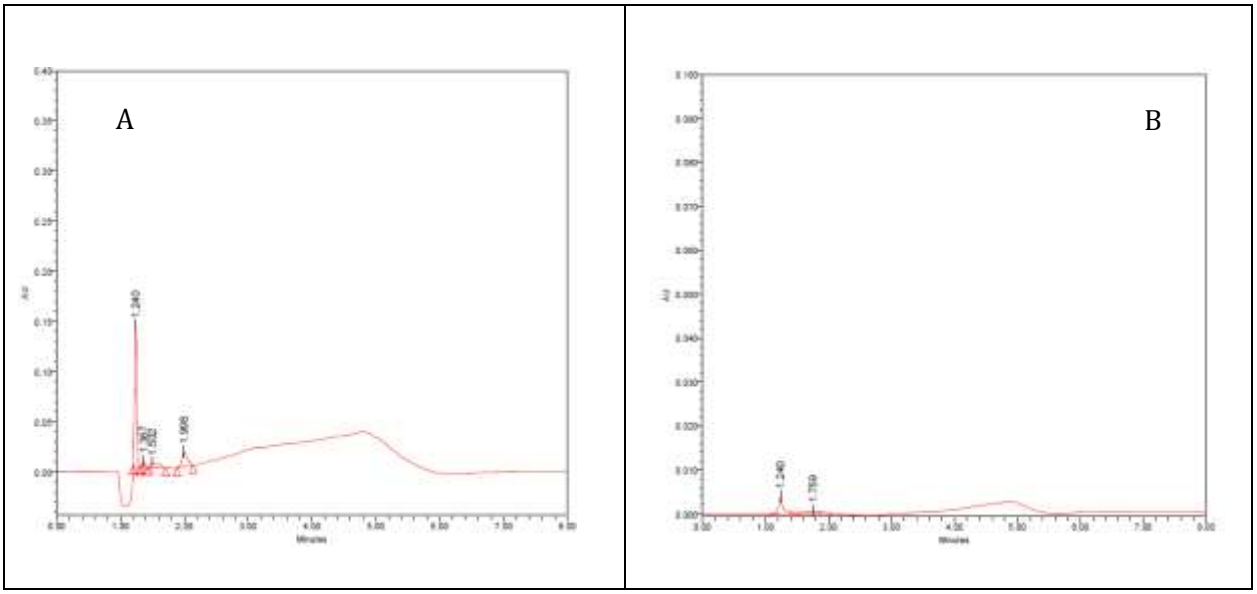

Figure 1. Chromatogram of blank. Solvent blank scanned at 205nm (A) and paper blank scanned at 279nm (B).

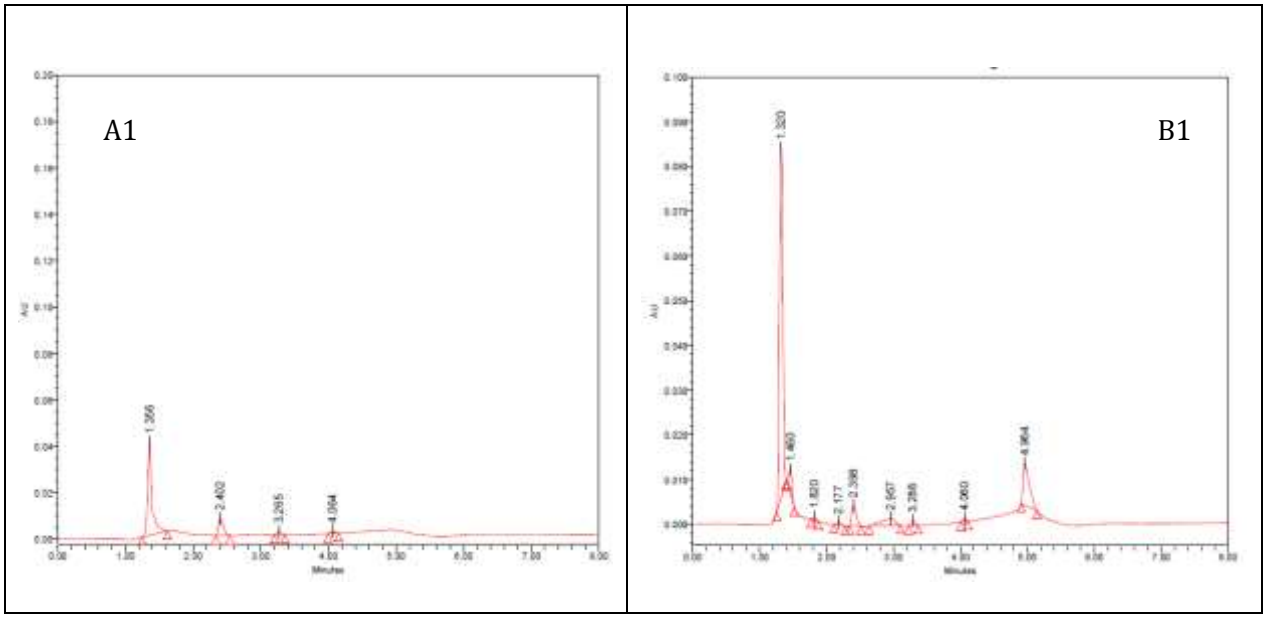

Figure 2. The representative chromatogram of two red ballpoint pen inks, i.e. A1 and B1 scanned at 279 nm.

Since we could not standardize the amount of ink deposited on paper for every ink entry, bias could be introduced if the obtained peak area value is compared directly. To ensure more reliable comparative analysis, the data was normalizing towards a single selected peak to eliminate variations occurred due to uneven initial ink deposition on paper [15]. After careful inspection on all the chromatograms, the first peak (i.e. retention time 1.280 – 1.399) in both chromatograms scanned at 205 and 279 nm was selected to be the normalization factor. It was chosen for the purpose of normalization as its peak is sharp and is the highest in the chromatogram. The peak area value of the other peaks is then divided with the normalization factor.

One-way between groups ANOVA was conducted based on the normalized peak area values. Pen pair that gives *p*-value less than 0.05 is determined to be discriminated pair and pair that give *p*-value more than 0.05 will be labelled as non-discriminated pair. The summary result of the comparative analysis between 66 possible pen-pair is shown by Figure 3. Only three pen-pair cannot be discriminated based on their chromatograms, i.e. B1-F1, B1-E1 and E1-F1. Pen-pairs that cannot be differentiated from each other may have the same or very similar formulation. In other words, this indicates the possibility of purchasing inks from a single ink manufacturer as an inks manufacturer may sell their ink to more than one instrument manufacturers [14]. In brief, the proposed approach gave discrimination power around 95.45 %.

The obtained DP is comparable to other approaches that involved much complicated analytical instrument, i.e. real time mass spectrometry (DART MS) [21] or advanced analysis tools such as image analysis [10]. In this study, differentiation of inks was based purely on the relative peak area of peaks at pre-defined wavelength range. And the objectivity of comparative analysis is secured by applying one-way ANOVA and decision is made based on the *p*-value. The approach proposed here is fast and simple.

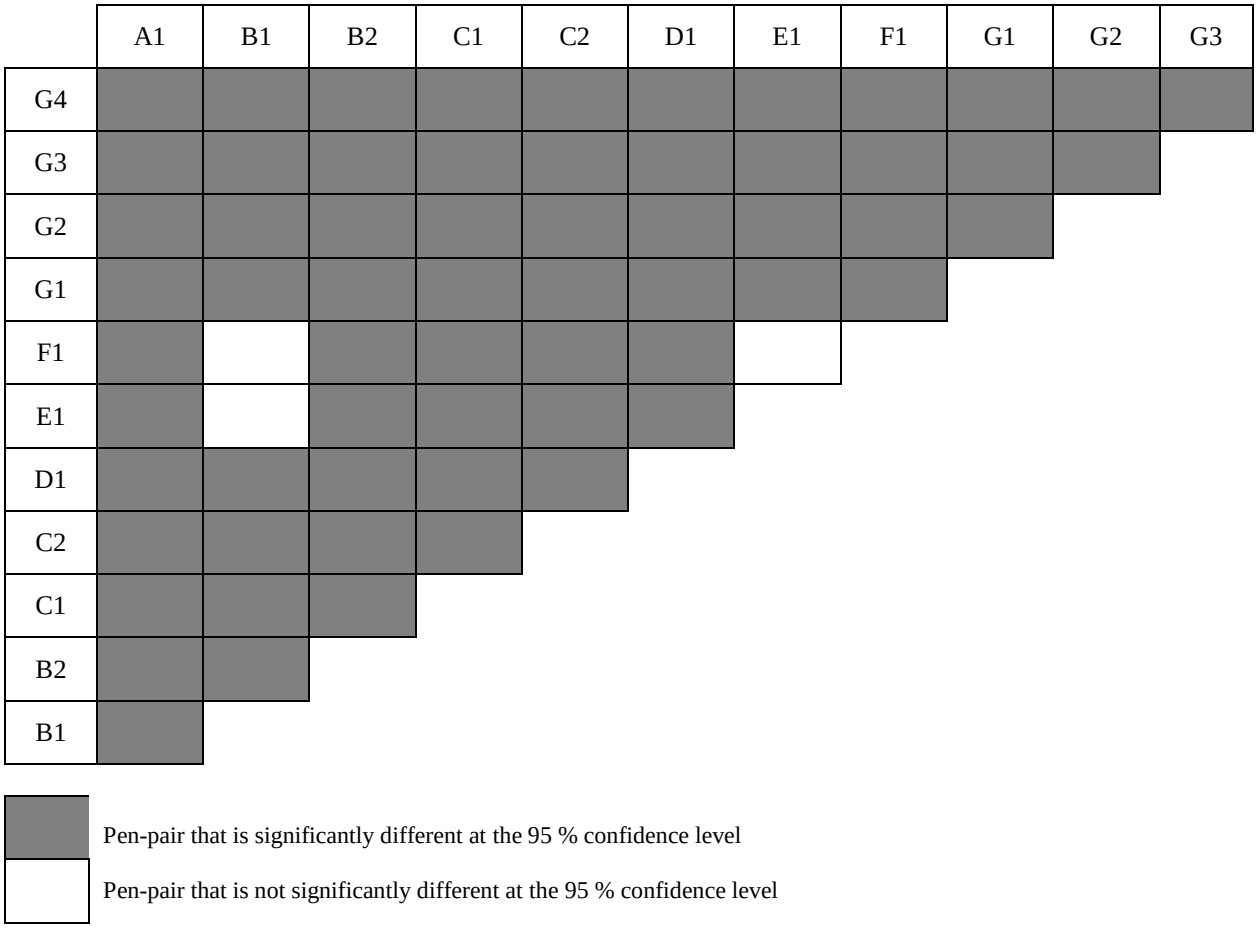

Figure 3. Matrix showing summary result of differentiation of red ballpoint pen inks based on UPLC chromatograms via one way ANOVA analysis

Conclusion

The present study showed that the written extracts from different ballpoint pens can be differentiated at satisfactory level with UPLC coupled with UV/PDA detection. The proposed technique found to be effective as it only involved common chemical, i.e. acetonitrile, and simple statistical techniques, i.e. one-way ANOVA. Besides, composition of minor components in ballpoint pen inks could be as efficient as dye components in classification of pen inks since it was supported by the high level of discriminating power calculated in this study.

Abstrak

Sebatian baru terbitan tiourea, 1-etil-1-(2-hidroksi-etil)-3-naftalen-1-il-tiourea **(3a)** dan 1-(fenil-amino)-3-naftalen-1-il-tiourea **(3b)** telah berjaya disintesis melalui tindak balas antara 1-naftil isotiosianat **(1)** dengan etilena 2-etilaminoetanol **(2a)** dan fenilhidrazina **(2b)** menggunakan kaedah penyinaran mikrogelombang dan kaedah refluks. Peratusan hasil bagi kedua-dua kaedah yang digunakan untuk sebatian **3a** dan **3b** masing-masing adalah **3a** (refluks: 66%, mikrogelombang: 98%) dan **3b** (refluks: 72%, mikrogelombang: 97%). Hasil sintesis dianalisa dengan menggunakan alat spektroskopi FT-Inframerah (FT-IM), Spektroskopi Resonan Magnetik Nuklear (RMN) dan Spektrometri Jisim. Kajian antimikrob juga dilakukan dengan menggunakan *Staphylococcus aureus* dan *Bacillus subtillus* sebagai Gram positif, *Escherichia coli* dan *Salmonella typhimurium* sebagai Gram negatif dan kulat yang digunakan adalah *Aspergillus niger*. Kawalan positif yang digunakan adalah *streptomisin* dan *kanamisin*, manakala kawalan negatif yang digunakan adalah DMSO. Walaubagaimanapun hasil kajian mendapati tiada perencatan yang ketara terhadap pertumbuhan bakteria dan kulat (hanya 6-7mm kawasan perencatan) menggunakan sebatian tiourea ini.

Kata kunci: sebatian tiourea, mikrogelombang, aktiviti antimikrob

Abstract

New thiourea derivatives, 1-ethyl-1-(2-hydroxy-ethyl)-3-naphthalen-1-yl-iourea **(3a)**, 1-(phenyl-amino)-3-naphthalen-1-yl-Tiourea **(3b)** have been synthesized from the reaction of naphthylisothiocyanate with 2-(ethylamino)ethanol **(2a)** and phenylhydrazine **(2b)** using microwave irradiation method. The percentage yield for both method used for compound **3a** and **3b**, respectively **3a** (reflux: 66%, microwave: 98%) and **3b** (refluks: 72%, mikrogelombang: 97%).The compounds were analyzed by using Spectrometer FT-Infrared (FT-IR), Spectrometer Nuclear Magnetic Resonance (NMR) and Mass Spectrometry. Antimicrobial study was also conducted using *Staphylococcus aureus* and *Bacillus subtillus* as Gram positive, *Escherichia coli* and *Salmonella typhimurium* as Gram negative and fungi *Aspergillus niger* is used. The positive control used was streptomycin and kanamycin, while DMSO was used as the negative. However, this study shows no inhibition of bacteria and fungi (6-7mm of inhibition area) using these thiourea compounds.

Keywords: thiourea compound, microvawe, antimicrob activity

Pengenalan

Tiourea adalah sebatian organosulfur yang mempunyai formula $SC(NH_2)_2$. Struktur molekulnya sama seperti urea kecuali kedudukan oksigen digantikan dengan sulfur. Dalam satu kajian terbitan tiourea, kompleks poli(etilena

glikol)–tiourea (PEG.TU) telah menunjukkan sifat mangkin dengan membantu tindak balas untuk menghasilkan produk dalam masa lebih singkat [1]. Selain itu, tiourea juga digunakan sebagai sumber sulfida di mana apabila bertindak balas dengan alkil halida, sebatian tiol dihasilkan. Tiourea juga telah banyak digunakan dalam kajian biologi sebagai racun serangga, racun rumput, anti-bakteria, anti-kulat, penawar penyakit paru-paru, antitiroid, dan pengatur pertumbuhan tumbuhan [2]. Terbitan tiourea juga merupakan blok binaan kimia yang penting dalam bidang kimia dan farmasi [3]. Terdapat juga kajian lepas yang membuktikan keberkesanan tiourea sebagai antimikrob. Tiourea juga mampu bertindak sebagai bahan antimikrob yang baik. Bahan tiourea yang mempunyai gelang benzotiazola mempunyai aktiviti antimikrob yang lebih tinggi berbanding tiourea tanpa gelang benzotiazola [4]. Selain itu, kajian tersebut juga mendapati kehadiran kumpulan pengganti nitro pada gelang benzotiazola dapat meningkatkan aktiviti antimikrobnya.

Sintesis sebatian tiourea dengan menggunakan kaedah refluks merupakan kaedah yang telah lama digunakan. Pada tahun 1940, penggunaan tenaga mikrogelombang dalam proses pemanasan makanan diperkenalkan. Kemudian, pada tahun 1950, inovasi dalam aplikasi teknikal seperti dalam bidang kimia dan industri telah diperkenalkan [5]. Kini dengan adanya kemajuan teknologi, sintesis sebatian ini sudah semakin diperbaharui dengan menggunakan kaedah mikrogelombang. Kaedah mikrogelombang ini bukan sahaja dapat menghasilkan produk dengan cepat, malah dapat meningkatkan ketulenan hasil berbanding kaedah konvensional [6]. Sintesis ini mengambil masa dua jam hingga semalaman [2]. Penggunaan mikrogelombang ini juga dikaitkan dengan konsep 'Kimia Hijau' kerana kaedah ini menggunakan tenaga mikrogelombang untuk tindak balas kimia [7]. Pada tahun 2012, satu kajian untuk sintesis sebatian N-fenil-4-(6-fenilimidazo[2,1-b]tiazol-5-il)tiazol-2-amina turut menggunakan kaedah mikrogelombang [8]. Peratusan produk yang terhasil adalah tinggi iaitu 89–95%. Penggunaan mikrogelombang adalah mempercepatkan transformasi serta tindak balas bahan kimia organik [9,10]. Di dalam kajian ini, dua sebatian terbitan naftalentiourea (**3a** dan **3b**) telah berjaya disintesis melalui bahan pemula amina, 2-(etilamino)etanol **(2a)** dan fenilhidrazina **(2b)** melalui kaedah refluks dan kaedah mikrogelombang. Sifat antimikrobnya juga turut diuji dalam kajian ini.

Bahan dan Kaedah

Bahan kimia

Bahan-bahan kimia berserta pembekal yang digunakan dalam penyelidikan ini adalah 1-1-naftil isotiosianat (Acros), 2-(etilamino)etanol (Sigma Aldrich), fenil hidrazina (Sigma Aldrich), etilena diamina (Sigma Aldrich) dan pelarut organik seperti diklorometana, dimetilsulfoksida dan klorofom yang diperolehi dari syarikat Fisher. Semua bahan kimia dan pelarut digunakan tanpa perlu dilakukan proses penulenan terlebih dahulu.

Instrumentasi

Spektrum Infra Merah direkodkan menggunakan Perkin Elmer FT-IR pada suhu bilik. Sampel disediakan secara kaedah KBr dan dianalisis pada panjang gelombang 400 – 4000 cm^{-1}. ^{1}H NMR and ^{13}C NMR spektrum direkodkan menggunakan spektrometer Bruker Advance (400 MHz) dan tetrametilsilana (TMS) sebagai rujukan. Kaedah pemisahan dan penulenan dilakukan menggunakan kaedah kromatografi lapisan nipis (KLN) di atas gel silika jenama Merck DC Kieselgel 60 F_{254}.

Sintesis tiourea 1-etil-1-(2-hidroksi-etil)-3-naftalen-1-il-tiourea (3a) dan 1-(fenil-amino)-3-naftalen-1-il-tiourea (3b)

Dalam kajian ini, penyediaan sebatian tiourea 1-etil-1-(2-hidroksi-etil)-3-naftalen-1-il-tiourea **(3a)** dan 1-(fenil-amino)-3-naftalen-1-il-tiourea **(3b)** dilakukan dengan menggunakan dua kaedah, iaitu kaedah refluks dan kaedah mikrogelombang. Bagi sintesis sebatian **(3a)**, 2-(etilamino)etanol **(2a)** (0.179g, 2.00 mmol) ditindak balaskan dengan 1-naftil isotiosianat **(1)** (0.370g, 2.00 mmol). Kedua-dua bahan pemula ini dimasukkan ke dalam kelalang dengan kehadiran pelarut diklorometana (DKM) sebanyak 10 ml. Kemudian, campuran tersebut dibiarkan refluks [11] selama semalaman. Setelah kajian kualitatif menggunakan kromatografi lapisan nipis (KLN) menunjukkan semua bahan telah bertindak balas, pelarut DKM akan disejat menggunakan penyejat berputar untuk mendapatkan hasil kasar.

Penyediaan sebatian **(3a)** menggunakan kaedah sinaran mikrogelombang bermula dengan mencampurkan bahan pemula, 2-(etilamino)etanol **(2a)** (0.060g, 0.667 mmol) dan 1-naftil isotiosianat **(1)** (0.123g, 0.667mmol) ke dalam

botol sampel dengan kehadiran pelarut DKM yang sedikit (0.5 ml). Campuran tersebut disinarkan dengan mikrogelombang [12] pada 250W selama 5 minit. Mendakan putih terhasil dan ditentukan melalui analisis KLN.

Kedua-dua kaedah di atas diulangi dengan menggunakan fenilhidrazina **(2b)** (0.216g, 2.00 mmol) bagi menggantikan 2-(etilamino)etanol **(2a)** untuk penyediaan sebatian **(3b).** Kaedah konvensional yang digunapakai adalah kaedah tindak balas biasa iaitu tindak balas penambahan nuklofilik dan kaedah mikrogelombang adalah seperti yang telah dilaporkan oleh Atisya et al. [13].

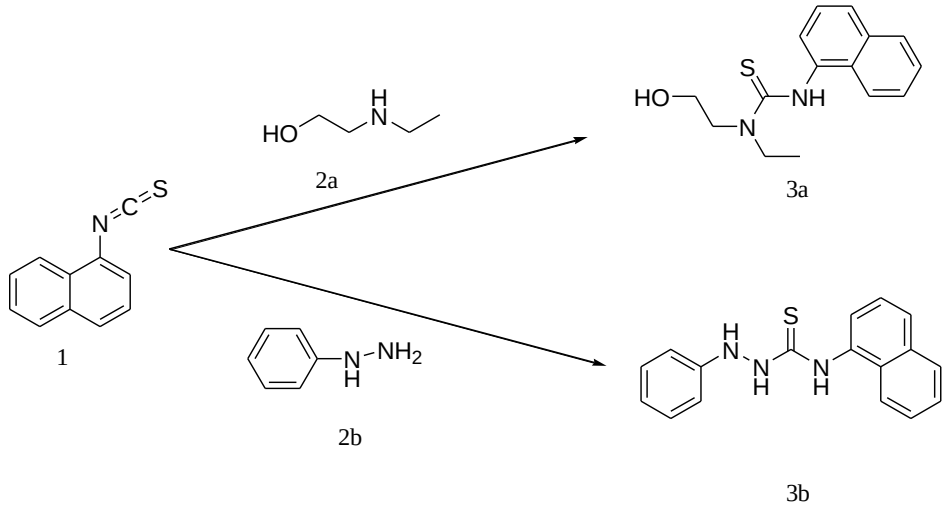
(3a) Pepejal berwarna putih; takat lebur 114 -116 ^{o}C; FT-IM (KBr, cm^{-1}) 3343, 3291, 1565, 776; ^{1}H NMR (400 MHz, DMSO) δ 1.23 (3H, *t*, J=6.8 Hz, -C*H*$_3$), 3.76 (2H, *t*, J=4.8 Hz, -C*H*$_2$-), 3.82 (2H, *t*, J=5.6 Hz, -C*H*$_2$-), 3.86(2H, *q*, J=6.8 Hz, -C*H*$_2$-), 7.35 (1H, *m*, Ar*H*), 7.47 (3H, *m*, Ar*H*), 7.77 (1H, *m*, Ar*H*), 7.84 (1H, *m*, Ar*H*), 7.89 (1H, *m*, Ar*H*), 9.43 (1H, *s*, -N*H*-); ^{13}C NMR (100 MHz, *d*-DMSO) δ 12.9 (*C*H$_3$), 47.0 (*C*H$_2$), 53.0 (*C*H$_2$), 60.2 (*C*H$_2$), 124.0 (C$_{Ar}$), 124.6 (C$_{kuarternari}$), 126.3 (C$_{Ar}$) 126.6 (C$_{Ar}$), 128.0 (C$_{Ar}$), 128.5 (C$_{Ar}$), 131.1 (C$_{kuarternari}$), 134.1 (C$_{kuarternari}$), 134.3 (C$_{Ar}$) 138.0 (C$_{Ar}$), 182.7 (C=S); MS (ESI) m/z 297.08 [M + Na]$^{+}$.

(3b) Pepejal berwarna putih; takat lebur 189 -193 ^{o}C; FT-IM (KBr, cm^{-1}) 3215, 3169, 1599, 1545, 759; ^{1}H NMR (400 MHz, *d*-DMSO) δ 6.83 (3H, *m*, Ar*H*), 7.22 (1*H*, *m*, Ar*H*), 7.38 (3H, *m*, Ar*H*), 7.74 (4H, *m*, Ar*H*), 7.81 (4H, *m*, Ar*H*), 9.53 (1H, *s*, -N*H*-), 9.87 (1H, *s*, -N*H*-); ^{13}C NMR (100 MHz, *d*-DMSO) δ 113.3 (C$_{Ar}$), 121.6 (C$_{Ar}$), 123.8 (C$_{Ar}$), 126.7 (C$_{Ar}$), 127.4 (C$_{kuarternari}$), 127.9 (C$_{Ar}$), 128.2 (C$_{kuarternari}$), 128.5 (C$_{Ar}$), 129.5 (C$_{kuarternari}$), 129.7 (C$_{Ar}$), 130.8 (C$_{Ar}$), 134.5 (C$_{Ar}$), 134.6 (C$_{kuarternari}$), 135.5 (C$_{Ar}$), 183.3 (C=S); MS (ESI) m/z 316.06 [M + Na]$^{+}$.

Kajian antimikrob sebatian 3a dan 3b

Aktiviti antimikrob diuji menggunakan kaedah penyebaran agar *'agar diffusion method'* [14] dengan menggunakan *Staphylococcus aureus* dan *Bacillus subtillus* sebagai Gram positif, *Escherichia coli* dan *Salmonella typhimurium* sebagai Gram negatif dan kulat yang digunakan adalah *Aspergillus niger*. Kawalan positif yang digunakan adalah S*treptomisin* dan *Kanamisin*, manakala kawalan negatif yang digunakan adalah DMSO.

Stok sebatian tiourea yang telah disintesis disediakan dengan melarutkan 1mg sebatian tiourea ke dalam 1ml pelarut DMSO. Kemudian, 50 µl dan 150 µl dicairkan dalam kelalang isipadu 5ml untuk menghasilkan sebatian tiourea dengan kepekatan 10 µg/ml dan 30 µg/ml masing-masing. Sebanyak 10µl diambil dan diserapkan percakera sampel. Piring agar disebarkan mikrob dan dieramkan pada suhu 37°C selama 24 jam. *Streptomisin*, *Kanamisin* dan DMSO digunakan sebagai agen kawalan positif dan negatif ujian ini dengan menggunakan kaedah yang sama. Selepas 24 jam, diameter kawasan yang tidak ditumbuhi bakteria atau kulat sekitar cakera diukur untuk dibandingkan tahap aktiviti antimikrob dengan agen kawalan anti-bakteria yang digunakan [14, 15].



Keputusan dan Perbincangan

Sintesis terbitan tiourea telah berjaya dijalankan melalui tindak balas antara 1-naftil isotiosianat **(1)** dengan beberapa sebatian amina menggunakan kaedah konvensional iaitu kaedah refluks dan juga kaedah mikrogelombang. Tindak balas keseluruhan penghasilan tiourea ditunjukkan pada Rajah 1.

Merujuk kepada pencirian sebatian menggunakan spektroskopi infra merah, terdapat puncak pada 3343 cm^{-1} (OH) dan puncak pada 3291 cm^{-1}(NH) bagi sebatian **3a** dan kehadiran regangan 3215 (NH 1) dan 3169 cm^{-1} (NH 2) bagi sebatian **3b**. Selain itu, ikatan C-N dapat dikenal pasti pada puncak 1565 cm^{-1} dan 1599 cm^{-1} bagi sebatian **3a** dan **3b**. Puncak ikatan C=S pula dapat dilihat pada puncak 776 cm^{-1} dan 759 cm^{-1} bagi sebatian **3a** dan **3b**. Puncak ini adalah penting bagi menunjukkan pembentukan tiourea telah berlaku.

Pencirian ^{1}H NMR bagi sebatian **3a** menunjukkan pada anjakan kimia 3.76 dan 3.82 ppm puncak ini memberikan nilai integrasi 3.27 yang menunjukkan 3 proton –CH$_2$- yang merupakan hidrogen yang terikat kepada karbon pada bahagian etanol sebatian tersebut. Manakala pada anjakan kimia 3.86 ppm pula merupakan proton pada ikatan –CH$_2$- yang bersebelahan dengan –CH$_3$. Ini dapat dibuktikan dengan kewujudan penggandaan spin *quintet* dengan nilai skala penggandingan 6.8 Hz pada anjakan kimia tersebut. Puncak yang penting adalah puncak bagi kumpulan amina yang terbentuk daripada tindak balas antara isotiosianat dan amina yang mana dapat dilihat pada pada anjakan kimia 9.43 ppm. Ini juga disokong oleh spektrum ^{13}C NMR yang menunjukkan terdapat pembentukan

kumpulan C=S yang dibuktikan melalui kehadiran puncak pada anjakan kimia pada 180.7 ppm. Bagi sebatian **3b** pula, terdapat puncak pada anjakan kimia antara 6.83 ppm dan 7.81 ppm yang merupakan puncak bagi kumpulan aromatik. Pada anjakan kimia 9.87 ppm dan 9.53 ppm pula merupakan puncak bagi kumpulan amina. Hidrogen pada amina naftil dijangkakan memiliki anjakan kimia 9.87 ppm manakala pada anjakan kimia 9.53 ppm merupakan puncak pada amina hidrazina. Puncak yang terdapat pada nilai anjakan kimia 183 ppm pula adalah karbon pada ikatan C=S, yang merupakan puncak yang utama bagi sebatian tiourea.

Rajah 1. Sintesis terbitan naftiltiourea 1-etil-1-(2-hidroksi-etil)-3-naftalen-1-il-tiourea **(3a)** dan 1-(fenil-amino)-3-naftalen-1-il-tiourea **(3b)**.

Spektrometri jisim menggunakan mod pengionan elektron (ESI) memberikan puncak sebatian **3a** (274.38 g/mol) bernilai m/z 297.07 merupakan puncak bagi molekul ion $[M+Na]^+$. Begitu juga bagi sebatian **3b** yang mempunyai formula molekul $C_{17}H_{15}N_3S$ (293.39 g/mol) menunjukkan berat ion $[M+Na]^+$ pada nilai m/z 293.38. Ion sodium sebagai ion molekul pseudo biasa digunakan bagi penentuan berat molekul menggunakan mod pengionan elektron. Jadual 1 di bawah menunjukkan peratusan hasil yang diperolehi daripada kaedah refluks dan kaedah mikrogelombang.

Jadual 1. Peratusan hasil kaedah refluks dan kaedah mikrogelombang

Sebatian/ Kaedah	**Peratusan Hasil (%)**	
	Refluks	**Mikrogelombang**
3a	66%	98%
3b	72%	97%

Teknik mikrogelombang menghasilkan pemanasan dalaman yang lebih cekap disebabkan tenaga gelombang mikronya selari dengan molekul-molekul pelarut dan reagen yang terlibat dalam tindak balas. Maka masa tindak balas menjadi lebih cepat [7]. Jadual di atas membuktikan bahawa peratusan hasil daripada kaedah mikrogelombang adalah lebih tinggi berbanding dengan kaedah refluks. Hal ini kerana penggunaan teknik mikrogelombang dapat memberikan hasil tindak balas yang lebih bersih serta dapat mengurangkan pembentukan produk sampingan [16]. Melalui kaedah konvensional pula, peratusan hasil bagi sebatian **3a** dan **3b** adalah masing-masing 66 % dan 72 %. Kaedah ini juga memerlukan masa yang lebih lama bagi suatu tindak balas lengkap. Hal ini disebabkan berlakunya

pemindahan tenaga ke dalam sistem yang mana suhu luar lebih tinggi berbanding suhu di dalam campuran tindak balas [17]. Kebolehulangan tindak balas tidak dijalankan kerana kaedah mikrogelombang telah menghasilkan nilai peratusan yang kuantitatif.

Aktiviti antimikrob

Sebatian tiourea **3a** dan **3b** telah dicirikan dan ujikaji aktiviti antimikrobnya [14] telah dijalankan menggunakan antibiotik *Streptomisin* (10μg/ml) dan *Kanamisin* (30 μg/ml) sebagai kawalan positif dan DMSO sebagai kawalan negatif. Jadual 2 dan Jadual 3 di bawah merupakan hasil daripada kajian yang telah dijalankan:

Jadual 2. Aktiviti antimikrob bagi sebatian terbitan tiourea dan antibiotik (10 μg/ml)

Sebatian	**Bakteria Gram positif (mm)**		**Bakteria Gram negative (mm)**		**Kulat (mm)**
	Staphylococcus aureus	***Bacillus subtilis***	***Escherichia coli***	***Salmonella typhimurium***	***Aspergillus niger***
Antibiotik *streptomisin*	16	17	16	19	10
1-etil-1-(2-hidroksi-etil)-3-naftalen-1-il-tiourea **(3a)**	7	7	6	7	6
1-(fenil-amino)-3-naftalen-1-il-tiourea **(3b)**	6	6	6	7	6

Jadual 3. Aktiviti antimikrob bagi sebatian terbitan tiourea dan antibiotik (30μg/ml)

Sebatian	**Bakteria Gram positif (mm)**		**Bakteria Gram negatif (mm)**		**Kulat (mm)**
	Staphylococcus aureus	***Bacillus subtilis***	***Escherichia coli***	***Salmonella typhimurium***	***Aspergillus niger***
Antibiotik *Kanamisin*	20	20	18	24	24
1-etil-1-(2-hidroksi-etil)-3-naftalen-1-il-tiourea **(3a)**	7	7	6	7	6
1-(fenil-amino)-3-naftalen-1-il-tiourea **(3b)**	6	6	6	7	6

Merujuk pada kedua-dua jadual di atas, aktiviti antimikrob yang dihasilkan oleh sebatian tiourea yang dihasilkan adalah sangat rendah. Keluasan kawasan yang mampu direncat pertumbuhan bakteria dan kulat adalah sekitar enam hingga tujuh milimeter diameter manakala antibiotik pula mampu untuk merencat pertumbuhan bakteria sejauh 10 hingga 24 milimeter diameter. Hasil menunjukkan terbitan tiourea yang dihasilkan tidak bersesuaian untuk dijadikan bahan antimikrob bagi bakteria-bakteria yang diuji. Kehadiran kumpulan penderma elektron atau kumpulan aromatik tanpa kumpulan pengganti penarik elektron menjejaskan aktiviti antimikrob sebatian berkenaan [15]. Sehubungan dengan itu, naftil tanpa kumpulan berfungsi penarik elektron dan kumpulan pengganti lain yang bertindak sebagai penderma elektron kepada kumpulan berfungsi tiourea akan memudaratkan aktiviti antimikrob

tiourea tersebut. Selain itu, beberapa idea juga turut diketengahkan untuk meningkatkan keputusan perencatan bakteria oleh sebatian tersebut seperti meningkatkan kepekatan sebatian yang digunakan dalam merencatkan pertumbuhan mikrob. Terdapat juga cadangan untuk menggunakan kaedah lain yang berkemungkinan lebih efektif dalam menentukan aktiviti antimikrob ini seperti kepekatan perencatan asai minimum.

Kesimpulan

Sebatian 1-etil-1-(2-hidroksi-etil)-3-naftalen-1-il-tiourea (**3a**) dan 1-(fenil-amino)-3-naftalen-1-il-tiourea (**3b**) berjaya disintesiskan dengan menggunakan dua kaedah iaitu kaedah pemanasan secara refluks dan juga kaedah mikrogelombang. Hasil sebatian terbitan tiourea daripada kaedah mikrogelombang membuktikan bahawa peratusan hasil yang diperolehi adalah lebih banyak berbanding kaedah refluks. Jika dibandingkan pada faktor masa, kaedah mikrogelombang juga lebih cepat dan jimat kerana masa yang diperlukan untuk sintesis adalah singkat dan memerlukan pelarut yang paling minima (0.5 – 1.0 ml).

Penghargaan

Kami ingin mengucapkan setinggi-tinggi penghargaan kepada pihak Pusat Pengajian Sains Kimia dan Teknologi Makanan (PPSKTM) Universiti Kebangsaan Malaysia, Pusat Pengurusan Penyelidikan dan Instrumentasi (CRIM), dan juga pihak yang terlibat dalam menjayakan penyelidikan ini. Kajian ini dijalankan dibawah geran penyelidikan FRGS/1/2015/ST01/UKM/02/2 dan PRGS/2/2015/SG01/UKM/02/1.

Abstract

Entada spiralis Ridl. (Leguminosae) is a woody climber which locally known as 'akar sintok'. The isolation and structure determination of two crystalline solids from active methanol fraction of *E. spiralis* stem bark had been examined. The structure identification of both solids was based on spectroscopic data (^{1}H and ^{13}C NMR, HMQC, HMBC, DEPT135 and MS) along with comparison with literature data. The results revealed that these two crystalline solid sugars isolated from the most active fraction were known as penta-2-acetoxy-β-D-digitoxopyranosyl-(1→2)-fructofuranosyl-(6→4)-β-D-glucopyranosyl-(1→4)-glucopyranosyl-(1→2)-β-D fructofuranosyl-(6→1)-β-D-glucopyranosyl-(4→1)-acetylglucosamine **(1)** and β,D-glucopyranosyl(1→2)-β,D-glucopyranosyl)-(1→3)-β,D-xylopyranosyl(1→4)-α,L-rhamnopyranosyl)-(1→3)-β,D- glucopyranosyl(1→3)-β,D-glucopyranoside **(2)** Thus, this finding can be utilized as a scientific baseline information for further skin disease studies, since both constituents were isolated from moderate antidermatophytic active fraction.

Keywords: *Entada spiralis*, crystalline saponin, glycosides, isolation

Abstrak

Pemencilan dan penentuan struktur dua komponen bersifat kristal dari batang pokok *E. spiralis* yang juga dikenali sebagai akar sintok telah dijalankan. Eksperimen penentuan struktur berdasarkan data – data spektroskopi menggunakan ^{1}H, ^{13}C NMR, HMQC, HMBC, DEPT135 dan spektrometer jisim dan juga perbandingan dengan kajian terdahulu. Hasil analisa spektroskopi yang terperinci menunjukkan kedua – dua kristal tersebut dikenali sebagai penta-2-asetoksi-β-D-digitoxopiranosil-(1→2)-fruktofuranosil-(6→4)-β-D-glukopiranosil-(1→4)-glukopiranosil-(1→2)-β-D fruktofuranosil-(6→1)-β-D-glukopiranosil-(4→1)-acetilglukosamina **(1)** and β,D-glukopiranosil(1→2)-β,D-glukpiranosil)-(1→3)-β,D-xilopiranosil(1→4)-α,L-rhamnopiranosil)-(1→3)-β,D-glukopiranosil(1→3)-β,D-glukopiranosid **(2).** Penemuan ini boleh dijadikan maklumat asas untuk kajian penyakit kulit kerana kedua-dua komponen ini dipencilkan dari fraksi metanol yang bersifat antiderma.

Kata kunci: *Entada spiralis*, kristal saponin, glikosid, pemencilan

Introduction

Medicinal herbs have been consumed traditionally by people throughout the world to cure various diseases long enough before the emerging of modern medicine. Due to their higher content of such valuable chemical compounds, they could be used to prevent microbial invasion. Secondary metabolites produced by plants contain a tremendous source of bioactive compounds such as flavonoid, alkaloid, tannin, saponin and terpenoid. Knowing their

importance, scientific investigation has increased rapidly to overcome the development of resistant pattern of certain microorganisms such as skin disease caused microbes [1].

The structure identification of bioactive constituents from the various types of species of Leguminoceae family had been reported [2-6]. The stem of *E. spiralis* is believed to exhibit antimicrobial properties since it is capable to treat hair problem, itching and body cleansing. Previous phytochemical investigation of other *Entada* species encountered oleanolic acid, echinocystic acid, entagenic acid and acacic acid glycosides Okada et al. [7, 8]. *E. rheedii* Spreng was found to possess saponins [7-10], thiomides [11] and phenylacetic derivatives [12-13]. Investigation also revealed entagenic acid isolated from seed kernels of *E.rheedii* which exhibited moderate cytotoxic potency and antioxidative properties [14]. Phenolic and flavonoid were isolated from the root of *E. Africa* [15], octadecanoic acid from the stem bark of *E. abyssinica* [16] and Entadoiside from kernel nut of *E. phaseoloides* [17].

In this present study, we embark upon isolation and structure identification of two novel crystalline solids from active fractions of *E.spiralis* stem bark.

Materials and Methods

General Experimental Procedures

The general experimental procedures were adapted from Aiza et al. [18]. The ^{1}H Nuclear Magnetic Resonance (NMR) and ^{13}C NMR spectra were recorded in $CDCl_3$, Fourier Transform NMR (FT-NMR) analysis was done using a Cryoprobe on a Bruker Avance 111 600 MHz spectrometer. Tetramethylsilane (TMS) was used as an internal standard in NMR spectrometer analysis. Electronspray ionization mass spectrometer (ESIMS) was performed using a Bruker micrOTOF-Q 86 mass spectrometer operating in positive-ion mode. Vacuum liquid chromatography (VLC) was conducted using silica gel 60 with a 230 – 400 mesh particle size (Merck). Thin layer chromatography (TLC) was performed on Kiesegel 60 F254 (Merck) aluminium support plates developed using chloroform: methanol system. TLC plates were visualized at UV_{366} and UV_{254}.

Fractionation and Isolation

The extraction and fractionation procedures were conducted as previously reported with few modifications [19, 20]. The extraction process involved consecutive soaking with petroleum ether, chloroform and methanol, fractionation process was conducted using vacuum liquid chromatography with the use of several binary solvents to obtain fractions.

Antidermatophytic Evaluation

The antidermatophytic activity of fractions was determined as previously reported by Aiza et al [21]. Generally, all extracts were used against three types of skin diseases dermatophytes namely as *Trychophyton tonsurans*, *Trychophyton mentagrophytes* and *Microsporum gypseum* through disc diffusion method susceptibility testing. The effectiveness of the fractions was evaluated by means of inhibition zone (IZ) measurement around the disk.

Results and Discussion

Compound **(1)** was obtained as white crystalline solid after subjecting methanol extract to vacuum liquid chromatography with an elution system of $CHCl_3$-MeOH (6:4 v/v) to obtain fraction 1 which was previously found to possess moderate antidermatophytic activity [20]. The melting point of white crystalline solid was 187 ^{o}C and two ultra violet (UV) absorption peaks appeared at 228 nm and 280 nm when analyzed with UV VIS-1800 Series (Shimadzu, Japan). The results indicated the absorption of light in the region of 200 – 300 nm, corresponded to the presence of atom with non-bonding orbital such as oxygen and nitrogen. Two peaks observed in the UV spectra were due to the presence of the chromophores, molecules that absorb light with bathochromic effect.

The Electron Spray Ionization Mass Spectrum (ESIMS) of compound **(1)** showed an $[M+H]^+$ ion peak at *m/z* 1905 in accordance with the molecular formula of $C_{78}H_{123}NO_{52}$. The fragment ion peaks were observed on the ESIMS at *m/z* 1049 [M+H-171-172-171-171-171], 365[M+H-171-172-171-171-171-342-342] corresponding, to the consecutive loss of five pentosyls, two hexoxyls (Glc and Fru) and again two hexoxyls (Glc and Fru) respectively. Table 1 and Figure 1 showed the fragmentation of sugar moieties in the whole structure.

Table 1. Fragmentation of ions in compound **(1)** by ESIMS

Mass	Fragmentation of ions
1734	$[M+H] - 171]^+$
1562	$[M+H] - 171\text{-}172]^+$
1391	$[M+H] - 171\text{-}172\text{-}171]^+$
1220	$[M+H] - 171\text{-}172\text{-}171\text{-}171]^+$
1049	$[M+H] - 171\text{-}172\text{-}171\text{-}171\text{-}171]^+$
707	$[M+H] - 171\text{-}172\text{-}171\text{-}171\text{-}171\text{-}342]^+$
365	$[M+H] - 171\text{-}172\text{-}171\text{-}171\text{-}171\text{-}342\text{-}342]^+$

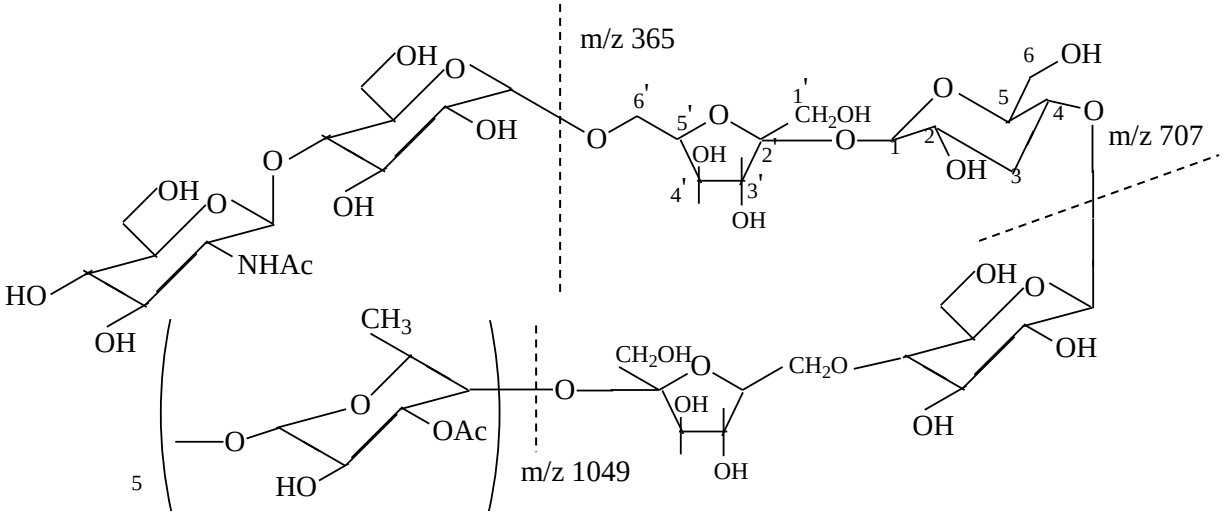

Figure 1. The mass fragmentation of compound **(1)** from *E. spiralis* stem bark

The ^{1}H NMR spectrum of compound **(1)** displayed three sugar anomeric protons at chemical shifts, ppm δ 4.41, 5.18 and 4.80, which indicated the presence of sugar moieties GlcNAc, Glc, acetyl digitoxose, respectively. These values were quite close to those reported in literature. The δ_H for GlcNAc was reported [22] as 4.40 ppm, δ_H 5.44 and δ_H 5.0 for acetyl digitoxose [23]. The proton NMR spectrum furnished nine hydroxyl protons at chemical shifts δ_H 3.14, 3.20, 3.47, 3.49, 3.55, 3.58, 3.68, 3.78 and 3.90, giving direct coupling with nine carbon atoms at δ 70.30, 72.09, 73.27, 60.95, 62.59, 83.01, 73.33, 74.74 and 77.47 ppm, respectively based on HMQC spectrum. The correlation between δ_H 5.18 and chemical shifts of carbon at δ_C 92.21 corresponded to the direct correlation of anomeric proton and anomeric carbon of Glc.

According to ^{13}C NMR spectrum, the chemical shifts at δc 104.49 and δc 92.21 suggested the presence of anomeric carbon for fructose (Fru) and glucose (Glc) respectively, and were quite close to those reported for Fru (δc 104.0) and Glc (δc 93.9) [10, 21]. The high intensity of overlapped peaks indicated more than one sugar present and this was same for absorption peaks of carbon hydroxyl. Thus, it may explain why compound **(1)** showed high molecular weight as displayed in the mass spectrum.

Long range correlations observed in the HMBC spectrum between signals at δ_H 5.18 (Glc-I) and δ_C 104.49 (C2'-Fru) showed three bond correlations between Glc and Fru. The four bond correlation was observed between anomeric proton of GlcNAc δ 4.4 and δc 73.27 (C3-Glc-II) suggested the location GlcNAc in AC1 structure. The anomeric proton of Glc-II (δ_H 5.18) was linked with Fru by four bond correlations at C5'(δ_C 83.01) of Fru. The spectrum also depicted three bond correlations between anomeric proton δ_H 4.80 of acetyldigitoxose moiety and δc 104.49 (C2'-Fru) which showed the linkage to Fru. The two bond correlations can be seen between signal at δ_H 3.90 (C5-glc-I) and δc 62.69 (C6-glc-I), δ_H 3.47 (C3-glc-I) and δc 72.09 (C2-glc-I) and δc 70.30 (C4-glc-I), δ_H 3.14 (C4-glc-I) and δc 73.33 (C3-glc-I), δ_H 3.68 (C3'-Fru) and δc 74.74 (C4'-Fru) and δc 83.01 (C5'-Fru). The three bond correlations were depicted between signal at δ_H 3.68 (C3'-Fru) and δc 83.01 (C5-Fru) and δc 74.74 (C4'-Fru), δ_H 3.49 (C1'-Fru) and δc 73.33 (C3'-Fru), δ_H 5.18 (C1-Glc) and δc 70.30 (C4-Glu), δ_H 3.58 (C5'-Fru) and δc 104.49 (C2'-Fru). The structure of sugar moieties and the HMBC correlation are shown in Figure 2 and 3 respectively. The proton and carbon NMR data of compound (1) in DMSO were summarized in Table 2.

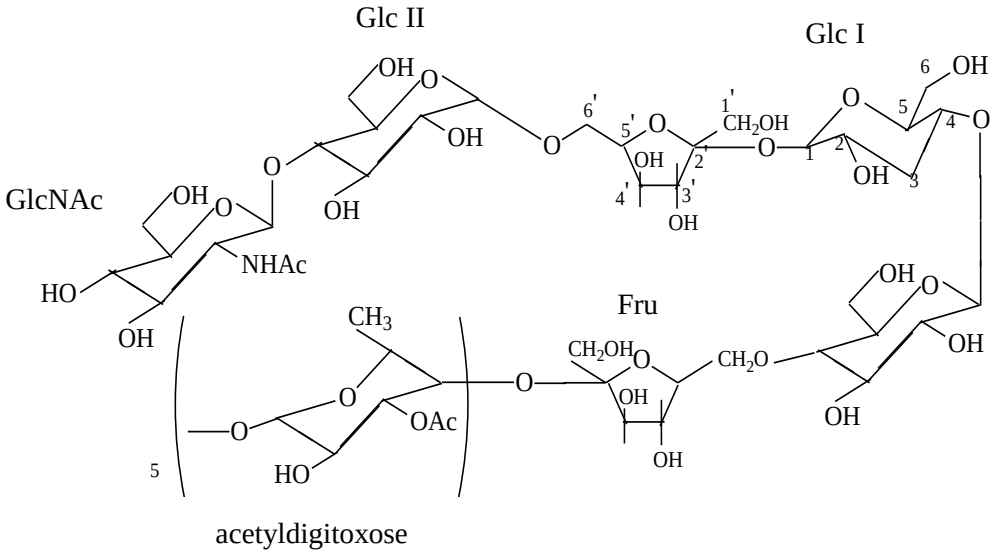

Figure 2. The structure of compound **(1)** from *E. spiralis* stem bark

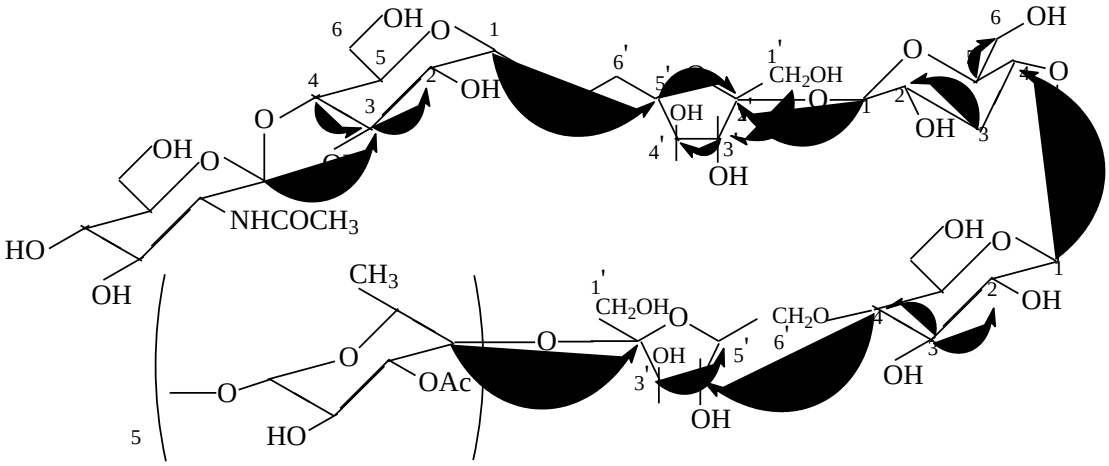

Figure 3. The key HMBC correlation of compound **(1)** from *E. spiralis* stem bark

After gone through an extensive spectroscopic analysis and comparison with literature, compound **(1)** was identified as penta-2-acetoxy-β-D-digitoxopyranosyl-(1→2)-fructofuranosyl-(6→4)-β-D-glucopyranosyl-(1→4)-gluco pyranosyl-(1→2)-β-Dfructofuranosyl-(6→1)-β-D-glucopyranosyl-(4→1)-acetylglucosamine.

Compound **(2)** was isolated as white crystalline solid after subjecting to vacuum liquid chromatography with an elution system of $CHCl_3$-MeOH (7:3 v/v), whereby fraction obtained was found to exhibit moderate antidermatophytic activity. The UV absorption analysis has displayed two absorption peaks at 256 and 280 nm which indicated chromophore of C-O group. The ESIMS displayed $[M+H]^+$ ion peak at *m/z* 922.0135, supported a molecular formula of $C_{35}H_{59}O_{28}$. The fragment ion peaks were observed on the ESIMS at *m/z* 600.5184$[M+H-325]^+$ corresponding to the consecutive loss of two hexosyls. The *m/z* 325.1126 $[M+H-325-278]^+$ referred to the loss of

one pentosyl and again one hexosyl. Further fragmentation ion peak is observed at *m/z* 163.0607 [M+H-325- 278-162]$^{+}$, which showed the loss of another one hexosyl. The mass fragmentation is illustrated in Figure 4.

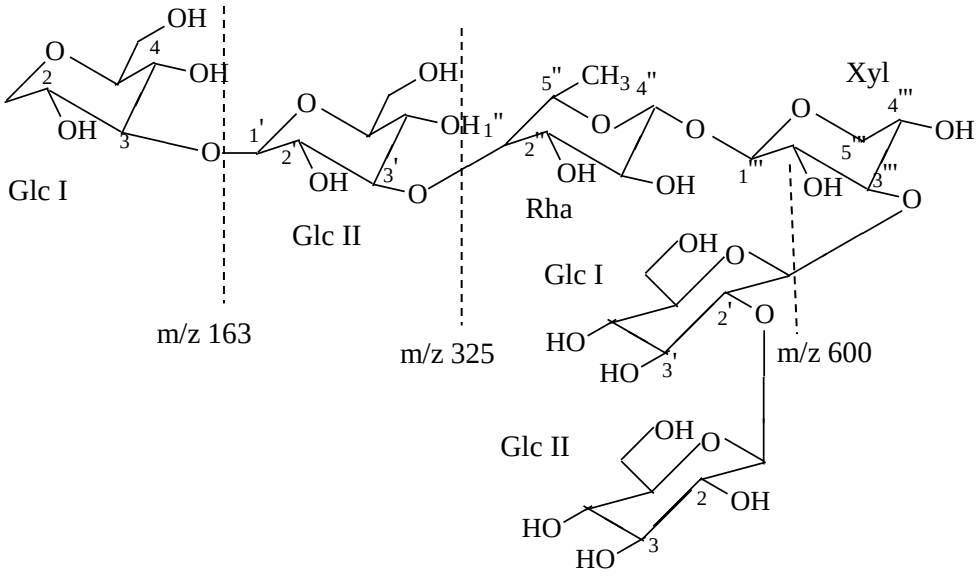

Figure 4. The mass fragmentations of compound **(2)** from *E. spiralis* stem bark

The sequences of the sugar chain were confirmed by HMBC experiments. The cross-peak observed in the HMBC spectrum between anomeric proton at signal δ_H 4.4 (Glc-1) and δ_C 83.02 (C2'), δ_H 5.05 (Rha-1) and δ_C 73.28 (C3'), δ_H 4.78 (Xyl) and δc 73.33 (C4''), δ_H 5.20 (Glc-II) and δ_C 73.28 (C3), showed the location of sugar moieties.

Other correlations with two bond correlations can be observed between proton signal δ_H 3.58 (C2-glc I) and δ_C 73.28 (C3), and δ_H 3.58 (C2'-Glc II) with δ_C 73.28 (C3'-Glc II). Three bond correlations can be seen between proton signal δ_H 3.43 (C5''-Rha) and δc 70.30 (C2''), 3.55 (C5'''-xyl) and δc 74.75 (C4''') and between δ_H 5.20 (C1'-Glc II) and δc 77.48 (C3'''-Xyl). The HMBC correlation is shown in Figure 5 and Table 3 showed the NMR data of compound **(2)**.

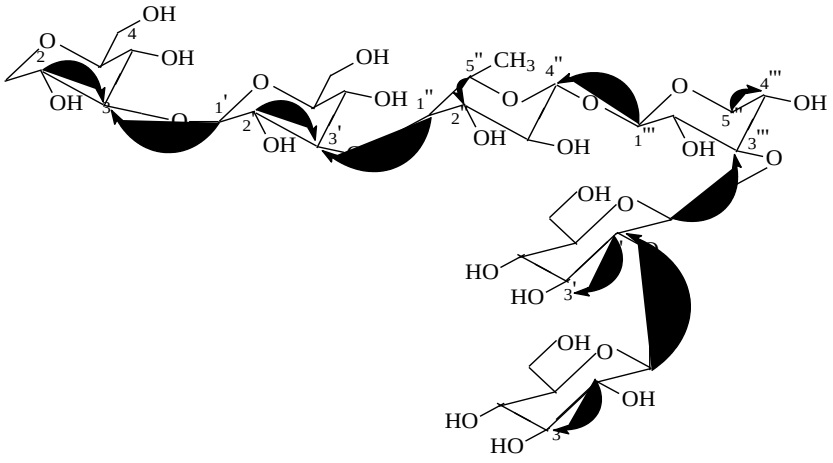

Figure 5. The key HMBC correlation of compound **(2)** from *E. spiralis* stem bark

After went through an extensive spectroscopic analysis and comparison with literature, compound **(2)** was elucidated as β,D-glucopyranosyl(1→2)-β,D-glucopyranosyl)-(1→3)-β,D-xylopyranosyl(1→4)-α,L-rhamno pyranosyl)-(1→3)-β,D-glucopyranosyl(1→3)-β,D-glucopyranoside as shown in Figure 6.

Conclusion

Two types of crystalline solids from *E.spiralis* stem bark have been successfully isolated and characterized and they were determined as penta-2-acetoxy-β-D-digitoxopyranosyl-(1→2)-fructofuranosyl-(6→4)-β-D-glucopyranosyl-(1→4)-glucopyranosyl-(1→2)-β-Dfructofuranosyl-(6→1)-β-D-glucopyranosyl-(4→1) acetylglu cosamine **(1)** and β,D-glucopyranosyl(1→2)-β,D-glucopyranosyl)-(1→3)-β,D-xylopyranosyl(1→4)-α,L-rhamnopyranosyl)-(1→3)-β,D-glucopyranosyl(1→3)-β,D-glucopyranoside **(2).** Both compounds have been isolated from methanol extract which is antidermatophytic active constituents.

Abstract

Stability-indicating High Performance Liquid Chromatographic (HPLC) method was developed for simultaneous Aspirin and Clopidogrel, A Phenomenex Gemini C-18, 5 µm column having 250mm x 4.6 mm i.d. in isocratic mode, with mobile phase containing buffer solution 0.3% orthophosphoric acid : acetonitrile (65: 35, v/v). The flow rate was 1 ml/min and effluents were monitored at 266 nm. For linearity seven points calibration curve were obtained in a concentration range from 0.030 –0.120 mg/ml for aspirin and 0.015 – 0.060 mg/ml for clopidogrel with correlation coefficient 0.9999. In the present study stability indicating HPLC method for the combination was tested by degrading the drugs together under various stress conditions like acid hydrolysis, base hydrolysis, oxidation, thermal and photolytic stress which is recommended by ICH guideline.

Keywords*:* revere phase high performance liquid chromatography, stability indicating method, aspirin, clopidogrel

Abstrak

Kestabilan Kaedah Kromatografi Cecair Prestasi Tinggi (KCPT) – indikator telah dibangunkan bagi penentuan serentak Aspirin dan Clopidogrel. Turus Phenomenex Gemini C-18, 250mm x 4.6 mm i.d. diguna dalam mod isokratik, bersama fasa bergerak yang mengandungi larutan penimbal iaitu 0.3% asid orthofosforik : acetonitril. Kadar aliran adalah 1ml/min dan effluent dipantau pada panjang gelombang 266 nm. Tujuh titik lengkung kalibrasi dipilih bagi ujian kelinearan yang diperolehi dari julat 0.030 – 0.120 mg/ml dan 0.015 – 0.060 masing – masing bagi aspirin dan clopidogrel dengan nilai pekali korelasi adalah 0.9999. Dalam kajian ini, kestabilan kaedah KCPT- indikator bagi gabungan analit diuji di bawah pelbagai tekanan seperti hidrolisis asid, hidrolisis bes, pengoksidaan, termal dan tekanan fotolitik seperti yang dicadangkan oleh garis panduan ICH.

Kata kunci*:* kromatografi cecair prestasi tinggi fasa terbalik, kestabilan kaedah indikator, aspirin, clopidogrel

Introduction

Platelet aggregation and thrombus formation play a critical role in the initiation and development of key complications of acute coronary syndromes (ACSs). Antiplatelet therapy and antithrombotic therapy have been demonstrated to favorably modify clinical outcome, and recent trials of revascularization in ACSs have demonstrated a reduction in the frequency of major cardiac events [1 – 12]. Antiplatelet and anti-thrombin have synergistic actions that reduce the risk of spontaneous or revascularization, especially percutaneous coronary intervention (PCI)-related events. Yet, all effective antithrombotic agents also increase the risk of bleeding,

especially bleeding that results from vascular accessor associated with surgery, including coronary artery bypass grafting (CABG). The Clopidogrel in unstable angina to prevent recurrent ischemic Events (CURE) trial demonstrated that the combination of clopidogrel and aspirin was superior to aspirin alone for patients hospitalized with non-ST-elevation ACSs.

Aspirin is chemically acetylsalicylic acid (Figure 1). Its molecular formula is $C_9H_8O_4$ having molecular weight 180 g/mole [14]. It is slightly soluble in water, freely soluble in alcohol, soluble in chloroform and ether, sparingly soluble in absolute ether. Aspirin, one of the first drugs to come into common usage, is still the most widely used drug in the world, is a non-steroidal anti-inflammatory drug that exhibits anti-inflammatory, analgesic and antipyretic activities.

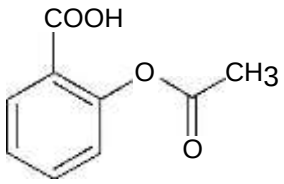

Figure 1. Chemical structure of aspirin

Clopidogrel bisulfate, chemicall y it is [S - (a)(2 - chlorophenyl) - 6,7 - dihydrothieno (3,2-C) pyridine-5 (4H) acetic acid methyl ester sulphate] (Figure 2). The empirical formula of clopidogrel bisulfate is $C_{16}H_{16}ClNO_2S•H_2SO_4$ and its molecular weight is 419.9 g/mole [14]. It is a white to off-white powder. It is practically insoluble in water at neutral pH but freely soluble at pH 1. It also dissolves freely in methanol, dissolves sparingly in methylene chloride and is practically insoluble in ethyl ether. It has a specific optical rotation of about +56°. The structural formula is as follows:

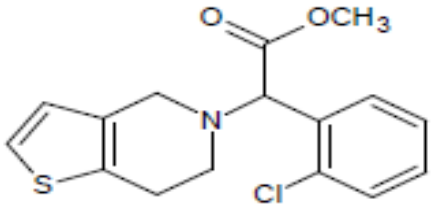

Figure 2. Chemical Structure of clopidogrel

The combination of clopidogrel with aspirin provides enhanced prevention of atherothrombotic events by blocking the platelet aggregation by both ways. (ADP pathway and collagen induced pathway) and it shows a synergistic antiplatelet action in controlling the ischemic events.

Literature reveals that various methods simultaneous determination of aspirin and clopidogrel in pharmaceutical formulation HPTLC [5 – 6]. Various publications are available regarding determination method of aspirin and clopidogrel but most of the methods are applicable to alone aspirin or clopidogrel in pharmaceutical dosage form or in bilogical fluids. Only three methods are reported for the simulteneous determination of apirin and clopidogrel. One is semi-micro column HPLC-UV method for simultaneous determination of clopidogrel metabolite, aspirin and salicylic acid in rat plasma. Second is a spectrophotometric method, which is able to determine aspirin and clopidogrel in combine dosage form and third is simple high performance liquid chromatography, which applicable to routine quality control sample analysis. The separation is performed by high

performance liquid chromatography for reasons of robustness and familiarity of analysts with this technique. To our knowledge, no stability-indicating analytical method for the determination of aspirin and clopidogrel in combine dosage forms has been published.

In the present study stability indicating HPLC method for the combination was tested by degrading the drugs together under various stress conditions like acid hydrolysis, base hydrolysis, and oxidation, thermal and photolytic stress which is recommended by ICH guideline.

Materials and Methods

Pharmacopoeial grade standards of aspirin and clopidogrel bisulphate were provided by Blue Cross laboratory. A tablet containing 150 mg aspirin and 75 mg clopidogrel was commercially available. HPLC grade acetonitrile, methanol and water were obtained from Spectrochem Pvt. Ltd., Mumbai (India). Analytical grade hydrochloric acid, sodium hydroxide pellets, orthophosphoric acid and hydrogen peroxide solution (30 % v/v) were obtained from Ranbaxy Fine Chemical, New Delhi (India).

HPLC instrumentation and conditions

The chromatographic system used to perform development and validation of this assay method was comprised of (SHIMADZU, HPLC) with LC- 20AT (VP series) pump, with software Spinchrom and UV-Visible detector SPD-20A (VP series). Chromatographic analysis was performed on a Phenomenex Luna C8 (250 mm 4.6 mm i.d., 5 µm particle size) column. The mobile phase was consisted of 0.3 % orthophosphoric acid (v/v) - acetonitrile (65:35, v/v). The flow rate of the mobile phase was adjusted to 1.0 ml/min and the injection volume was 20 µl. Detection was performed at 226 nm.

In the presence work, an analytical method based on LC using UV detection was developed and validated for assay determination of aspirin and clopidogrel in tablet formulation. The analytical conditions were selected, keeping in mind the different chemical nature of aspirin and clopidogrel. The development trials were taken by using the degraded sample of each component was done, by keeping them in various extreme conditions.

The column selection has been done on the basis of backpressure, resolution, peak shape, theoretical plates and day-to-day reproducibility of the retention time and resolution between aspirin and clopidogrel peak. After evaluating all these factors, C8 (2) (250 mm 4.6 mm i.d., 5 µm particle size) column was found to be giving satisfactory results. The selection of buffer based on chemical structure of both the drugs.

Preparation of stock solution for stress studies

The degradation samples were prepared by transferring powdered tablets, equivalent to 150 mg aspirin and 75 mg clopidogrel into a 250 ml round bottom flask. Then prepared samples were employed for acidic, alkaline and oxidant media and also for thermal and photolytic stress conditions. After the degradation treatments were completed, the stress content solutions were allowed to equilibrate to room temperature and diluted with mobile phase to attain 0.075 mg/ml of aspirin and 0.0375 mg/ml of clopidogrel concentration.

Results and Discussion

The acidic pH range was found suitable for solubility, resolution, stability, theoretical plates and peak shape of both components. Best results were obtained with 0.3 % orthophosphoric acid solution improved the peak shape of aspirin and clopidogrel. Finally, by fixing 0.3 % orthophosphoric acid (v/v) and mobile phase composition consisting of a mixture of 0.3% orthophosphoric acid (v/v) into ratio 65:35, v/v. Optimized mobile phase proportion was providing good resolution between aspirin and clopidogrel and also for degradation product which is generated during force degradation study. For the selection of organic constituent of mobile phase, acetonitrile was chosen to reduce the longer retention time and to attain good peak shape. Figure 1 and Figure 2 represent the Chromatograms of standard and test preparation respectively.

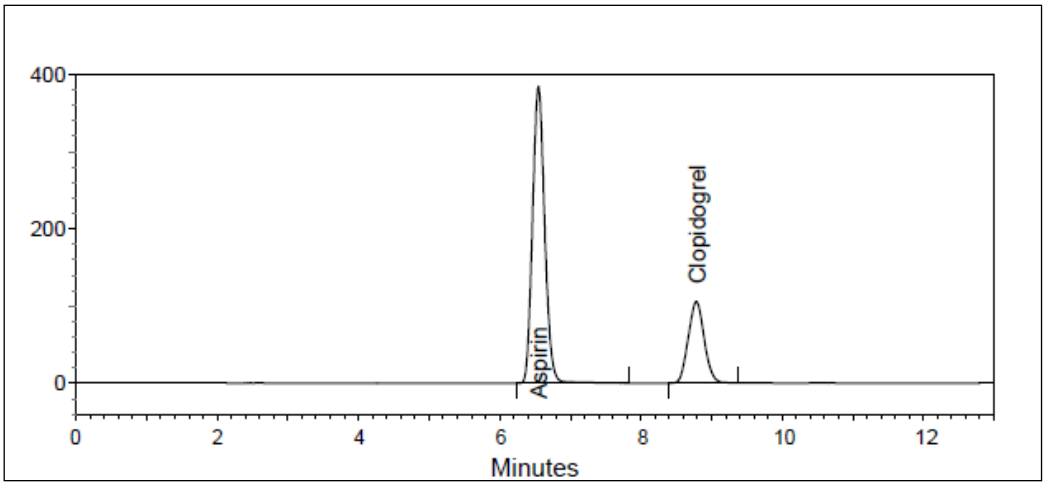

Figure 1. Chromatogram of standard preparation (0.08mg/ml)

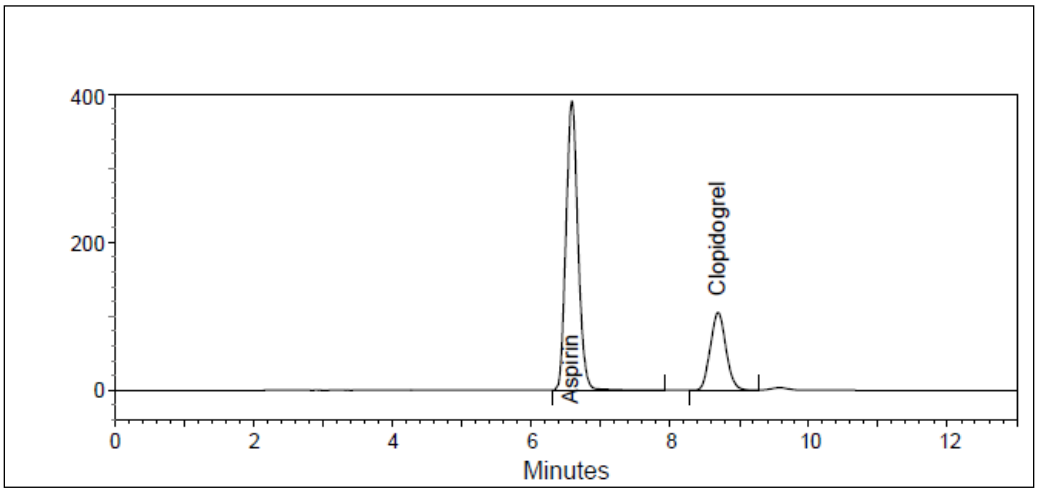

Figure 2. Chromatogram of test preparation (0.08mg/ml)

In order to determine whether the analytical method or assay were stability- indicating, aspirin and clopidogrel combine tablets were stressed under various conditions to conduct forced degradation studies. Regulatory guidance in ICH Q2A, Q2B, Q3B and FDA 21 CFR section 2 11 all require the development and validation of stability-indicating potency assays. Unfortunately, the current guidance documents do not indicate detailed degradation conditions in stress testing. However, the used forced degradation conditions, stress agent concentration and time of stress, were found to effect degradation and not complete degradation of active materials. The discovery of such conditions was based on development trial.

Acidic condition

Acidic degradation study was performed by heating the drug content in 1 N HCl (50 ml) at 80 °C for 1 hour and mixture was neutralized with 1 N NaOH solution. The drug content was found to be degrading up to 16.93 % in acidic condition. Clopidogrel was more susceptible to acid hydrolysis under experimental conditions. In all degradation conditions the drug degrades as observed by by the decreased area in the peak of the drug when

compared with peak area of the same concentration of the undegraded drug, with giving one additional degradation peak at 9.02 min.

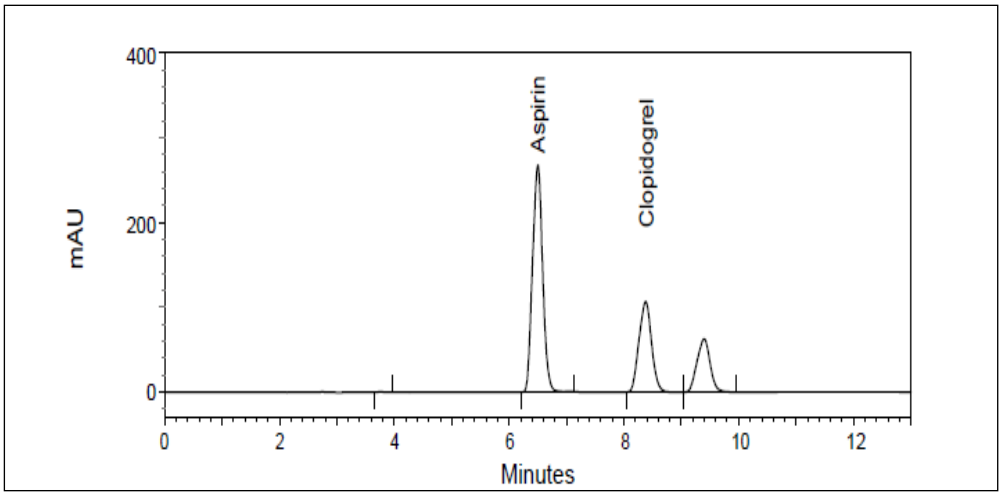

Figure 3. Chromatogram of acidic forced degradation study

Alkaline condition

Alkaline degradation study was performed by heating the drug content in 1 N NaOH (50 ml) at 80 °C for 1 hour and mixture was neutralized with 1 N HCl solutions. In alkali degradation, it was found that around approximately 22 % of the drug was degraded (Figure 4). Aspirin was more susceptible to alkaline hydrolysis under experimental conditions. In all degradation conditions the drug degrades as observed by the decreased area in the peak of the drug when compared with peak area of the same concentration of the undegraded drug, with giving one additional degradation peak at 4.72 min.

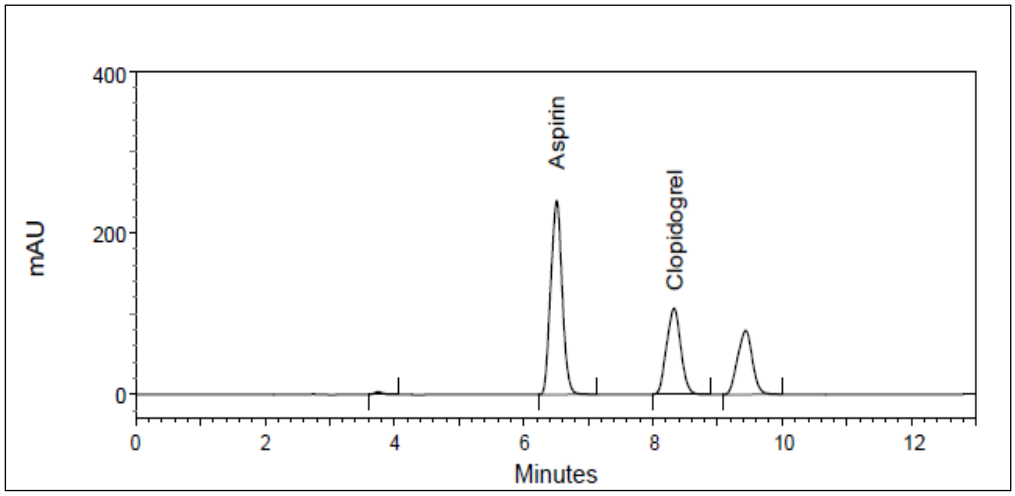

Figure 4. Chromatogram of alkali forced degradation study

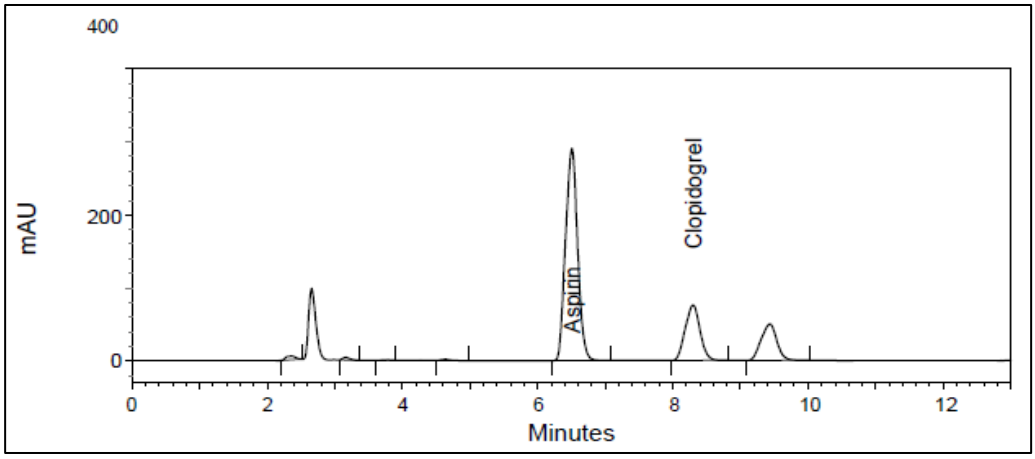
Oxidative condition

Oxidation degradation study was performed by heating the drug content it's in initial concentration carried out in 1% v/v hydrogen peroxide no significant changes then will increase into 3% v/v hydrogen peroxide at 80 °C for 30 minutes. In oxidative degradation, it was found that approximately 15.84 % of drug was degraded (Figure 5). .



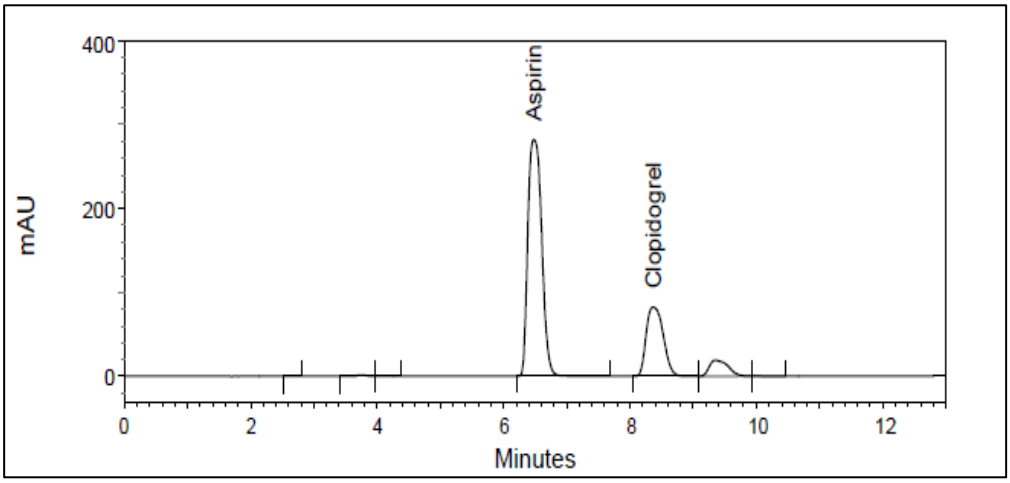


Figure 5. Chromatogram of oxidative forced degradation study

Thermal condition

Thermal degraded samples wherever degradation possible from about 1% to 30%.Preferably, the following stress conditions are was performed by exposing solid drug at 80 °C for 72 hours. Resultant chromatogram of thermal degradation study (Figure 6) indicates that aspirin is found to be slightly stable under thermal degradation condition. Only 7.0 % of drug content was degraded.

.

Figure 6. Chromatogram of thermal degradation study

Photolytic condition

Exposure of drug molecules may produce photolytic degraded products. The rate of photo degradation depends upon the

intensity of incident light and quantity of light absorbed by the drug molecule. Photolytic degradation is carried out by exposing the drug substance (in solid as well as in the solution form) or drug product to a combination of visible and UV light. Photolytic degradation study was performed by exposing the drug above specific photolytic condition. Drug content was found to be more stable than other stress condition stable in UV-light. Aspirin is stable under UV light compare to clopidogrel. (Figure 7).

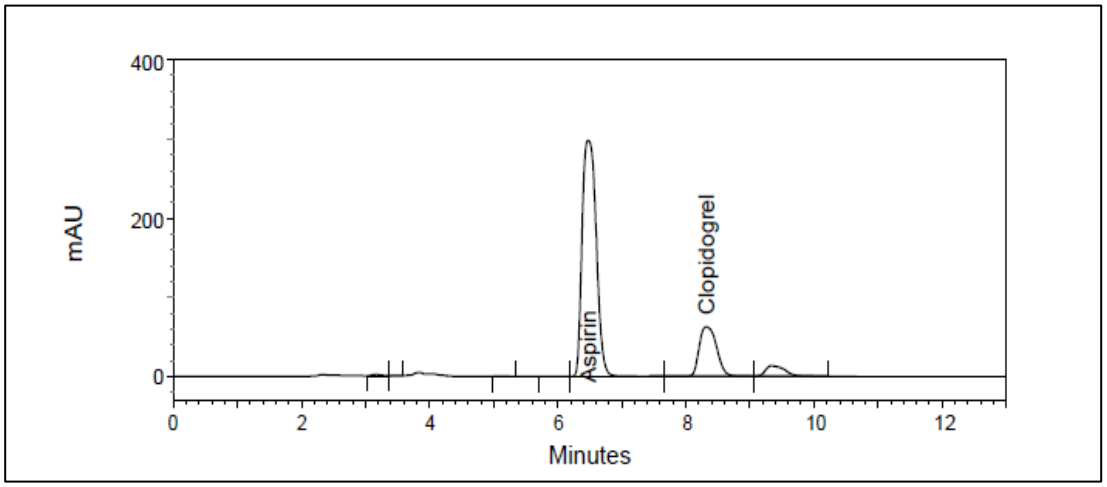

Figure 7. Chromatogram of UV-light degradation study

Linearity

For linearity seven points calibration curve were obtained in a concentration range from 0.030 – 0.120 mg/ml for aspirin and 0.015 – 0.060 mg/ml for clopidogrel, respectively. The response of the drug was found to be linear in the investigation concentration range and the linear regression equation for aspirin was y = 60026378.57x + 51410.11 with correlation coefficient 0.9999 (Figure 8) and for clopidogrel was y = 44544414.03x - 1890.29 with correlation coefficient 0.9999 (Figure 9). Where x is the concentration in mg/ml and y is the peak area in absorbance unit.

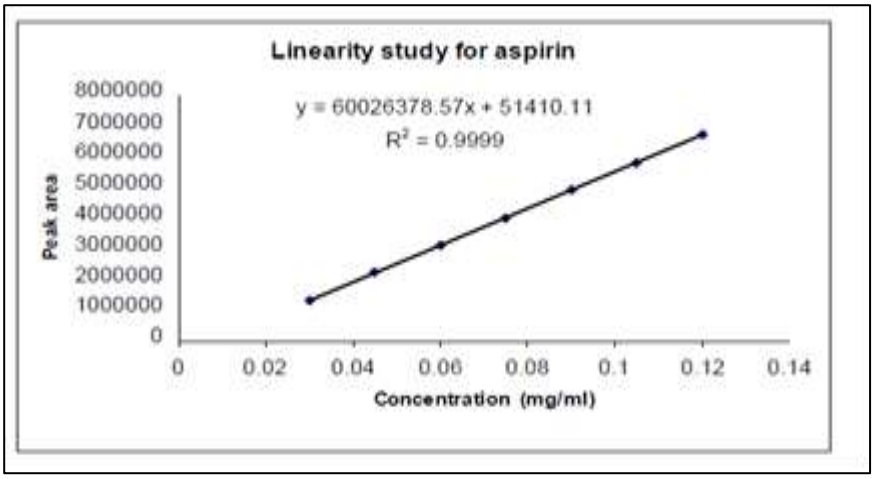

Figure 8. Linearity curve for aspirin

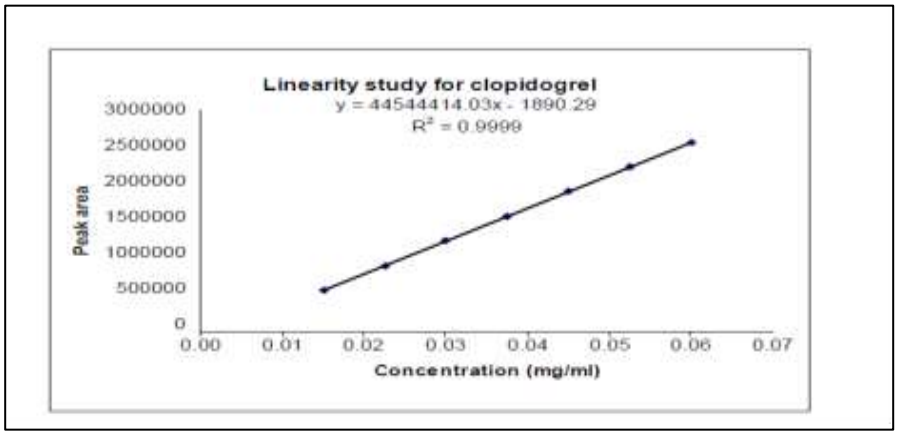

Figure 9. Linearity curve for clopidogrel

Detection and Quantification Limit (LOD and LOQ)

The limit of detection and limit of quantification were evaluated by serial dilutions of aspirin and clopidogrel stock solution in order to obtain signal to noise ratio of 3:1 for LOD and 10:1 for LOQ. The LOD value for aspirin and clopidogrel were found to be 0.05 ppm and 0.15 ppm, respectively and the LOQ value 0.2 ppm and 0.3 ppm, respectively. Chromatogram of LOD study for aspirin and was illustrated in Figure 10.

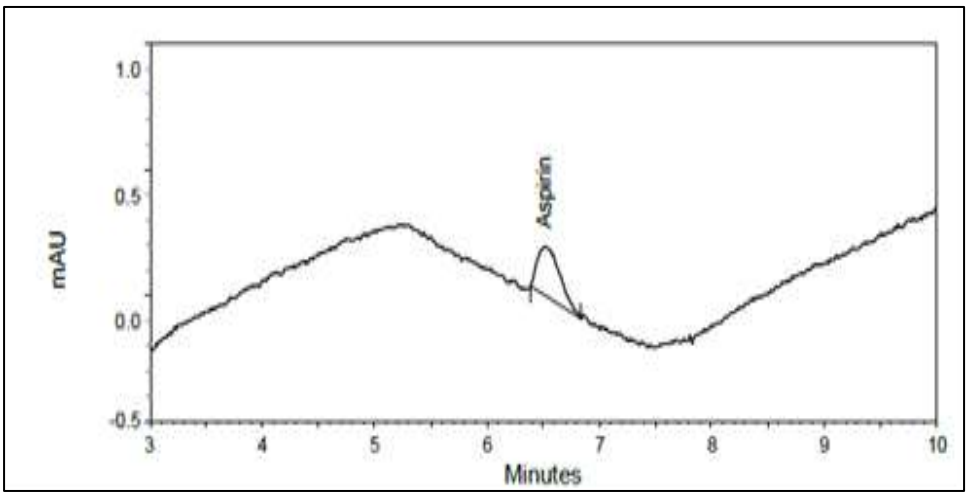

Figure 10. Chromatogram of LOD study of aspirin

Precision

Data obtain from precision experiments are given in Table 1 for intraday and interday precision study for both aspirin and clopidogrel. The RSD values for intraday precision study and interday precision study was < 2.0 % for aspirin and clopidogrel. It was confirmed that the developed method was precise for analysis. Results of precision in this study was summarized in the Table 1 below

Table 1. Results of precision study

Set	Aspirin (%Assay)		Clopidogrel (%Assay)	
	Intraday (n = 6)	**Interday (n = 6)**	**Intraday (n = 6)**	**Intraday (n = 6)**
1	99.1	100.2	99.3	99.6
2	100.0	99.9	98.7	99.6
3	99.6	100.5	98.6	100.1
4	99.5	100.3	99.0	100.1
5	100.3	101.0	100.0	100.6
6	99.1	100.8	99.5	100.7

150	0.05627	0.05647	100.35	0.24

a Each value corresponds to the mean of three determination

Robustness

The result of robustness study of the developed assay method was established in Table 3 and Table 4, respectively. The result had shown that during all variance conditions, assay value of the test preparation solution was not affected and it was in accordance with that of actual. System suitability parameters were also found satisfactory hence the analytical method would be concluded as robust method.

Table 3. Evaluation data of robustness study of aspirin

	% Assay	System Suitability Parameters		
		Theoretical	Asymmetry	% RSD
Flow 0.9 ml/min	100.5	6460	1.05	0.22

Table 4. Evaluation data of robustness study for clopidogrel

Robust Conditions	% Assay	System Suitability Parameters			
		Theoretical	Asymmetry	% RSD	Resolution
Flow 0.9 ml/min	98.5	6975	1.07	0.67	5.75
Flow 1.1 ml/min	100.0	5992	1.06	0.39	5.14
0.28 % H_3PO_4-ACN(65:35,v/v)	98.8	6899	1.03	1.03	6.35
0.32 % H_3PO_4-ACN(65:35,v/v)	99.2	6113	1.03	0.69	5.6
0.3% H_3PO_4-ACN(63:37,v/v)	99.5	5850	1.11	0.70	4.31
0.3% H_3PO_4-ACN (67:33,v/v)	99.0	6185	1.04	0.30	5.71
Column change (different lot)	100.0	5996	1.04	0.25	4.97

Conclusion

The method was validated for all validation parameters as per ICH guidelines. The linearity range for aspirin and clopidogrel was 0.030 – 0.120 mg/ml for aspirin and 0.015 – 0.060 mg/ml for clopidogrel with correlation coefficient 0.9999. The % RSD for intra-day precision was < 2%. The developed and validated stability indication HPLC method is found to be linear, accurate, precise, specific and robust, confirming the stability indicating method for the simultaneous estimation of aspirin and clopidogrel.

Abstract

An experimental design methodology was performed in the optimization of removal of malachite green dye by multi-walled carbon nanotubes. A Central Composite Design (2^5) was chosen to develop a mathematical model and determine the optimum condition for adsorption of malachite green by carbon nanotubes. Five experimental factors, namely initial dye concentration, mass of adsorbent, pH, contact time and agitation speed were studied. Maximum adsorption of malachite green was achieved at the suggested optimum conditions: initial dye concentration (20 ppm), weight of adsorbent (0.03 g), pH solution (7) contact time (17 min) and agitation speed (150 strokes per min). The experimental value of adsorption by multi-walled carbon nanotubes were found to be in good agreement with the predicted value (R^2 = 0.922).The experimental equilibrium data were best fitted to isotherm model (Langmuir) and kinetic model (pseudo second-order) respectively. Maximum adsorption by carbon nanotubes at monolayer for malachite green was obtained at 112.36 mg/g while kinetic rate constant was calculated to be 0.0017 g mg^{-1} min^{-1}.

Keywords: carbon nanotubes, adsorption, malachite green, experimental design

Abstrak

Metodologi reka bentuk eksperimen telah dijalankan dalam pengoptimuman penyingkiran pewarna malakit hijau oleh karbon tiub nano multi-dinding. Reka bentuk komposit berpusat (2^5) telah dipilih untuk membentuk satu model matematik dan menentukan kondisi yang optima untuk penjerapan malakit hijau oleh karbon tiub nano. Lima faktor eksperimen yang terdiri daripada kepekatan awal pewarna, berat bahan penjerap, pH larutan, masa sentuhan dan kelajuan goncangan telah dikaji. Malakit hijau telah mencapai penjerapan yang optima oleh karbon tiub nano pada kondisi: kepekatan awal pewarna (20 ppm), berat bahan penjerap (0.03 g), pH larutan (7), masa sentuhan (17 minit) dan kelajuan goncangan (150 strok/minit). Nilai eksperimen untuk penjerapan oleh karbon tiub nano multi-dinding telah mencapai persetujuan yang baik pada nilai jangkaan (R^2 = 0.922). Data eksprimen keseimbangan menunjukkan kesesuaian pada model Langmuir dan model pseudo tertib kedua. Penjerapan maksimum oleh karbon tiub nano pada monolapisan untuk malakit hijau ialah 112.36 mg/g manakala pemalar kadar kinetik ialah 0.0017 g mg^{-1} min^{-1}.

Introduction

The wide consumption of dyes in textile industries has produced a large amount of waste in the environment. There are structural varieties of dyes such as acidic, basic, disperse, azo, diazo, metal complex and anthraquinone that have been utilized in industries [1]. Malachite Green (MG) is a N-dimethylated diaminotriphenyl-methane dye that was first introduced during the mid-1933s [2] and is extensively used in aquaculture and dyes industries. MG is a basic dye, readily soluble in water and has been used as a dye in silk, jute, leather, cotton, paper and acrylic industries as well as food colouring agent, food additive, medical disinfectant and anthelmintic [3]. In aquaculture, MG has been used as an effective antifungal and antiprotozoal agent. The fungicidal properties of MG can control fungal attack, protozoan infections and some other diseases in aquatic organisms [4].

Even though MG was not approved by the US Food and Drug Administration, it is still being consumed around the world since it is relatively inexpensive, ready to be used and highly efficacious [5]. The disposal of MG in the environment can cause environmental problems, especially water pollution. MG is classified as a Class II Health Hazard and shows significant health risk to human through consumption of fish that contains MG residue [6]. MG is easily absorbed by fishes after treatment and reduced in the tissues of fish to its colourless metabolite compound known as leucomalachite green (LMG), which is also a suspected mutagen and teratogen [7]. LMG excretes very slow ($t^{1/2}$ ~ 40 days) in certain fatty tissues and this causes the accumulation of LMG in fishes [8]. In addition, MG can cause harm to the aquatic environment; in a way, it is reducing light penetration and photosynthesis [9, 10]. The disposal of dye wastewater without proper treatment is a big challenge since most of the dyes are difficult to eliminate from the environment and dyes are usually hard to biodegrade due to their complex molecular structures [11].

Various techniques have been applied for the removal of MG from wastewater, which included physical, chemical and biological methods. Chemical techniques such as advanced oxidation process consumed more chemical reagent while high cost of chemicals and operation brought about this method as an unattractive option. Meanwhile, biological methods, which include microbial degradation, bioremediation system and fungal discoloration, do not usually achieve a satisfactory elimination of the dyes on a continuous basis and require longer time [9, 12]. Adsorption, which is one of the physical techniques for wastewater treatment, becomes an appealing method in the removal of dyes from wastewater since it offers a simple and easy design, does not contribute to harmful substances, has high efficiency and versatile techniques compared to the others [13].

Recently, carbon nanotubes (CNTs) have been recognized to have a potential to be a superior adsorbent in the adsorption of dye from wastewater because of the unique chemical and physical properties of CNTs. Generally, CNTs are divided into two types, namely single-walled carbon nanotubes (SWCNT) and multi-walled carbon nanotubes (MWCNT). CNTs consist of highly porous and hallow structure, large specific surface area, light mass density and provide a chemically inert surface for physical adsorption. These tremendous morphologies have given an advantage for a good adsorption [14, 15], thus an efficient removal of contaminants. CNTs have been successfully applied to remove numerous contaminants in wastewater such as heavy metals [16, 17], volatile organic compound [18] and dye [10, 15, 19, 20].

Optimization of adsorption studies can be performed by varying experimental factors and conventionally, the classical method has limitations as it only can vary one factor at one time while the other factors are fixed. In addition, it requires a large number of experiments to be performed each time. Meanwhile, the response surface methodology (RSM) is one of the approaches by the researchers to study the interaction of several factors at one time. RSM is a collection of mathematical and statistical techniques in which describing the response to the experimental data fitted in a polynomial equation and the experimental data were achieved by the systematic design [21]. Designing and evaluating experiments by experimental design allows the researchers to optimize the interest factors for the adsorption process and depict the linear, interaction and quadratics effects of all factors involved at the same time. The systematically varied design by RSM also controls and reduces the number of experiments. Beneficially, this made the research become faster, more economical and effective compared to the classical method, which consumes more chemicals and time [21, 22].

In the present study, a central composite design (CCD) has been chosen to be applied in the optimization of MG removal by MWCNTs. The batch experiments under optimized conditions were then tested for isotherm and kinetic model respectively.

Materials and Methods

Reagents and Instruments

Multi-walled Carbon Nanotubes (6 – 9 nm outer diameter, 5 μm in length and >95% purity) were purchased from Sigma-Aldrich (St. Louis, USA) and have been used for adsorption experiment without further purification. The malachite green dye, sodium acetate with analytically graded was purchased from R & M Chemicals (Essex, UK). Acetic acid used for preparation of acidic buffer (Merck, Germany) and for basic buffer, ammonium hydroxide from J. T. Baker (Pennsylvania, USA) and ammonium chloride from Ridel-De Haen (Seelze, Germany) were used. Deionized water was obtained from a Milli-Q EasypureRodi system (Barnstead, USA).

The initial and final concentrations of malachite green were determined by UV-Vis spectrophotometer (Shimadzu Model UV-1650PC) at a wavelength of 617 nm. The pH measurements were carried out by using pH meter (Eutech Model pH 700 series). An agitation effect was performed by shaking water bath (Memmert WNB 22). The cellulose nitrate membrane filter with pore size 0.45 μm produced by Millipore (Merck, Germany) was used for filtering MWCNTs from aqueous solution after adsorption experiment.

Adsorption Experiments

The stock solution of malachite green was prepared by weighing the appropriate mass of malachite green dye salt and dissolved with deionized water. Then, working solutions of malachite green were prepared by diluting volume of stock solution required with deionized water.

In general, the adsorption of malachite green was performed as follows: A specified mass of MWCNTs powder was added into 100 mL of MG solution. The pH of the solution was adjusted with a buffer solution of acetate acid-sodium acetate and ammonium hydroxide-ammonium chloride. Then, each of the solution was shaken in a shaker for a specific time which following the designed experiments (Table 2) and the adsorption experiments were carried out based on central composite design (CCD). The MWCNTs then was filtered using vacuum filter, and the filtrate solution was analyzed to UV-Vis spectrophotometer to determine the final concentration of the dye.

Central Composite Design

A central composite design (2^5) was used to evaluate the implication and influence of variables toward the removal of dye by MWCNTs. The efficiency of malachite green adsorption by MWCNTs was observed by different experimental factors, namely mass of adsorbent, initial concentration of dye, pH of solution, contact time and agitation speed (Table 1). A total of 54 experiments were designed by using Minitab Software version 17 (Minitab Inc., State College, USA). The mathematical relationship between the factors can be approximated by the second order polynomial model as expressed in Eq. 1 [23]:

$$y = \beta_0 + \sum_{i=1}^{5} \beta_i x_i + \sum_{i=1}^{5} \sum_{j=1}^{5} \beta_{ij} x_i x_j + \sum_{i=1}^{5} \beta_{ii} x_i^2 \quad (1)$$

where y is the predicted response (percentage of removal); x_i's are the input variables (mass of adsorbent, initial concentration of dye, pH of solution, contact time and agitation speed) that are known for each experimental run. The parameter β_0 is the model constant; β_i is the linear coefficient; β_{ii} is the quadratic coefficient and β_{ij} is the cross-product coefficient. Generally, CCD consists of three operations which are $2n$ axial run, 2^n factorial run and central run. The CCD in present research is designed based on carrying out 12 axial points, 32 factorial point and 12 replicates at the center (54 experiments) as listed in Table 2. Total of experiments can be calculated by Eq. 2 below:

$$\text{Total number of experiments} = 2n + 2^n + n_c \quad (2)$$

where n is the number of factors, n_c is the number of center points [24].

Table 1. Experimental factors and levels in the CCD

Factors	Levels			Star point $\alpha = \pm 2.00$	
	Low (-1)	Central (0)	High (+1)	-α	+α
(X_1) Mass of adsorbent (g)	0.04	0.06	0.08	0.02	0.10
(X_2) Initial concentration of MG (ppm)	40	60	80	20	100
(X_3) pH of solution	5.5	7	8.5	4	10
(X_4) Contact time (min)	15	20	25	10	30
(X_5) Agitation speed (stroke/min)	60	90	120	30	150

Analysis of variance (ANOVA) was also performed to discriminate the significance of the variables. Interaction between latent experimental factors was visualized using surface plot graph.

Measurement of Dye Concentration

The malachite green removal for each experiment was calculated using the following Eq. 3 [25]:

$$\%\ \text{MG removal} = \frac{(C_0 - C_t)}{C_0} \times 100 \quad (3)$$

where C_0 (mg/L) is the initial concentration of dye, C_t (mg/L) is the concentration at time t. The amount of adsorbed malachite green, Q_e (mg/g) was calculated by using the following Eq. 4 [26]:

$$Q_e = \frac{(C_0 - C_e)V}{m} \quad (4)$$

where C_0 and C_e (mg/L) are the initial dye concentrations and equilibrium dye concentrations in aqueous solution respectively, V (L) is volume of the solution and m (g) is mass of the adsorbent.

Isotherm and Kinetic Study

In identifying the isotherm and kinetics of MG adsorption by MWCNTs, adsorption experiments were performed in 250-mL conical flask with 100 mL of MG solution. The initial concentration of MG was varied in a range from 20 to 60 ppm and the other parameters were kept constant for isotherm experiment. For kinetic study, a series of experiment was carried out with different contact times from adsorption while the others parameters were under optimized condition.

Results and Discussion

Optimization of Adsorption Condition

A total of 54 experiments were run according to the Central Composite Design and their responses are presented in Table 2.

An empirical relationship between the response and independent variables was obtained based on results and expressed by the following second-order polynomial Eq. 5:

$$Y = 69.18+14.04X_1 - 4.98X_2+6.99X_3+4.02X_4+12.03X_5 - 4.32X_1^2 +3.81X_2^2+3.57X_3^2 - 2.79X_4^2 - 2.74X_1X_4 - 3.04X_2X_4 -3.52X_3X_5 \quad (5)$$

where Y is the percentage of MG removal, X_1 is mass of adsorbent, X_2 is the initial concentration of MG, X_3 is pH of solution, X_4 is contact time and X_5 is agitation speed. In this equation, only variable X_2 showed negative linearity, whereas the other factors showed positive linearity of the fitted model.

*Bold value is significant $p<0.05$

To analyze the significance of each variable, analysis of variance (ANOVA) is necessary. ANOVA subdivides the total variation into two parts; variation associated with the model and the variation associated with the experimental error. These will show whether the variation from the model is significant or not when compared to the ones associated with the residual error [27]. To carry out this comparison, the *F*-values were used by calculating the ratio between mean square of the model and the residual error. Meanwhile, the *p*-values were used to check the statistical significance of each coefficient, which in turn is necessary to understand the pattern of the mutual interactions between the test variables. A *p*-value of less than 0.05 in the ANOVA table indicates the statistical significance of an effect at 95% confidence level. The test of significance of regression model for response was evaluated and the result of ANOVA is presented in Table 3.

In this study, all individual experimental factors were significant with p-value<0.05. The p-value of lack-of-fit shows a non-significant value (0.079) which confirms the suitability of the model with the data and the model is significant [24]. The value R^2 predicted is used to measure the how the model fits with the data. A good agreement was shown by the coefficient of determination between R^2 (0.922) and R^2 adjusted (0.899) from the fitted model. In addition to correlation coefficient, the data were also evaluated based on the plots of residual (difference between the observed and the predicted response value).

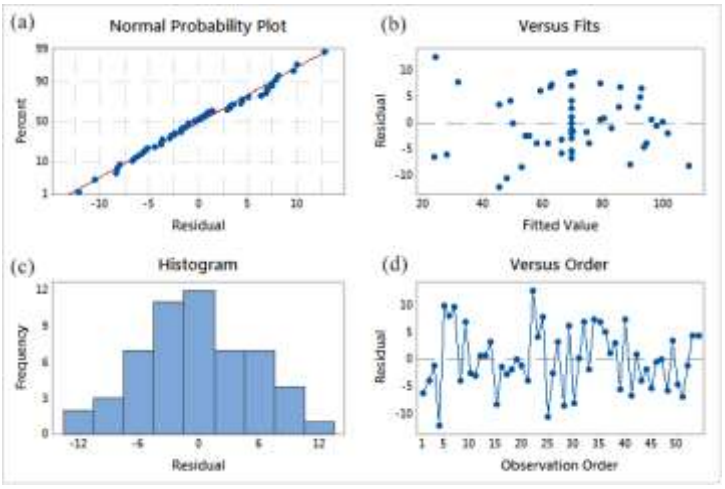

Figure 1. Residual plot for the removal of MG by MWCNTs (a) percentage of removal vs. residual, (b) residual vs. fitted value, (c) frequency vs. residual, (d) residual vs. observation order

Normal probability in Fig. 1(a) plot showed the data followed the straight line, which indicated there is normal distribution and no evidence of non-normality, skewness, outliers or undefined variables. Residuals versus fitted graph (Fig. 1(b)) can explain the consistency of the variance in errors, whereas the residual versus observation order (Fig. 1(c)) is useful in identifying the effect of observation order in inducing the results when the data were collected in a different time sequence. For residual versus fitted graph and residual versus observation order graph in Fig. 1 (d), both of the graphs in this study showed the residuals randomly scattered about zero, thus signified that residuals have constant variance in error terms and data were not affected by the observation order respectively.

The curvature nature of Fig. 2 shows the response surface plots of the removal of MG by MWCNTs confirming strong interaction among latent variables. Fig. 2 (a) and 2 (d) shows the interaction of adsorbent dosage with contact time and agitation speed respectively, in influencing the removal of MG. The increase in percentage of MG removal was observed with the increase amount of adsorbent dosage. As the mass of adsorbent increasing, there are more sites and specific area for adsorption, in which provide more availability for the dye molecules to vacant on the surface of MWCNTs.

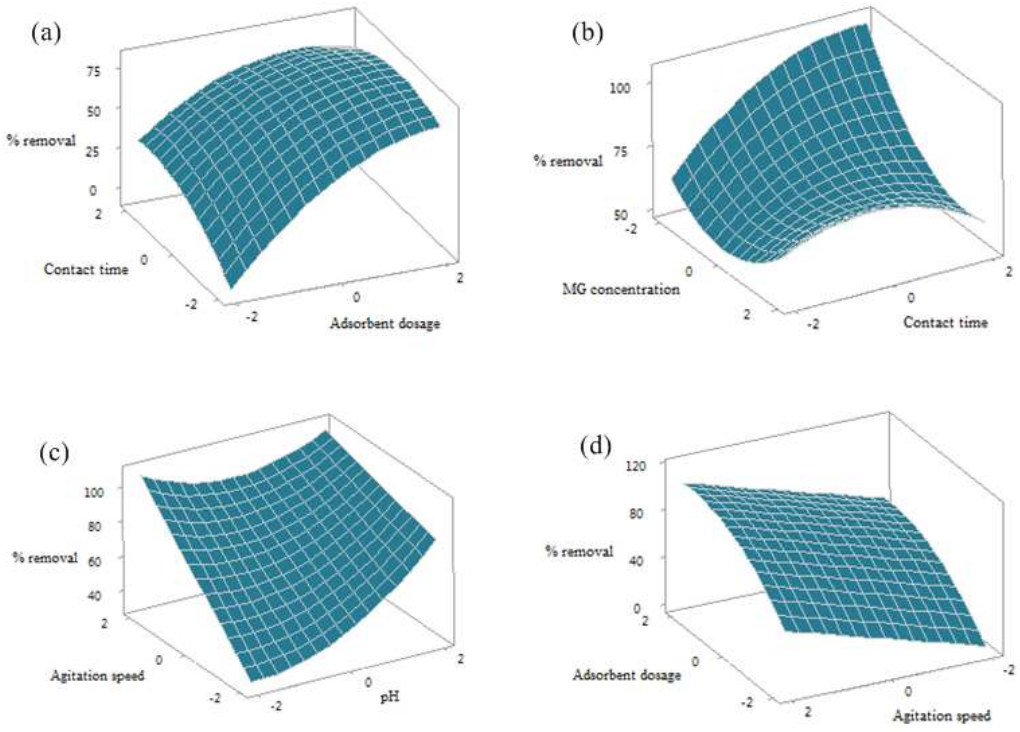

Figure 2. Surface plot for CCD: (a) contact time-adsorbent dosage; (b) initial concentration MG-contact time; (c) agitation speed-pH; (d) adsorbent dosage-agitation speed

The response surface plots shown in Fig. 2 (b) demonstrate the changes in the percentage removal for MG initial with initial MG concentration-contact time interaction. It can be seen that the percentage of MG removal decreased when the concentration of MG increased. At lower dye concentrations, the ratio of solute concentration to adsorbent sites is lower, which increases the rate of dye uptake. However, the yield of adsorption of MG by the MWCNT decrease at higher concentration since there is no vacancy for the adsorption dye on the adsorbent as the adsorbent sites were saturated with dye molecules.

The pH of the system plays important roles in affecting the ability of adsorbent surface for the interaction and dye molecule tendency for binding solid surface [28]. Surface plot in Fig. 2 (c) shows the percentage of MG removal with interaction of pH with agitation speed. The removal of dye was more favourable at higher pH compared to lower pH. This result can be clarified by the fact that at lower pH, the presence of excess H+ ions was competing with MG molecules as a cationic dye to be adsorbed on the surface of MWCNTs. However, on basic condition, the surface of the MWCNTs was enhanced with negatively charge sites and the electrostatic attraction exists between cationic dye molecules and adsorbent site [29]. The effect of contact time was illustrated by the graph in Fig. 2 (a) and 2 (b). Generally, both of surface plot show the removal of MG was increased as the contact time increased, and gradually reaching equilibrium. This is due to a lot of specific surface areas available at initial time, causing the rapid adsorption rate between MG molecules and MWCNTs. However, as the vacancies on the surface of MWCNTs were filled with MG molecules, the adsorption process becomes slower and reached equilibrium.

Another important parameter influencing the rate of adsorption is the speed of agitation. A range of agitation speed from 30 to 150 strokes/min has been studied in the adsorption experiments. As shown in surface plot in Fig. 2 (c) and 2 (d), the percentage of MG removal increased directly with increase of agitation speed. The boundary layer exists between adsorbent particles and solution decreasing as the speed of agitation increasing which results in the

higher of dye uptake by MWCNT. Besides, high agitation speed also increases the distribution of adsorbent in solution [29].

The profile for desirable option with predicted values in the Minitab software was used for the selection of optimum conditions of the dye removal. The profile of desirable responses was chosen after specifying the desirability function (DF) for each dependent variable (removal percentage) by assigning predicted values. The scale in the range from 0.0 (undesirable) to 1.0 (very desirable) was used to achieve a global function (D) that should be maximized to obtain 100% removal by optimizing designed variables. Based on the desirability score of 1.0, maximum removal (99.9%) was achieved at suggested optimum conditions set as: 0.03 g of adsorbent, initial MG concentration of 20 ppm, pH solution of 7, with equilibrium time of 17 minutes and agitation at speed 150 strokes per minute. Three additional experiments were carried out under the optimal conditions, in which a good agreement between the calculated and experimental responses was obtained (99.9 % removal) with 2.17% of RSD value.

Adsorption Isotherm Study

Basically, isotherm analysis was performed to understand the relationship between adsorbate and the surface of adsorbent when the equilibrium is achieved. It gives useful information about mechanism, properties and tendency of adsorbate being adsorbed by the adsorbent. In this study, the data obtained during the equilibrium study were fitted to both Langmuir and Freundlich isotherm models, as a way to evaluate the equilibrium characteristics of the adsorption process.

The most basic of isotherm model was Langmuir isotherm, which assumed that there is no interaction between the adsorbate molecules and the adsorption localized in a monolayer [30]. Langmuir isotherm is expressed by the following Eq. 6:

$$\frac{C_e}{Q_e} = \frac{1}{(K_a Q_m)} + \frac{C_e}{Q_m} \tag{6}$$

where C_e is the concentration of MG at equilibrium (mg L^{-1}); Q_e is the amount of dye adsorbed per mass of MWCNTs (mg g^{-1}); K_L represents the Langmuir constant (L mg^{-1}); and Qm is the theoretical saturation capacity of the monolayer (mg g^{-1}) [23]. The values of Q_m and K_L were calculated from the intercept and slope of the linear plot of C_e/Q_e versus C_e.

The Freundlich model is an empirical equation that assumes heterogeneous adsorption due to the diversity of adsorption sites. The Freundlich isotherm is represented by Eq. 7 below:

$$\ln Q_e = \ln K_F + \frac{1}{n} \ln C_e \tag{7}$$

where Q_e is the amount of dye adsorbed per mass of MWCNTs (mg g^{-1}); C_e is the concentration of MG at equilibrium (mg L^{-1}); K_F (L mg^{-1}) and n are Freundlich constant, which represents the adsorption capacity and the adsorption strength respectively [23]. K_F and 1/n were obtained from the intercept and slope of the linear plot of ln Q_e versus ln C_e. Table 4 summarizes the coefficient of the Langmuir and Freundlich isotherms obtained in this study.

By comparing both Langmuir and Freundlich models, it can be seen clearly that the R^2 values of both models exceeded 0.9, suggesting experimental results fitted well in both of the models. However, as R^2 of Langmuir comparatively higher than Freundlich model, it can be demonstrated that the adsorption is much favourable with Langmuir model. This can be assumed that adsorbed MG molecules formed monolayer coverage on the surface of MWCNTs, and all the adsorption sites.

Table 5. Linear regression of isotherm adsorption and its constant parameter

Isotherm	Linear Regression	Parameter	Value of parameter
Langmuir	y = 0.0089x + 0.0117	Q_m (mg/g)	112.360
		K_a (L/mg)	0.761
		R^2	0.998
Freundlich	y = 0.1198x + 4.2967	*1/n*	0.120
		K_F (L mg/g)	73.457
		R^2	0.933

Another important parameter is separation factor, R_L which is a dimensionless constant that evaluates whether the adsorption is favourable or unfavourable. The R_L equation is represented as follows (Eq. 8):

$$R_L = \frac{1}{(1+K_i C_0)} \quad (8)$$

where K_L is the Langmuir constant (mg L^{-1}) and C_0 is the initial concentration of MG. The value of R_L indicates the type of isotherm to be unfavourable ($R_L > 1$), linear ($R_L = 1$), favourable ($0 < R_L < 1$) or irreversible ($R_L = 0$) [31]. All the values of R_L ranged between 0 and 1 (shown in Fig. 3), denoting that the adsorption of MG onto MWCNTs was favourable. In addition, the R_L values decreased as the initial concentration of MG increased, suggesting that the adsorption process was more favourable at higher concentration [32].

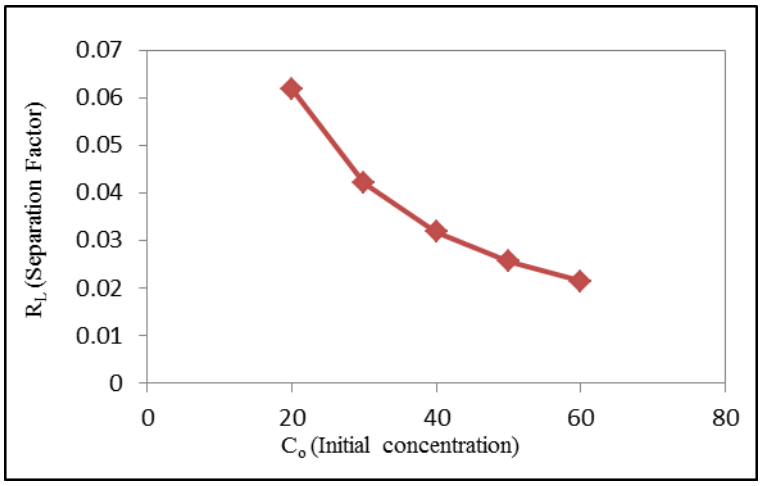

Figure 3. Separation factor, R_L versus initial concentration of MG, C_0 for adsorption of MG by MWCNTs

Adsorption Kinetic Study

Adsorption is a physicochemical process that involves mass transfer of solute from the solution to the surface of the adsorbent [33]. An ideal adsorption is not only having high adsorption capacity, but it also must have high rate of adsorption. Kinetic analysis does not only depict the adsorption rate of the adsorbent but also can provide important information about the mechanism of adsorption on the adsorbent. To elucidate the kinetic properties of the adsorption process of MG on MWCNTs, three most widely use kinetic models were applied, which are the pseudo-first-order, pseudo-second-order and intraparticle diffusion model.

Generally, the pseudo-first-order model is used in explaining the adsorption rate based on the adsorption capacity. The equation of pseudo-first-order is expressed as Eq. 9 below:

$$\log(Q_e - Q_t) = \log Q_e - \frac{k_1 t}{2.303} \quad (9)$$

where Q_e and Q_t are the amount of MG adsorbed per mass of MWCNTs (mg g^{-1}) at equilibrium and time t (min) respectively, and k_1 (min^{-1}) is rate constant of pseudo-first-order model for the adsorption [23]. Values of k_1 and Q_e of pseudo-first-order were obtained from the slope and intercept of plot log ($Q_e - Q_t$) versus t.

For pseudo-second-order, the equation is given as Eq. 10 below:

$$\frac{t}{Q_t} = \frac{1}{k_2 Q_e^2} + \frac{t}{Q_e} \quad (10)$$

where Q_e and Q_t are the amount of dye adsorbed per mass of MWCNTs (mg/g) at equilibrium and time t (min) respectively, and k_2 (g mg^{-1} min^{-1}) is rate constant for pseudo-second-order model of adsorption [23]. For values of k_2 and Q_e of pseudo-second-order, both of the values were obtained from the slope and intercept of plot (t/Q_t) versus t, respectively.

However, pseudo-first-order and pseudo-second-order have their own limitation as both of the models cannot identify the diffusion mechanism of adsorption. Generally, bulk diffusion and adsorption are assumed to be rapid and not rate-determining [31]. Therefore, the kinetic data were also analyzed using the intraparticle diffusion model in describing the diffusion mechanism. This is important in considering the diffusion mechanism between MG molecules and MWCNTs as MWCNTs have porous structure. The intraparticle diffusion model equation is given by Eq. 11 below:

$$Q_t = K_{diff} t^{1/2} + C \quad (11)$$

where k_{diff} is intraparticle diffusion rate constant (mg/g $min^{1/2}$) and C is the intercept. The value of k_{diff} and C value of intraparticle diffusion were obtained from the slope and intercept of plot Q_t versus $t^{1/2}$ [23]. The data from adsorption of MG by MWCNTs at mass of 0.03g were examined and experimental data are presented in Table 5. The best-fit model was selected based on the linear regression correlation coefficient values (R^2).

Table 6. Linear regression of kinetic adsorption and its constant parameter

Model	**Linear regression**	**Parameter**	**Value of parameter**
Pseudo first-order	y = -0.0235x + 1.7648	k_1	0.054
		Q_e (calc)	58.184
		Q_e (exp)	85.700
		R^2	0.916
Pseudo second-order	y = 0.0114x + 0.0746	k_2	0.0017
		Q_e (calc)	87.719
		Q_e (exp)	85.700
		R^2	0.978
Intraparticle diffusion	y = 11.093x + 16.136	k_{diff}	11.093
		C	16.136
		R^2	0.928

Table 5 presents the kinetic parameter for the adsorption of MG by MWCNTs. Both of R^2 values of pseudo-first-order and pseudo-second-order have a good correlation coefficient; however, pseudo-second-order showed a better result as pseudo-second-order has higher R^2 (0.978) compared to pseudo-first-order (0.916). In addition, the value of Q_e (calc) derived from pseudo-second-order is comparatively much closer to Q_e (exp).

For intraparticle diffusion model, the plot of Q_t versus $t^{1/2}$ should give a linear plot if intraparticle diffusion participated in the adsorption and the intraparticle diffusion is the only rate-controlling step if the line of linear regression passes through the origin [34]. Otherwise, there are other mechanisms that also contributed to intraparticle diffusion. The *C* value of intraparticle diffusion is also helpful in boundary thickness; a larger *C* corresponds to a greater boundary layer diffusion effect [31]. Besides, the larger value of the intercept also shows the greater surface adsorption that contributes to the rate-controlling step [33]. The regression (Q_t versus $t^{1/2}$) of MG removal by MWCNTs showed a linear plot; however, the line did not pass through the origin. This indicates that the adsorption involved in intraparticle diffusion was not only rate-controlling step [34].

Conclusion

The present study showed that the MG dye from aqueous solution was successfully removed by MWCNTs and the adsorption condition was efficiently optimized by applying central composite design. The adsorption MG by MWCNT achieved optimum removal in equilibrium time of 17 minutes with 20 ppm of initial dye concentration, 0.03g of mass of MWCNT, pH 7 and agitation speed of 150 strokes/min. Analysis of variance also showed a good coefficient of determination (R^2 = 0.922), ensuring that the model was well-fitted. Central composite design successfully proved the significance of all the experimental factors which affect the rate of the adsorption. The isotherm and kinetic of adsorption were also investigated. For the isotherm model, both Langmuir and Freundlich models were fitted with experimental equilibrium data but the results showed the Langmuir model (R^2=0.998) is best fitted for the concentration range studied. The maximum adsorption capacity of MWCNTs for MG dye was 112.36 mg g^{-1}. The experimental data depicted that the adsorption kinetic of MG by MWCNTs was controlled by pseudo-second-order kinetic model (R^2 =0.978) with rate constant calculated at 0.0017 g mg^{-1} min^{-1}.

UTILIZATION OF ENCAPSULATED $CACO_3$ IN LIQUID CORE CAPSULES FOR IMPROVING LACTIC ACID FERMENTATION

(Penggunaan Kapsul Berteras Cecair yang Mengandungi $CaCO_3$ untuk Menambah Baik Penapaian Bakteria Asid Laktik)

Abstract

Lactic acid bacteria (LAB) have been used for food fermentation due to its fermentative ability to improve and enhance the quality of the end food products. However, the performance of LAB is affected as fermentation time elapsed because the microbial growth is inhibited by its end product, i.e. lactic acid. In this study, a new approach was introduced to reduce the product inhibition effect using $CaCO_3$ which is encapsulated in spherical liquid core capsules of diameter 3.5mm and 3.6 mm produced through extrusion dripping method. The results showed that the pH and lactic acid concentration of LAB fermentation was well maintained by the capsules. The results of the fermentation conducted to control pH and lactic acid concentration using the capsules were better than those of the control set and comparable with that of the free $CaCO_3$ set. In addition, the viable cell concentration of *L. casei shirota* was high at the end of fermentation when the fermentation was conducted using the capsules. The results of this study suggested that the capsules have high potential to be applied for pH and lactic acid level control in LAB fermentation for various productions.

Keywords: calcium carbonate, lactic acid bacteria fermentation, liquid core capsule, pH

Abstrak

Bakteria asid laktik (LAB) telah banyak digunakan untuk penapaian makanan disebabkan oleh keupayaannya untuk meningkatkan dan memperkayakan kualiti produk makanan yang dihasilkan melalui penapaian. Namun, prestasi LAB adalah dipengaruhi oleh hasil penapaian iaitu asid laktik kerana pertumbahan mikrob terencat. Dalam kajian ini, satu kaedah baru diperkenalkan untuk mengurangkan kesan perencatan dengan mengapsulkan $CaCO_3$ di dalam kapsul berteras cecair yang berbentuk sfera dan berdiameter 3.5 mm dan 3.6 mm yang dihasilkan dengan menggunakan kaedah penitisan-penyemperitan. Hasil kajian menunjukkan pH dan kepekatan asid laktik semasa penapaian LAB telah dikawal dengan baik oleh kapsul – kapsul yang dihasilkan. Keputusan kajian yang dijalankan dengan menggunakan kapsul – kapsul untuk mengawal pH dan kepekatan asid laktik adalah lebih baik daripada keputusan kajian yang dijalankan dengan set kawalan, dan setanding dengan set yang menggunakan tanpa $CaCO_3$. Tambahan pula, kepekatan sel hidup bagi *L. casei shirota* adalah tinggi pada akhir penapaian apabila penapaian dijalankan dengan menggunakan kapsul – kapsul. Keputusan daripada kajian ini mencadangkan bahawa kapsul – kapsul yang dihasilkan menpunyai potensi yang tinggi untuk digunakan sebagai kawalan pH dan kepekatan asid laktik dalam pelbagai jenis pengeluaran.

Introduction

Lactic acid bacteria (LAB) are one of the microbes used in traditional food fermentation. LAB has been used for the fermentation of dairy and non-dairy products [1, 2]. For example, yogurt, cultured milk, cheese are dairy products that produced from LAB fermentation [2]. LAB is reported to play an important role in a number of Asian fermented non-dairy products such as '*tempoyak*' (acid fermented condiment) [3], "*tapai*" (rice wine) [4], '*kimchi'* (fermented vegetables) [1], "*idli*" in India, "*puto*" in Philippines (steamed bread) [1], "*sikhae*" in Korea and "*burong isda/dalag*" in Philippine (fermented mixture of salted fish and cereals) [1].

LAB has been recognised for their fermentative ability to enhance food safety and nutrients, improve organoleptic quality, as well as increase health related benefits [1, 4]. However, the role of LAB in food fermentation is diminished by the production of its end products, i.e. lactic acid [5, 6]. As the fermentation time elapsed, the concentration of lactic acid in the fermentation broth increased and hence the pH of the broth is consequently increased [5].

In common practice, calcium carbonate or advance instrument like pH controller is used to control the concentration of lactic acid and pH in the fermentation broth. However, the direct addition of calcium carbonate in the fermentation broth is not favorable for the subsequent purification process, and the use of pH controller is limited due to high cost. Therefore, in this research, it is proposed to develop a new approach to control pH during LAB fermentation using liquid core capsules. Liquid core capsules are easy to form at low cost.

Materials and Methods

Liquid core solution and gelation bath preparation

The inner liquid-core solution was prepared by adding 15 g/L of calcium chloride (CaCl2) (R&M Chemical, United Kingdom), 400 g/L of calcium carbonate ($CaCO_3$) (HmbG Chemical, France) and 15 g/L of carboxylmethylcellulose (CMC) (Calbiochem, Germany). The mixture of 15 g/L of alginate (Kimitsu-Kimica, Japan) and 1.5 g/L of Tween-80 (Merck, Germany) was prepared as the gelation bath.

Liquid core capsules formation

Liquid-core capsules were prepared using the extrusion-dripping method. The liquid-core solution was extruded through a hypodermic needle (Terumo, Japan) into the gelation bath. In this study, the outer diameter of the needles used was 0.6 mm and 1.1 mm. After the capsules were formed, the capsules were cured in 5 g/L alginate solution for 1 hour to strengthen the capsules. Then the capsules were washed with distilled water and stored in 15 g/L $CaCl_2$ solution.

Capsule properties characterization

A digital camera (Coolpix S2600, Nikon, Japan) was used to capture the image of 30 capsules. The image was analysed using Sigma ScanPro5 software (SPSS, USA) to determine the diameter, maximum length (Dmax) and minimum length (Dmin) of capsules. The sphericity of the capsules was quantified in term of sphericity factor (SF) using the following equation 1 [7]:

$$SF = (Dmax-Dmin)/(Dmax + Dmin) \quad (1)$$

Lactic acid bacteria fermentation

Lactobacillus casei shirota was selected as the model strain for this study. For each fermentation run, four sets of fermentation flask were prepared. The flask was filled with the de Man, Rogosa and Sharpe (MRS) broth. In which, Flask I was labeled for blank broth as control; Flask II was labeled for the broth with addition of free $CaCO_3$; Flask III and IV was labeled for the broth with addition of two sizes of liquid core capsules that encapsulated $CaCO_3$.

All the experiments were conducted at temperature of about 37 ^oC. The pH of the fermentation broth was measured using a pH meter (Mettler Toledo, Switzerland) at an interval of 4 hours. The lactic acid and glucose content were measured by a reflectometer (Merck, Germany), as per described in the standard procedure [8].

Viable cell concentration determination

The total number of viable cells was determined by the plate counting on the de Man, Rogosa and Sharpe (MRS) agar (Oxoid, UK) incubated at 37°C for 48 hours.

Results and Discussion

Diameter and sphericity of capsules

Table 1 shows the diameter and SF of the liquid core capsules formed from needles with the diameter of 0.6 and 1.1 mm. The diameter of the capsules formed from 0.6 mm needle was smaller than that of capsules formed from 1.1 mm needle. The diameter of the capsule was proportional to the needle diameter because the diameter of the pendant droplet detached from the diameter was also proportional to the needle diameter [7, 9].

Table 1. Diameter and SF of the capsules

Needle diameter, mm	Diameter, mm	Sphericity factor (SF)
0.6	3.53 (±0.09)	0.0261 (±0.002)
1.1	3.62 (±0.04)	0.0648 (±0.006)

Note: The standard error of the measurements was shown in parentheses

The results showed that the capsules formed from the needles were generally spherical as the SF was less than 0.07. Although the capsules were formed using different diameter of needle, the capsules formed were spherical. This is because the capsules were formed from liquid core solution of sufficient viscosity and $CaCl_2$ concentration. The past studies showed that the addition of CMC in the liquid core solution increased the viscosity of the solution and consequently improved the sphericity of the capsules [10, 11]. In general, the concentration of $CaCl_2$ greater than 10 g/L is sufficient to form spherical ca-alginate particles [9]. In this study, the concentration of $CaCl_2$ of 15g/L was used, which is above the suggested critical concentration.

Effect of using encapsulated $CaCO_3$ in monitoring pH of fermentation process

Figure 1 shows the pH of the LAB fermentation broth for different experiment conditions. The pH of the broth in Flask I dropped from pH 5.4 to 3.5 after 40 hours of LAB fermentation, which was the greatest drop among the tested conditions. The results of the capsules (Flask III and Flask IV) were comparable to that of free $CaCO_3$ (Flask II). The pH of the broth was maintained above pH 5.5. Previous study has been reported that $CaCO_3$ has the ability to maintain LAB fermentation broth in the similar range [12]. Even so, LAB fermentation with free $CaCO_3$ (Flask II) showed slightly better results in controlling the pH of the broth. This is because the $CaCO_3$ was free in contact with the lactic acid formed in the medium without any obstacles. Therefore, the $CaCO_3$ can neutralize the acid in more effective way as compared to the $CaCO_3$ in the capsules. The $CaCO_3$ which confined inside the capsules faced diffusion resistance problem as it needed to diffuse through the alginate membrane [11]. As a result, it reacts with the acid at a lesser rate to maintain the pH of the fermentation broth. As shown in Figure 1, there was no apparent difference in the pH control ability between the capsule of 3.5 mm and 3.6 mm.

Lactic acid concentration of fermentation broth

The concentration of lactic acid produced by LAB was monitored and the results are shown in Figure 2. Throughout the 40 hours of fermentation, the concentration of lactic acid in the fermentation broth was increased. The lactic acid concentration in Flask I (control) increased continuously until the end of fermentation at 16.0 g/L. However, the lactic acid concentration in Flask II, III, and IV was maintained by $CaCO_3$ at the level of 10 – 12 g/L. There is no apparent difference was observed between the results of free $CaCO_3$ and encapsulated $CaCO_3$. The free lactic acid in the fermentation broth reacted with $CaCO_3$ to form calcium lactate and hence reduced the concentration of lactic acid in the broth as well as neutralized the pH of the broth (see Figure 1) [13].

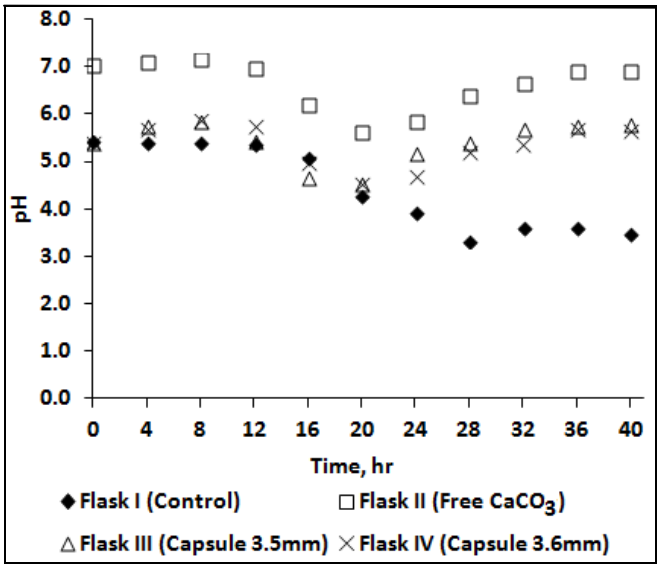

Figure 1. pH of LAB fermentation broth

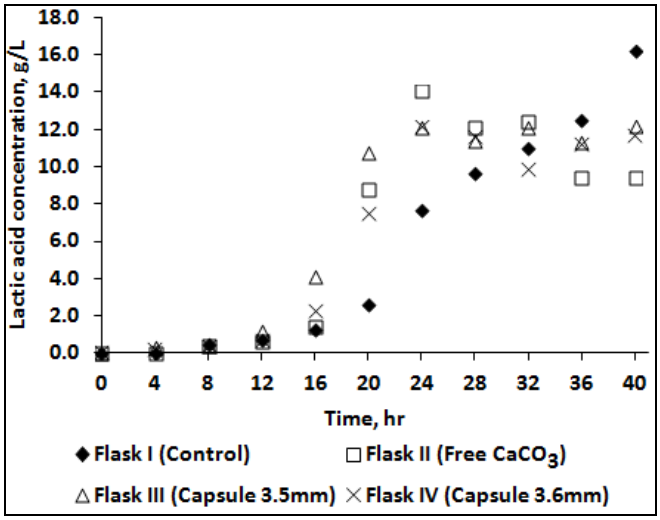

Figure 2. Lactic acid concentration of LAB fermentation broth

Viable cell concentration of LAB

The viable cell concentration of LAB (i.e. *L. casei shirota*) fermentation was at initial and at the end of the fermentation was determined and the results of different experimental conditions were compared, as shown in Table 2. The viable cell concentration of *L. casei shirota* at the end of fermentation was reduced in the case of Flask I (Control) and Flask II (Free $CaCO_3$). The results indicated that the viable cell concentration in LAB fermentation without $CaCO_3$ was reduced because the microbial growth is inhibited by its end-product, lactic acid [5, 6]. In the case of free $CaCO_3$ in Flask II, lower viable cell concentration was obtained at the end of fermentation could be due to the presence of $CaCO_3$ in free form created a less favorable environment for microbial growth. On the other hand, the viable cell concentration of *L. casei shirota* in Flask III and IV was high at the end of fermentation. The results suggested that the liquid core capsules provide a good condition for microbial growth as the pH and lactic acid

concentration were maintained at the desired level and the microbial cell was not in direct contact with the $CaCO_3$.

Table 2. Viable cell concentration of LAB fermentation

Flask number	Initial (0 hr), cfu/ml	End (40 hr), cfu/ml
I	12×10^9	1×10^8
II	18×10^9	5×10^8
III	1×10^9	1×10^9
IV	2×10^9	1×10^9

Note: The results were given based on the average of duplicate sampling

Conclusion

A new approach has been developed to maintain the pH and lactic acid concentration of LAB fermentation at the desired level. Spherical liquid core capsules of diameter of 3.5 mm and 3.6 mm were produced to encapsulate $CaCO_3$ from 0.6 mm and 0.8 mm hypodermic needle, respectively. The results showed that the pH of LAB fermentation was well maintained by the capsules at the desired level of above pH 5.5. Furthermore, the lactic acid concentration of LAB fermentation was averagely 11 g/L during the whole period of fermentation with the use of the liquid core capsules. In general, the results of the fermentation conducted using the capsules were better than that of control and comparable with that of free $CaCO_3$ in maintain the pH and lactic acid level during fermentation. In addition, the viable cell concentration of *L. casei shirota* was high ($> 10^9$ cfu/ml) at the end of fermentation when the fermentation was conducted using the capsules.

Abstract

Chemometric techniques namely hierarchical agglomerative cluster analysis (HACA), discriminant analysis (DA), principal component analysis (PCA) and factor analysis (FA) were applied to the distribution of selected organic contaminants (polycyclic aromatic hydrocarbons (PAHs), sterols, pesticides (chlorpyrifos), and phenol) to assess the potential of using these organic contaminants as chemical markers in Langat River Basin. Water samples were collected from February 2012 to January 2013 on a monthly basis for nine monitoring sites along Langat River Basin. HACA was able to classify the sampling sites into three clusters which can be correlated to the level of contamination (low, moderate and high contamination sites). DA was used to discriminate the sources of contamination using the selected organic contaminants and relate to the existing DOE local activities groupings. Forward and backward stepwise DA was able to discriminate two and five organic contaminants variables, respectively, from the original 13 selected variables. The five significant variables identified using backward stepwise DA were fluorene, pyrene, stigmastanol, stigmasterol and phenol. PCA and FA (varimax functionality) were used to identify the possible sources of each organic contaminant based on the inventory of local activities. Five principal components were obtained with 66.5% of the total variation. Result from FA indicated that PAHs (pyrene, fluorene, acenaphthene, benzo[a]anthracene) originated from industrial activity and socio-economic activities; while sterols (coprostanol, stigmastanol and stigmasterol) were associated to domestic sewage and local socio-economic activities. The occurrence of chlorpyrifos was correlated to agricultural activities, urban and domestic discharges. This study showed that the application of chemometrics on the distribution of selected organic contaminants was able to trace the sources of contamination in surface water.

Keywords: chemometrics, organic contaminants, chemical markers, Langat River

Abstrak

Teknik kemometriks iaitu Analisis Kelompok Agglomeratif Berhieraki (HACA), Analisis Diskriminan (DA), Analisis Komponen Utama (PCA) dan Analisis Faktor (FA) telah diaplikasi ke atas taburan bahan pencemar organik terpilih (aromatik hidrokarbon polisiklik (PAH), sterol, racun perosak (klorpirifos), dan fenol) untuk menilai potensi penggunaan bahan pencemar organik ini sebagai bahan pengesan di Lembangan Sungai Langat. Sampel air diambil dari bulan Februari 2012 hingga Januari 2013 pada setiap bulan di sembilan stesen pemantauan sepanjang Lembangan Sungai Langat. HACA dapat mengkelaskan kawasan persampelan kepada tiga kelompok yang boleh dikaitkan dengan tahap pencemaran (pencemaran rendah, pencemaran sederhana dan pencemaran tinggi). DA telah digunakan untuk membezakan sumber –sumber pencemaran dengan menggunakan bahan – bahan organik terpilih dan mengaitkannya dengan aktiviti – aktiviti setempat berdasarkan DOE. Analisis Diskriminan Langkah Hadapan dan Belakang masing – masing dapat mendiskriminasikan dua dan lima pembolehubah bahan pencemar organik daripada 13 pembolehubah asal yang dipilih. Lima pembolehubah yang penting adalah fluorena, pyrena, stigmastanol, stigmasterol dan fenol. PCA dan FA telah digunakan untuk mengenalpasti sumber – sumber bagi setiap bahan pencemar organik berdasarkan inventori aktiviti setempat. Lima komponen utama telah diperolehi dengan 66.5 % daripada jumlah variasi. Hasil

daripada FA menunjukkan PAH (pirena, flurena, asenaphtena, benzo[a]antrasena) berpunca dari kegiatan industri dan aktiviti sosio-ekonomi; manakala sterol (coprostanol, stigmastanol dan stigmasterol) daripada kumbahan domestik dan aktiviti – aktiviti sosio-ekonomi setempat. Kehadiran klorpirifos telah dikaitkan dengan aktiviti pertanian, bandar dan pelepasan domestik. Kajian ini menunjukkan bahawa teknik kemometriks yang diaplikasikan ke atas taburan bahan pencemar organik terpilih mampu mengesan punca pencemaran dalam air permukaan.

Introduction

Malaysia is a developing country whereby industrialisation and urbanisation becomes the main programme. Due to the rapid growth of industrialisation and urbanisation, Malaysia is facing a number of problems especially water pollution is brought about by discharges of all kinds of effluents, particularly from domestic sewage, industries, and construction sites during dry and wet deposition from the atmosphere. As a result, a wide range of organic contaminants are recognized as enviromentally relevent for their potential adverse effects on human and ecosystem health [1]. Thus, organic contaminants have become one of the rising issues in the field of environmental research. Environmental monitoring studies usually resulted in huge amounts of physical parameters and chemical concentrations collected in various geographical sites, time periods or environmental compartments (surface water, air, sediments and biota) [2].

In order to reveal relevant patterns and sources of variation in these large environmental datasets, chemometric analysis has been proposed [2,4]. Massart et al. [3] defined chemometrics as a chemical discipline that uses mathematics, statistics and formal logic to design or select optimal experimental procedures; to provide maximum relevant chemical data and to obtain knowledge about chemical systems. Chemometric techniques is very useful in tracing the sources and fate of the contaminants in the environment. Application of different pattern recognition techniques to reduce the complexity of large datasets have been proven to give a better interpretation and understanding of pollution source. Chemometric techniques covered three main areas of interest in environmental studies which are quantitative analysis, monitoring for environmental quality assessment and modeling or prediction of toxicology effects [2]. Commonly used chemometric techniques used for clustering are the hierarchical agglomerative cluster analysis (HACA) and principal components analysis (PCA) with factor analysis (FA). The three techiques of chemometric analysis were often used to interpret the data usually the data obtained had multivariate nature also several of variables were correlated [9].

Many studies have used chemometric techniques to identify the sources and distribution of organic (such as PAHs and sterols) or inorganic (such as heavy metal) contaminantions in environmental compartments such as water, air and sediment [4–8]. The application of chemometric techniques would be helpful in the interpretation of complex datasets and gives a better understanding into the sources of contamination. Previous study by Osman et al. [4] reported the application of this techniques provide a more objective interpretation of the results and able to apply organic contaminants as a chemical markers. Thirteen organic contaminants were analyzed which include polycyclic aromatic hydrocarbons (PAHs), sterols, pesticide (chlorpyrifos) and phenol to evaluate as they are potential chemical marker in the Langat River Basin. The dataset covers the period from February 2012 to January 2013 and the water samples were taken at nine monitoring sites provided by Department of Environment (DOE), Malaysia. The applications of chemometric techniques in this study will be able to give valuable information on the distribution and source of contamination of organic contaminants. This approach may reveal the possible sources of organic contaminants along Langat River Basin, Malaysia.

Materials and Methods

Chemicals and reagents

Solvents of gas chromatography (GC) grade or higher (methanol, dichloromethane, n-hexane and acetone) were purchased from Merck (Darmstadt, Germany). Hydrochloric acid (fuming 37% pro analysis) was obtained from Merck (Darmstadt, Germany). Individual standards PAHs; acenaphthene and pyrene were purchased from Dr. Ehrenstorfer GmbH (Augsburg, Germany) and acenaphthylene, fluorene, benzo[a]anthracene and benzo[a]pyrene were obtained from Supelco (Bellefonte, USA). Individual standard of sterols; 5β-cholestan-3-β-ol (coprostanol), 5-cholesten-3β-ol (cholesterol), stigmasterol and stigmastanol were purchased from Sigma-Aldrich (Steinheim,

Germany) while β-sitosterol was purchased from Supelco (Bellefonte, USA). Phenol was purchased from Supelco (Bellefonte, USA). Chlorpyrifos (PESTANAL® 98%) and N,O bis(trimethylsilyl)trifluoroacetamide + trimethylchlorosilane (TMCS), (99:1) were purchased from Sigma-Aldrich (Steinheim, Germany). SPE cartridges, C_{18} (EC) (1000 mg) and LiChrolut (EN 200 mg) were obtained from International sorbent technology (IST) (Mid Glamorgan UK) and Merck (Darmstadt, Germany) respectively.

Instrumentation and equipments

Water samples were extracted using solid phase extraction (SPE) using SPE Vacuum Manifold (Supelco, St. Louis, USA). Water samples were filtered prior to SPE extraction by using 0.45 µm glass fiber filter (Whatman International Ltd Maidstone, England). The pH of sample was measured using Metler Toledo AG, Analytical, (Switzerland) pH meter. Organic contaminants were analysed using gas chromatography (HP6890 series II, Agilent Technologies Palo Alto, CA, USA) with flame ionisation detector (GC-FID) (detection of PAHs sterols), gas chromatography (7890A Agilent Technologies) with electron capture detector (GC-ECD) (detection of chlorpyrifos), gas chromatography (Agilent GC6890/5973MSD) with mass spectrometry detector (GC-MSD) (detection of phenol).

Monitoring sites

Nine monitoring sites (Table 1 and Figure 1) were selected from a list (24 sites) of monitoring sites of the Department of Environmental (DOE), Malaysia. Sampling of water samples was conducted along Langat River Basin from February 2012 to January 2013. The selected monitoring sites represented the sites that experienced domestic sewage discharges, socio-economic and industrial activities.

Table 1. Langat River Basin monitoring sites

River	Station No	Coordinate		Location
		Longitude	Latitude

Extraction of organic contaminants using tandem solid phase extraction (SPE)

Extraction of PAHs, sterols, chlorpyrifos and phenol were done using tandem solid phase extraction procedure [10]. Two cartridges namely, C_{18} and LiChrolut EN were used to extract selected organic contaminants from water samples. PAHs, sterols and chlorpyrifos were extracted using non-polar sorbent (C_{18}) while phenol extracted using polymeric sorbent (LiChrolut EN). The SPE cartridges (C_{18} and LiChrolut EN) were conditioned separately. The C_{18} cartridge (1000 mg) was conditioned by using 10 mL of methanol followed by 6 mL of deionized water without applying vacuum while LiChrolut EN cartridge (200 mg) was conditioned using 10 mL of acetone followed with 3 mL methanol and 3 mL of acidified deionized water (pH 2) and also without applying vacuum. For sample loading, both cartridges C_{18} and LiChrolut EN were arranged in tandem whereby C_{18} cartridge was placed on top of the LiChrolut EN sorbent. Then, one litre (1 L) of water sample was loaded into the column using vacuum manifold at a flow rate of 6 mL min^{-1}. During the process, the column was not allowed to dry. After sample loading, the two

cartridges were separated. Elution of interference and elution of analytes were done separately. Each cartridge was vacuum dried for 30 min before the removal of interference matrix. For C_{18} cartridge, interferences were eluted by using 10 mL deionized water, while for LiChrolut EN cartridge the interferences were removed by using 5 mL 40% aqueous methanol. Both cartridges were vacuum dried. For C_{18} cartridge, the compounds of interest were eluted by gravity. First elution using 6 mL of n-hexane eluted PAHs and chlorpyrifos while second elution using 2×3 mL dichloromethane eluted sterols. For LiChrolut EN cartridge, phenol was eluted by gravity using 2×3 mL dichloromethane. Nitrogen was used to blow down both extract to a final volume of 1 mL for gas chromatographic analysis.

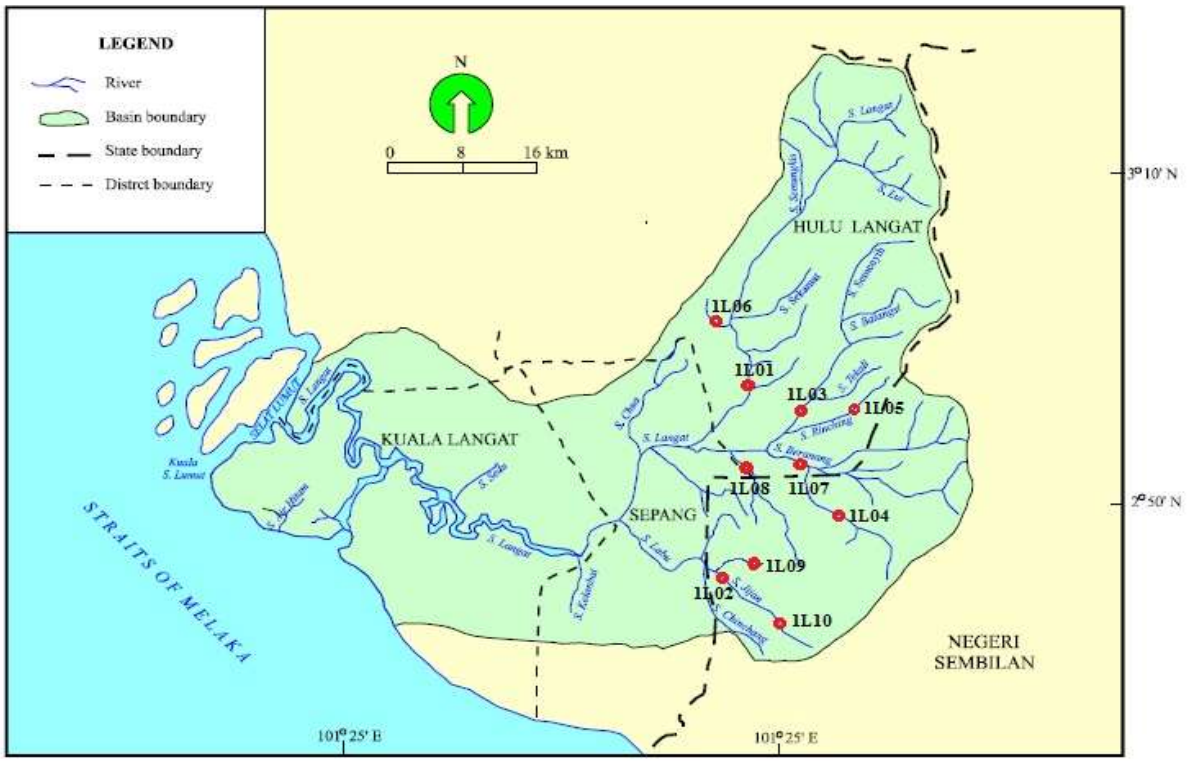

Figure 1. Monitoring sites in Langat River Basin (Source: Juahir *et al.* [13])

Chromatographic analysis

Gas chromatography with flame ionization detector (GC-FID) was used for the separation and quantification of PAHs and sterols. Chlorpyrifos and phenol were analysed using gas chromatography with electron capture detector (GC-ECD) and chromatography with mass spectrometry detector (GC-MSD), respectively [10].

GC-FID analysis

Separation and identification of PAHs and sterols was performed using gas chromatography with splitless injection and flame ionization detector. A 30 m × 0.25 mm id × 0.25 µm film thickness HP5-MS capillary column (Agilent technologies) was used to achieve separation of PAHs and sterols with the following temperature program: initial temperature, 50°C; held for 2 min; increased by 18°C min^{-1} to 250°C, increased by 10°C min^{-1} to 310°C; held for 11 min. The detector temperature was set at 310°C. PAHs quantification was carried out using a five-point calibration plot containing 1.00, 2.00, 3.00, 4.00 and 5.00 mg/L PAH standard mixtures. Sterols quantification was carried out using five-point calibration plot containing 1.00, 2.00, 3.00, 4.00 and 5.00 mg/L sterols standard. Prior to injection, sterols were derivatised by treatment with BSTFA: TMCS, (99:1) at 60°C for one hour.

GC-ECD analysis

Separation of chlorpyrifos was achieved using gas chromatograph equipped with 63 Ni electron capture detectors (GC-ECD). A 30 m × 0.25 mm id × 0.25 µm film thickness HP5-MS capillary column (Agilent technologies) was used for the quantitative analysis of chlorpyrifos. Injection port and detector temperatures were set at 250°C. The injection volume was 1 µL, with 2 min splitless period following the injection. The ECD detector utilized pure N_2 (>99.999%) and the carrier gas and make-up gas was at a controlled constant velocity of 60 mL min^{-1}. The temperature program was set to 150°C for 1 min, then increased by 25°C min^{-1} to 260°C for 8 min. Compounds were identified based on the retention time of the standards and quantified by external standard calibration. Chlorpyrifos quantification was carried out using five-point calibration plot containing 1.00, 2.00, 3.00, 4.00 and 5.00 mg/L chlorpyrifos standard.

GC-MSD analysis

Analysis of phenol was performed with gas chromatography with mass spectrometry detector (GC-MSD). Phenol was separated using a cross-linked fused silica capillary column HP5-MS (30 m × 0.25 mm id × 0.25 µm). The head pressure of the carrier gas (high purity helium) was 50 kPa. The temperature programmed was set at an initial temperature of 50°C, followed by an increased by 10°C min^{-1} to 200°C and held for 15 min. The MS detector was operated in the full scan using the electron impact (EI) ionization mode at 70 eV, scanning from 50-550 mass units at 0.45 s $scan^{-1}$. Phenol was quantified by single point external standard calibration. Prior to injection, phenol were derivatised by treatment with BSTFA: TMCS, (99:1) at 60°C for one hour.

Chemometric analysis

XLSTAT2013 software package was employed in the chemometric application using hierarchical agglomerative cluster analysis (HACA), discriminant analysis (DA) and principal component analysis (PCA) with the factor analysis (FA). These techniques were chosen to interpret and evaluate the organic contaminants dataset along Langat River Basin.

Results and Discussion

Hierarchical agglomerative cluster analysis (HACA)

HACA is a common method to classify variables or cases (observations/samples) into clusters with high homogeneity level within class and high heterogeneity level between classes [5,12]. HACA was performed on the selected organic contaminants data set to evaluate spatial variation among the nine monitoring sites. This analysis resulted in the grouping of sampling stations into three clusters as shown in Figure 2. Cluster 1 formed by five monitoring sites (1L01, 1L02, 1L03, 1L04 and 1L05) represents moderate contamination sites. 1L01, 1L03 and 1L04 monitoring sites located near city area which is experiencing urbanization over the past 15 years as several towns have grown and developed [13]. Possible sources of contaminations of these three monitoring sites are mainly from domestic discharges, and urban discharges. 1L02 and 1L05 monitoring sites located at rural areas but experiencing contamination from socio-economic activities and domestic sewage discharges. Cluster 2, formed by monitoring site (1L09) represents high contamination site located near the city and industrial area. This site is situated in a tributary of Batang Nilai, which carries high pollution flowing through the industrial areas [4]. Cluster 3 represents low contamination sites consisted of three monitoring sites (1L06, 1L07 and 1L08). These sites are located away from municipal discharges and industrial activities and correspond to socio-economic activities except 1L06 monitoring which is experiencing contamination from industrial activities and domestic sewage discharges. This analysis shows that HACA is able to classify the site based on the level of pollution and different possible sources of organic contaminant as the clusters in these groups have similar characteristic. Spatial variations of organic contaminants in water were further evaluated by using discriminant analysis.

Discriminant analysis (DA)

DA was used to discriminate the sources of contamination using the selected organic contaminants and relate the sources to the existing DOE inventory. Figure 3 shows the plot of discriminant functions obtained from water samples and three group's sources of contamination formed. These groups were related to the inventory of local activities provided by DOE, Malaysia and the contamination of Langat River can divide into three sources: domestic sewage/urban discharges, industrial activities and socio-economic activities.

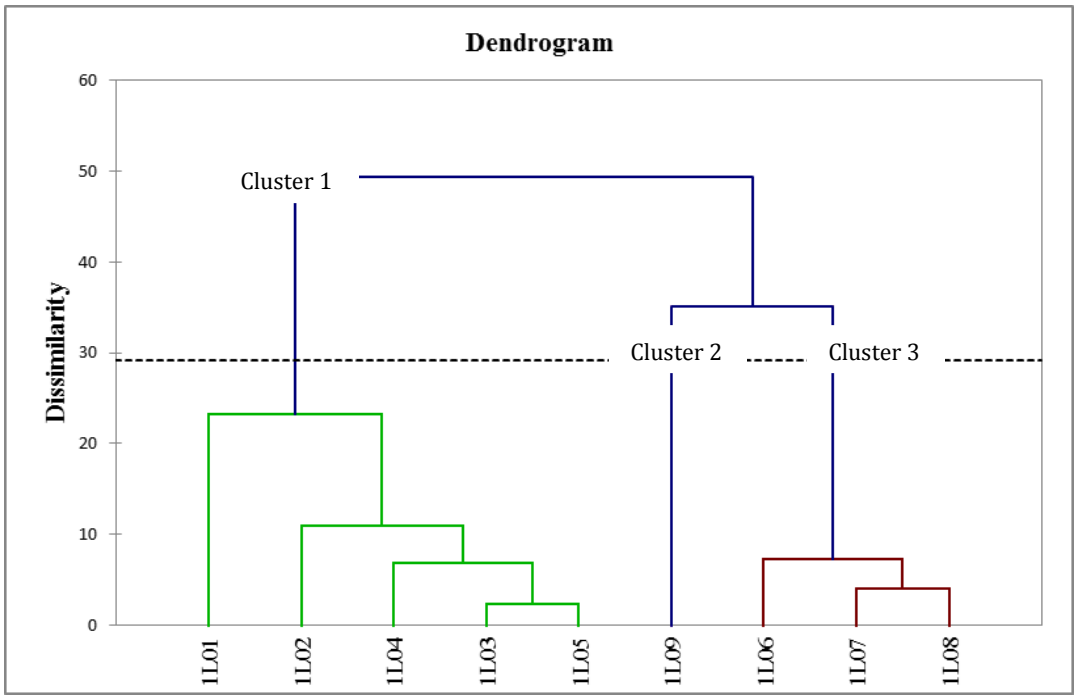

Figure 2. Dendrogram of clustering of monitoring sites according to organic contaminants analysed in water samples of Langat River Basin using Wards' method

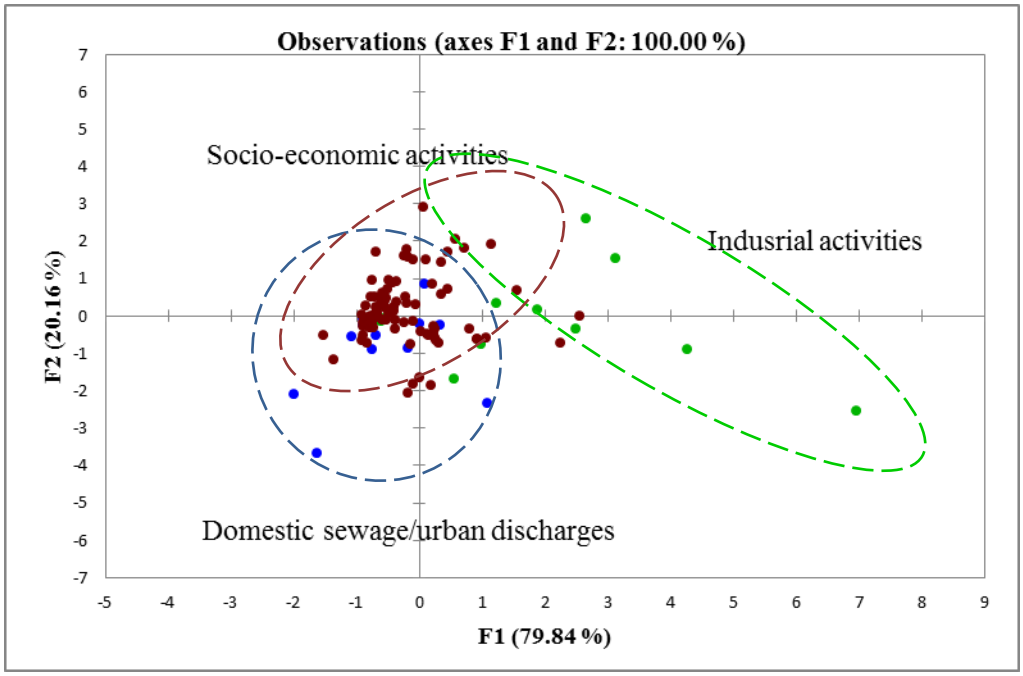

Figure 3. Plot of discriminant functions of water samples datasets

The three groups were treated as dependent variables, while the 13 selected organic contaminants were treated as independent variables. DA was carried out via three modes which are standard, forward stepwise and backward stepwise modes. Classification matrices (CMs) and discriminants functions (DFs) obtained from standard, forward stepwise and backward stepwise mode were tabulated in Table 2 and Table 3, respectively. The standard mode DA was able to discriminate the contamination source to 83.33 % correctly classified with 13 discriminant variables. The forward stepwise mode yielded 80.56 % correctly classified using only two discriminant variables (stigmastanol and stigmasterol), while the percent of cases correctly classified in backward stepwise mode also 79.63 % using only five discriminant variables (fluorene, pyrene, stigmastanol, stigmasterol and phenol). From the result of DA, the five organic contaminants based on backward stepwise DA were chosen as the significant variables to discriminate the sources contamination between the monitoring sites. Fluorene and pyrene were detected at relatively high concentration in the water samples. They were found high at socio-economic activities and industrial area. These contaminants represent the gasoline, coal and vehicular combustion [8,14,15]. Stigmastanol and stigmasterol were detected near domestic sewage area and urban discharges. Both compounds corresponded to faecal contamination and much related to the livestock farming activities [6,11]. Phenol clearly showed high concentration in wastewater of industrial area. This contaminant was associated with industrial activity. Industrial sources of this contaminant were from oil refineries, coal gasification sites and petrochemical units [16].

Principal component analysis (PCA) with factor analysis (FA)

PCA was performed to identify the possible sources of organic contaminants in Langat River Basin. It provides information on the most significant variables, which explains the whole data set by excluding the less significant variables with minimum loss of original information [17]. Five PCs with eigenvalues larger than one were obtained through the analysis. In reference to eigenvalues, only the PCs with eigenvalues greater than one are considered to carry out the FA. Equal numbers of varifactors (VFs) were obtained via factor analysis performed on the PCs and comprised of 66.5% total variance. Table 4 shows the corresponding VFs, variables loadings and explained variance. From the four VFs, VF1 explains 19.9 % from the total variance, showing strong positive loading of coprostanol and moderate loading of stigmastanol. These contaminants were detected from sampling sites associated with domestic sewage, urban discharge and socio-economic activities. Coprostanol and stigmastanol were indicators for faecal contamination [11]. Coprostanol especially is one of general marker of anthropogenic faecal contamination [18]. VF2 explains 16.8% of total variance was dominated by strong positive loading of fluorene and pyrene whereas VF3 accounted for 11.5 % of the total variance, was predominated by moderate loadings of acenaphthene and benzo[a]anthracene. Inputs of the contaminants in VF2 and VF3 can be associated with industrial activities and urban activities along Langat River Basin. As reported by Li et al. [14, 19], the possible sources of pyrene and fluorene were from anthropogenic activities such as combustion. Acenaphthene and benzo[a]anthracene were associated with vehicle exhaust [8]. VF4 and VF5 accounted for 9.9 % and 8.5 % of the total variance, and showing strong positive loading of chlorpyrifos and stigmasterol, respectively. The presence of chlorpyrifos much related to contamination effects of socio-economic activity (agricultural activities such oil plantation) within Langat River Basin [20] whereas presence of stigmasterol usually indicator of faecal contamination and much related to the livestock farming activities along the river basin.

Conclusion

The application of chemometric techniques provides valuable information in assessing the variation of organic contaminants in Langat River Basin. The sources of specific organic contaminants can be explained by correlating the groupings obtained through chemometric approach with local activities identified by DOE. HACA classified the sampling sites into three clusters which can be correlated to the sources of contamination. Forward and backward stepwise DA was able to discriminate two (stigmastanol and stigmasterol) and five (fluorene, pyrene, stigmastanol, stigmasterol and phenol) organic contaminants variables, respectively, from the original 13 selected variables. Result from PCA and FA, shows that the sources of contamination within the Langat River Basin were influenced by industrial, urban and socio-economic activities, represented by selected PAHs (pyrene, fluorene, acenaphthene and benzo[a]anthracene). Sources from domestic and urban discharges were represented by sterols (coprostanol, stigmastanol and stigmasterol). This study shows that the application of chemometric techniques can reveal meaningful information from the datasets of organic contaminant.

Abstract

In this study, non-conjugated polyvinylpyrrolidone(PVP) was investigated for the first time as the potential polymeric material to sense nitrate ions by fluorescence spectroscopy. The PVP was diluted into various concentrations (3-10%) and they were used to sense the nitrate ions in different concentrations (0.1-100 mM). The PVP showed two excitation peaks at 285 and 330 nm due to the presence of C=O and N-C groups, respectively. One strong emission at 400 or 408 nm was observed with the excitation at 285 or 330 nm. The higher value of quenching constant at excitation wavelength of 285 nm indicated that C=O site was more favored for NO_3^- ions sensing than the N-C site. The PVP 7% gave the highest quenching constant; where the K_{SV} value was 9.89×10^{-3} mM^{-1} and 2.44×10^{-3} mM^{-1} for excitation at 285 and 330 nm, respectively. The sensing capability was evaluated in the presence of interference ions (SO_4^{2-}, HCO_3^-, Cl^-, and OH^-). It was observed that the interference ions interacted strongly with the C=O, but weakly with the N-C. Therefore, in the presence of the interference ions, the PVP would be a potential fluorescent sensor when it is excited at 330 nm.

Keywords: polyvinylpyrrolidone; fluorescent sensor; nitrate ions; quenching

Abstrak

Dalam kajian ini, polivinilpirolidon (PVP) yang bersifat bukan konjugat dikaji untuk kali pertama sebagai bahan polimer yang berpotensi untuk mengesan ion nitrat dengan spektroskopi pendaflour. PVP dicairkan kepada kepekatan yang berlainan (3-10%) dan digunakan untuk mengesan ion nitrat dalam kepekatan yang berbeza (0.1-100 mM). PVP menunjukkan dua puncak pengujaan pada 285 and 330 nm dengan kewujudan C=O dan N-C masing-masing. Satu puncak pemancaran yang tinggi pada 400 atau 408 nm diperolehi dengan pengujaan pada 285 atau 330 nm. Pemalar pelidap kejutan dengan nilai yang lebih tinggi pada puncak pengujaan 285 nm menunjukkan bahawa tapak C=O lebih cenderung untuk mengesan ion NO_3^- daripada tapak N-C. PVP 7% memberi pemalar pelidap kejutan yang paling tinggi, dengan nilai K_{SV} 9.89×10^{-3} mM^{-1} and 2.44×10^{-3} mM^{-1} untuk puncak pengujaan pada 285 dan 330 nm masing-masing. Kemampuan pengesanan dinilai dengan kehadiran ion gangguan (SO_4^{2-}, HCO_3^-, OH^-, and Cl^-). Hasil kajian menunjukkan bahawa ion gangguan berinteraksi kuat dengan C=O, tetapi lemah dengan N-C. Oleh itu, dengan kehadiran ion gangguan, PVP berpotensi menjadi pendafluor sensor pada tapak pengujaan 330 nm.

Kata kunci: polivinilpirolidon; pengesan pendaflour, ion nitrat, pelidap kejutan

Introduction

Polymer consisting of repeating units of monomers is highly explored in various fields, owing to its non-toxicity [1], simple fabrication methodology and low cost [2, 3], large surface-to-volume ratio [4] and easy modification [5]. The conjugated polymers have received particular attentions with their wide applications in batteries [6], organic light emitting diodes [2, 4, 7], and sensor [2, 4-6, 8-10], due to their unique metallic and semiconducting properties [4] as well as the fluorescence properties [4, 5, 11]. On the other hand, the non-conjugated polymers are less explored and still poorly understood. To date, the non-conjugated polyvinylpyrrolidone (PVP) is mostly used as a passivator or a capping agent for semiconductor such as ZnS or CdS, with the purpose to reduce the agglomeration and improve the optical property [12]. Some studies reported the application of the PVP as a sensor [14, 15]. Wang *et al*. reported that the PVP can be used as electrochemical sensor for acyclovir molecule [14], while Zhang *et al*. used PVP nanocomposite as a humidity sensor [16]. Since the PVP has been also reported to have photoluminescence property [15], it is worthy to study the possibility to use the non-conjugated PVP as the fluorescence sensor. To the best of our knowledge, there is no investigation on the application of the PVP as the fluorescence sensor. In this study, the PVP is used as the fluorescent sensor for detection of nitrate ions.

The nitrate ions are usually found in fertilizer for agriculture purpose. When the fertilizer is used excessively, the excess nitrate ions in the environmental water system will lead to algae blooms and eutrophication phenomena [17-19]. On the other hand, nitrate ions that are consumed into body may cause methemoglobinemia and the nitrate ions might become the source of carcinogenic *n*-nitrosamines [17, 20]. These are some of the reasons to monitor nitrate ions in the environment. Extensive studies have been explored to detect the nitrate ions using different techniques, such as ion chromatography [18], capillary electrophoresis [3, 20], electrochemical [3, 21-24], and fluorescence spectroscopy [17]. However, the detection limit and linear detection range of existing nitrate ion sensor are still not in satisfactory level [21], and this urges researchers to develop better nitrate sensors.

In this study, the feasibility to develop PVP fluorescence sensor for nitrate ions was examined using different concentrations of PVP and nitrate ions. The favorable sites to interact with the nitrate ions were discussed based on the quenching phenomena. Besides, the selectivity of the PVP to the nitrate ions was evaluated in the presence of other interference ions such as SO_4^{2-}, HCO_3^-, Cl^-, and OH^-.

Materials and Methods

Materials

The PVP solution (K 60, Aldrich, Mw ≈ 160000, 45% in water), sodium nitrate ($NaNO_3$, Merck, 99.5%), sodium sulphate (Na_2SO_4, Fisher Scientific, > 99%), sodium hydrogen carbonate ($NaHCO_3$, Fisher Scientific, 99%), sodium chloride (NaCl, Fisher Chemical, 100.1%), and sodium hydroxide (NaOH, QRëC, 99%) were used as-received without any treatments.

Preparation of PVP

A series of various concentrations of PVP was prepared from the PVP (K 60) by dilution method using deionized water. The prepared solution was shown as x% of PVP, where x showed the concentrations of the PVP (3, 5, 7, and 10%).

Fluorescence, quenching and selectivity test

The fluorescence property and sensing capability of the PVP solutions for detection of nitrate ions were studied using a fluorescence spectroscopy (JASCO, FP-8500) at room temperature. The excitation spectra of the PVP solutions were monitored at emission wavelengths of 400 or 408 nm, while the emission spectra were monitored at the excitation wavelengths of 285 or 330 nm. For quenching test, the PVP solution was exposed to various concentrations of nitrate ions (0.1-100 mM) and the interaction between the emission sites and the nitrate ions was measured. The sensing capability of the PVP was evaluated in the presence of interference ions (SO_4^{2-}, HCO_3^-, Cl^-, and OH^-). The concentration for the nitrate ions and each interference ions was fixed at the concentration of 100 mM.

Results and Discussion

Fluorescence property of PVP

The fluorescence property of the PVP solution was studied by investigating its excitation and emission sites. As shown in Figure 1, all the prepared PVP (3-10%) exhibited two excitation sites at 285 and 330 nm and one emission site at 400 or 408 nm when they were excited at 285 or 330 nm. The excitation at 285 nm would be attributed to the presence of C=O, while the excitation at 330 nm would be corresponded to the presence of N-C in the PVP, similar to the reported one [12]. It was clear that the excitation and emission intensity increased with the increase of the PVP concentrations. The increased intensities were reasonable since they indicated the increased amount of excitation and emission sites of the PVP with the increase of the concentrations. Figure 1 also showed that the intensity of N-C sites was higher than that of C=O sites, suggesting that the N-C sites would be the main excitation sites in the PVP and the N-C sites showed greater fluorescence quantum yield than the C=O site [25].

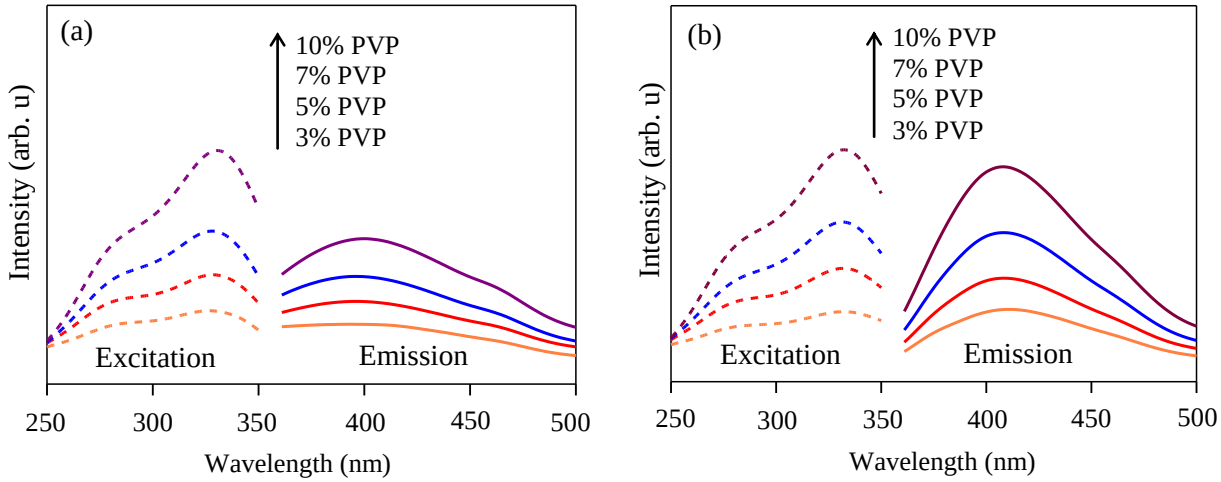

Figure 1. Excitation and emission spectra for 3, 5, 7 and 10% of PVP at (a) C=O and (b) N-C sensing sites

Quenching tests

In order to investigate the performance of the PVP to sense the nitrate ions, the interaction between emission sites and the nitrate ions were evaluated by quenching effect study. The quenching tests were evaluated by monitoring the changes in the emission intensity after addition of various concentrations of nitrate ions (0.1-100 mM). The emission spectra were monitored at two different excitation wavelengths, which were 285 nm and 330 nm. All the 3-10% of PVP showed similar results to each other, in which the emission intensities of the PVP were quenched after addition of the nitrate ions. The results of the quenching tests for the 7% of PVP are shown in Figure 2. The decrease in the emission intensity increased with the increase of nitrate ions concentrations for both emission sites, which were C=O and N-C sites. Among the prepared PVP, the 7% of PVP showed the most quenched intensity, suggesting that the 7% of PVP showed the strongest interaction with the nitrate ions (not shown).

As shown in Figure 2, quenching effects were observed on both C=O and N-C emission sites, suggesting that there were certain interactions between both the emission sites and the nitrate ions. Due to the difference of the charge between the emission sites and the nitrate ions, the most possible interactions between PVP and nitrate ions would be electrostatic interactions. Similar interactions have been proposed for the interactions between nitrates and polypyrrole [22], nitro-containing compounds with polymers [11, 26, 27]. In the presence of the same concentration of nitrate ions, especially at high concentrations, it was obviously observed that the C=O sites were more quenched than the N-C sites. This might be due to the reason that at each C=O can interact with more than one nitrate ions simultaneously and this can be more intense at higher concentration of nitrate ions. Moreover, a slight red shift in

the emission peak wavelength at high concentration of nitrate ions were also observed, suggesting that there was loss of energy through vibrational relation or internal conversion phenomena when the PVP interacted with nitrate ions [25].

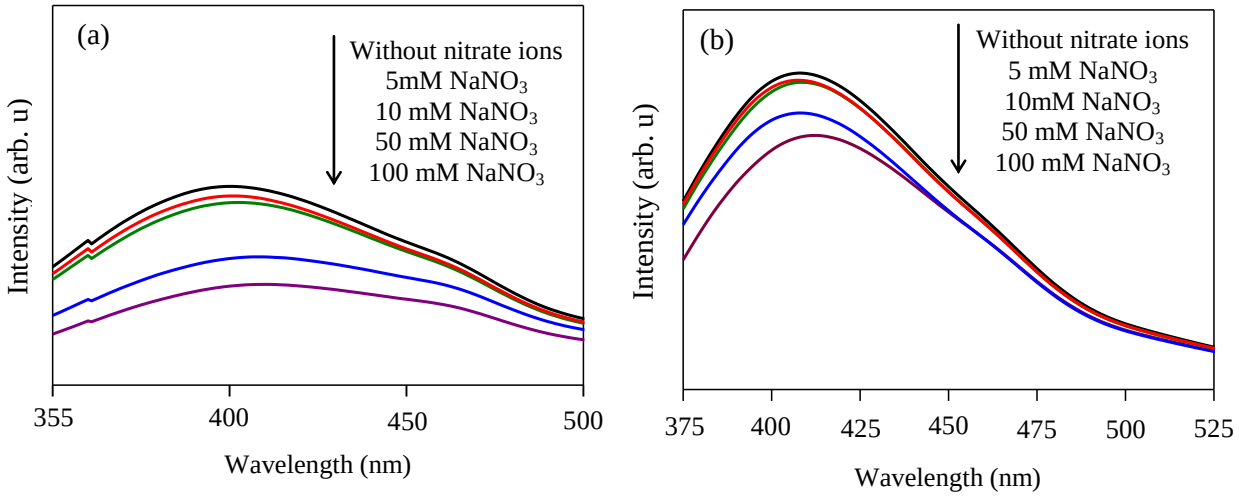

Figure 2. Emission spectra of 7% PVP with the absence and presence of nitrate ions in the 5-100 mM range for C=O sites and N-C sites, monitored at excitation wavelength of (a) 285 nm and (b) 330 nm

The interaction between the emission sites and nitrate ions can be evaluated by using the Stern-Volmer plot. When the illumination intensity and the amount of PVP are maintained to be constant, the relative emission intensity can be expressed as a function of the nitrate ions concentrations, according to the Stern-Volmer equation (Eq. 1),

$$\frac{I_o}{I} = K_{sv}[Q]+1 \quad (1)$$

where I_o and I are fluorescence intensities obtained in the absence and presence of nitrate ions, respectively, Q is the concentration of nitrate ions, and K_{sv} is the Stern-Volmer quenching constant.

Figure 3 shows the Stern-Volmer plots for the 7% of PVP. The plots were linear for both emission sites, suggesting that both C=O and N-C sites acted as the sensing sites for the nitrate ions. The slopes of the Stern-Volmer plots represented the quenching constant (K_{SV}), which values were 9.89×10^{-3} mM^{-1} and 2.44×10^{-3} mM^{-1} for C=O and N-C sites, respectively. The higher value of the K_{SV} for the C=O sites than that for the N-C sites indicated that the C= sites were more favorable to sense nitrate ions than the N-C sites. This might be due to the reasons that the C=O sites have higher polarity than the N-C sites, but with less steric hindrance effect. The higher K_{SV} values obtained on the C=O sites can be observed as well on other PVP with various concentrations, as can be seen in Figure 4. It can be clearly shown that the K_{SV} values increased with the PVP concentrations up to 7%, but decreased when the PVP concentration was 10%. This result clearly suggested that 7% of PVP was an optimum concentration to get the highest quenching efficiency.

Selectivity Tests

The sensing performance of 7% of PVP towards nitrate ions was evaluated with the co-existence of interference ions. The interference ions used in current study were SO_4^{2-}, HCO_3^-, Cl^- and OH^-.The extent of interference was determined according to the equation below (Eq. 2):

$$E = \frac{I_o - I}{I_o} \times 100\% \quad (2)$$

where I_o and I show the fluorescence emission intensity for the 7% of PVP with the presence of nitrate ions only and the presence of both nitrate and interference ions, respectively. The high value of the extent of interference suggested the high interference effect of the ions towards the performance of the 7% PVP for detection of the nitrate ions.

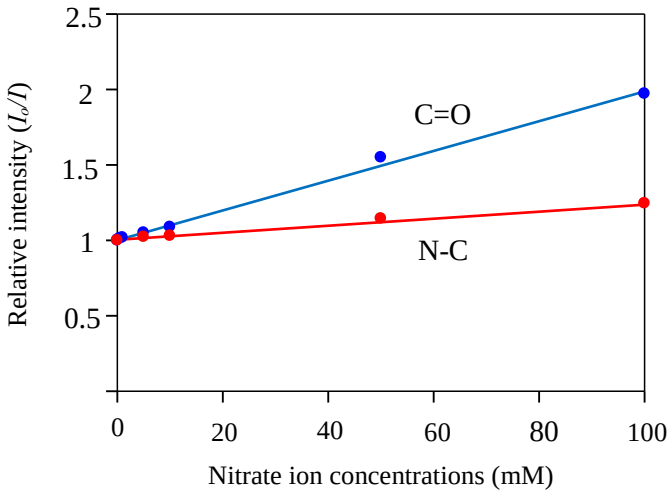

Figure 3. Linear Stern-Volmer plots for 7% PVP at C=O (●) and N-C (●)

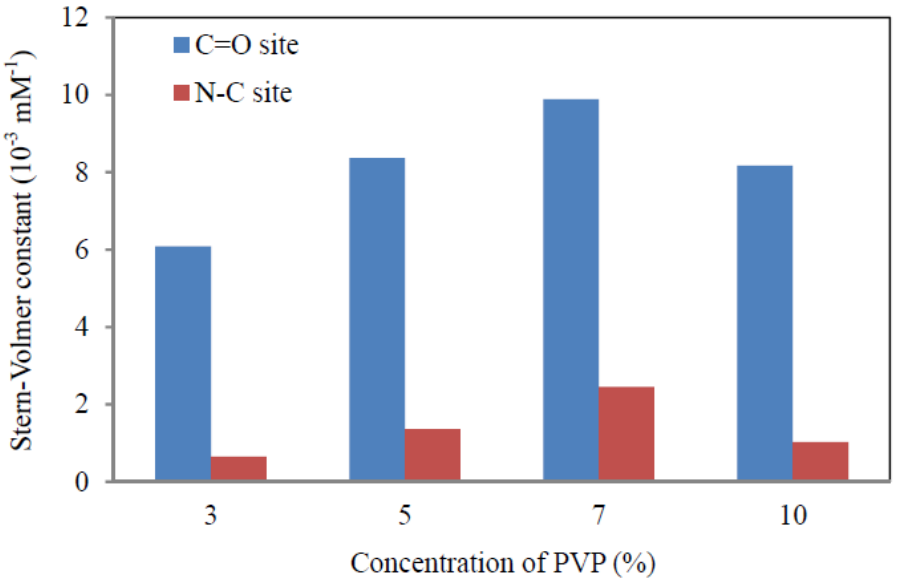

Figure 4. Stern-Volmer constants for nitrate ions detection on PVP with various concentrations for both C=O and N-C sites

The extent of interference for each interference ion was shown in Figure 5. As for the C=O sites, the presence of SO_4^{2-}, HCO_3^-, Cl^-, and OH^- ions gave extent of interferences, which values of 25, 12, 4, and 47%, respectively. This result suggested that the detection of nitrate ions by C=O sites were mostly influenced by OH^-, followed by SO_4^{2-}, HCO_3^-, and Cl^- ions. The high interference effect from OH^- would be caused by the small size and polarity of OH^- ions [27]. Therefore, the 7% of PVP would not be suitable to detect nitrate ions in the presence of OH^- ions. On the other hand, even though the co-existence of polyatom anions such as SO_4^{2-} and HCO_3^- resulted in lower effect than the OH^-, the C=O sites competitively interacted with SO_4^{2-} and HCO_3^-. Therefore, the sensing performance would be affected in the presence of these ions. It is worthy noted that the C=O sites showed much less interaction with Cl^-, suggesting that the C=O sites still could be used to detect the nitrate ions even in the presence of Cl^- ions.

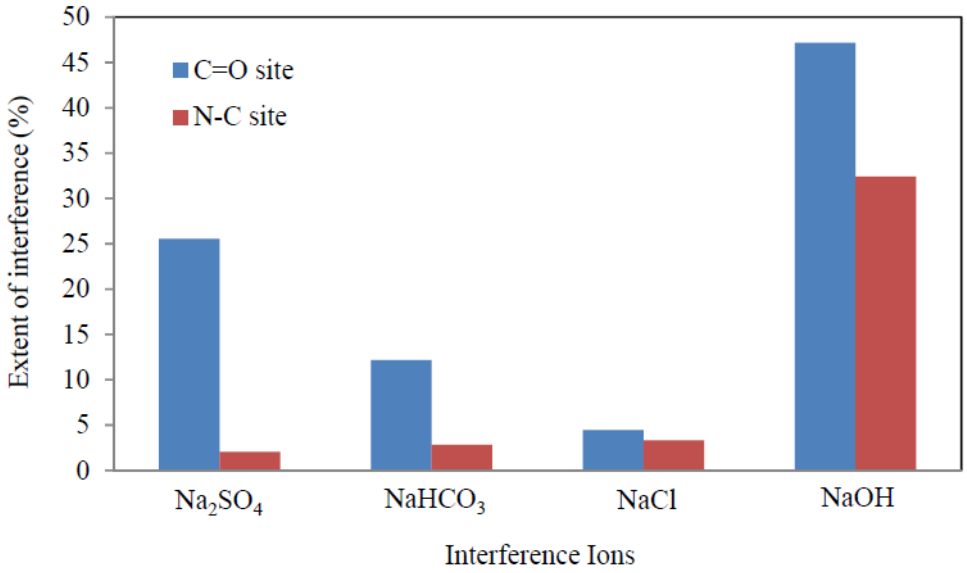

Figure 5. Extent of interferences of ions towards nitrate ions detection on 7% PVP

As for the N-C sites, the presence of SO_4^{2-}, HCO_3^-, Cl^-, and OH^- ions gave extent of interferences, which values of 2, 3, 3, and 32%, respectively. Similar to the C=O sensing sites, the N-C sites were found to be affected by the presence of OH^-. Different from the C=O sites, the performance of the nitrate sensing on the N-C sites were not much influenced by SO_4^{2-}, HCO_3^-, or Cl^- ions. These results suggested that the N-C sensing sites still can selectively interact with nitrate ions in the presence of these interfering ions.

Conclusion

The PVP showed two excitation peaks at 285 and 330 nm and one emission peak at 400 or 408 nm when excited at 285 and 330 nm. Among the prepared PVP, 7% of PVP showed the highest quenching constants toward the nitrate ions. The linear Stern-Volmer plot was observed, suggesting that the PVP can be used as a potential fluorescence sensor for nitrate ions. The C=O sites were found to show much stronger interactions with nitrate ions (four times higher) than the N-C sites, suggesting that the C=O sites were more favorable to sense the nitrate ions. The presence of interference ions were found to affect the fluorescence sensing of nitrate ions differently. As for C=O sites, it can still be used to sense nitrate ions in the presence of Cl^- ions. On the other hand, the N-C sites can selectively sense the nitrate ions in the presence of SO_4^{2-}, HCO_3^-, and Cl^- ions.

Abstract

Due to strict environmental legislation for ultra-low sulfur diesel fuels, increasing technical and operational challenges are imposed to conventional hydrodesulfurization (HDS) technology. Therefore, catalytic oxidative desulfurization (Cat-ODS) has been suggested to be an alternative method to replace a conventional method which is hydrodesulfurization. In this study, catalytic oxidation of commercial diesel was performed using an oil-soluble oxidant, tert-butyl hydroperoxide (TBHP), over polymolybdate supported on alumina MoO_3-PO_4/Al_2O_3 catalyst. A commercial Petronas diesel with 440 ppmw of total sulfur was employed to evaluate the elimination of sulfur compounds. Besides, the percentage of sulfur removal was measured by (GC-FPD). Alkaline earth metals, such as Calcium (Ca), Barium (Ba) and Strontium (Sr) were introduced on the surface of MoO_3-PO_4/Al_2O_3. The results showed that the catalytic activity decreased in the order, Ca/MoO_3-PO_4/Al_2O_3>Sr/MoO_3-PO_4/Al_2O_3> Ba/MoO_3-PO_4/Al_2O_3. The Ca/MoO_3-PO_4/Al_2O_3 catalyst was characterized by XRD and FESEM. XRD results showed that the best catalyst was highly amorphous while FESEM micrograph illustrated an aggregation and agglomeration of various particle sizes. The catalytic activity of Ca/MoO_3-PO_4/Al_2O_3 catalyst with various Ca/Mo ratios were also studied. When the Ca/Mo ratio was 15:85, the sulfur removal was the highest (79%) at 45ºC, 30 min and O/S molar ratio 3.0 with solvent = dimetylformamide (DMF), diesel/solvent ratio = 1.0.

Abstrak

Disebabkan undang-undang alam sekitar yang ketat untuk bahan api sulfur diesel ultra-rendah, peningkatan cabaran teknikal dan operasi dikenakan kepada hydropenyahsulfuran konvensional teknologi (HDS). Oleh itu, penyahsulfuran oksidatif mengunakan pemangkin (Cat-ODS) telah dicadangkan untuk menjadi satu kaedah alternatif untuk menggantikan kaedah konvensional iaitu hydopenyahsulfuran. Dalam kajian ini, pengoksidaan diesel komersial telah dijalankan menggunakan oksida larut minyak, tert-butil hidroperoksida (TBHP) dan mangkin molibdena berpenyokong alumina, MoO_3-PO_4/Al_2O_3. Diesel komersial Petronas yang mengandungi sulfur 440 ppmw telah digunakan untuk menilai penyahsulfuran. Selain itu, peratusan penyingkiran sulfur telah diukur menggunakan (GC-FPD). Logam alkali, seperti Kalsium (Ca), Barium (Ba) dan Strontium (Sr) telah dicelup pada permukaan MoO_3-PO_4/Al_2O_3 pemangkin. Hasil kajian menunjukkan bahawa aktiviti pemangkin menurun mengikut susunan, Ca/MoO_3-PO_4/Al_2O_3 > Sr/MoO_3-PO_4/Al_2O_3 > Ba/MoO_3-PO_4/Al_2O_3. Pemangkin Ca/MoO_3-PO_4/Al_2O_3 telah dicirikan menggunakan XRD dan FESEM. Keputusan XRD menunjukkan pemangkin yang terbaik adalah sangat amorfus manakala

FESEM mikrograf menggambarkan satu aglomerasi dalam pelbagai saiz zarah. Aktiviti pemangkin Ca/MoO_3-PO_4/Al_2O_3 dengan pelbagai nisbah Ca/Mo telah juga dikaji. Apabila nisbah Ca/Mo adalah 15:85, penyingkiran sulfur adalah tertinggi (79%) pada keadaan optimum: 45ºC, 30 min dan nisbah O/S molar = 3.0 dengan pelarut = dimetilformamida (DMF), nisbah diesel/pelarut = 1.0.

Introduction

Sulfur in transportation fuels is a major source of air pollution. Ultra-deep desulfurization of fuels is a matter of major interest not only because of increasing environmental concern and legal requirements, but also because ultra-low-sulfur fuel is a key requirement for fuel cell applications [1]. In the near future, the requirements for sulfur content in the fuel will become more stringent – with zero sulfur emission from the transport fuel, which calls for the development of advanced technologies for ultra clean fuel. Thus, great efforts have been made todecrease the content of sulfur in diesel oil [2]. HDS can produce lower sulfur level diesel oil, but this technology needs heavy cost in operating and capital. Therefore, oxidative desulfurization (ODS) has been considered as a further new technology for deep desulfurization of light oil [3]. This desulfurization process includes two stages: (i), oxidation in a first step; and (ii), liquid extraction at the end [4]. It is evident that the greatest advantages of the ODS process are low reaction temperature and pressure, and the expensive hydrogen gas is not used in the process. Most of the studies have been concentrated on heterogeneous molybdenum and tungsten supported on alumina. Recently, Wan Abu Bakar et al. [5], reported that MoO_3/Al_2O_3 was an active catalyst for the oxidation of dibenzothiophenic compounds. Therefore, it is interesting to explore the behavior of polymolybdate based catalyst doped with alkaline earth metal as dopant in the ODS reaction of commercial diesel in this paper.

Materials and Methods

Materials

All solvents and reactants were purchased and used without further purification. Phosphomolybdic acid hydrate (Across Organic), magnesium nitrate hexahydrate (Sigma-Aldrich), barium nitrate (Sigma-Aldrich), calcium nitrate tetrahydrate (Sigma-Aldrich) and strontium nitrate (Sigma-Aldrich), λ- Al_2O_3 beads 3-5 mm diameter (Sigma-Aldrich), *tert*-butyl hydroperoxide 70 wt.% in water (Acros Organic), dimethylformamide (MERCK) were used in this research. The fuel tested was a commercial diesel fuel from Petronas, Malaysia with 440 ppmw of sulfur content.

Preparation and characterization of catalysts

Calcium, barium, and strontium-doped MoO_3-PO_4/Al_2O_3 were prepared at ratio 15:85 by dissolving phosphomolybdic acid either with barium nitrate or calcium nitrate tetrahydrate or strontium nitrate in the sufficient volume of water and the solution were used for impregnation of Al_2O_3 (surface area: 292 m^2/g) at room temperature. The wet sample was dried overnight at room temperature before it was calcined at various temperatures for 5 h in air. XRD analysis was conducted by using Siemens D5000 crystalloflex X-Ray diffractometer equipped with 40 kV and 40 mA Cu target (λ CuKα) = 1.54Å) radiation. Using a step scan of 0.050° and a step time of a second per step, data were collected over the range of 2θ from 20° to 80°. FESEM-EDX analysis was accomplished by using Philips XL 40 microscope with energy of 15.9 kV coupled with EDX analyzer and bombarded using electron gun with tungsten filament under 25 kV resolutions to get the required magnification image.

Catalytic oxidative desulfurization

All oxidative desulfurization (ODS) reactions were conducted in a 100 mL round-bottom flask, equipped with a magnetic stirrer and fitted with condenser. In a typical run, the oil bath was first heated and stabilized at a constant temperature (45°C). Then, 10 ml of commercial diesel (440 ppmw) was added to the flask, followed by the addition of sulfur/TBHP in the ratio of 3 and 0.12 g catalyst. The mixture was refluxed for 30 minutes under vigorous stirring at atmospheric pressure. The oxidized diesel was extracted with DMF at ratio diesel/solvent = 1.0. The extraction process was conducted by vigorous stirring for 30 minutes followed by phase separation between diesel

and solvent. The treated diesel was analyzed by gas-chromatography (Agilent 6890N GC) equipped with FPD detector.

Results and Discussion

Catalytic Evaluation: Effect of alkaline earth metal dopants

Malka and Tatibouet [6] reported that Ca was a promoter of MoO_3-PO_4/Al_2O_3 catalyst in the oxidation of methanol. In the present study, several alkaline earth metals were used to modify MoO_3-PO_4/Al_2O_3 catalysts. Figure 1 shows that the activity of catalysts for oxidation of commercial diesel with TBHP decreased in the order: Ca/MoO_3-PO_4/Al_2O_3 >Sr/MoO_3-PO_4/Al_2O_3 > Ba/MoO_3-PO_4/Ba/Al_2O_3. As reported by Chang et al. [7], molybdenum oxide was a typical example of poorly dispersed catalyst, because molybdenum oxide, such as MoO_3, and alumina are considered to have an acidic character, thus weak interaction between molybdenum oxide and alumina is expected. Since alkaline earth metals possess strong basic characters, therefore it is possible to improve the dispersion of MoO_3 on the alumina by the introduction of alkaline earth metals.

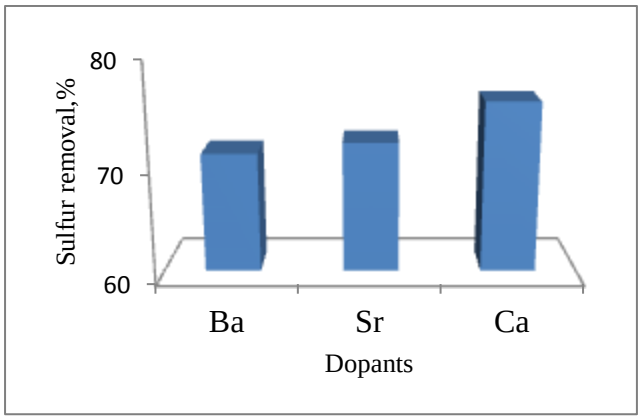

Figure 1. Effect of alkaline earth metal dopants on MoO_3-PO_4/Al_2O_3 catalyst calcined at 500 ºC for 5 h in the ODS reaction of commercial diesel

Effect of calcination temperature

Figure 2 shows the effect of calcination temperatures on Ca/MoO_3-PO_4/Al_2O_3 catalyst, calcined at 400, 500 and 600 ºC. The catalytic activity increase as the calcinations temperature was increased but further increase to 600 ºC would cause the decreasing of catalytic activity. This is because, the calcination temperature of 600 ºC could cause agglomeration of the catalyst particles thus decreasing the surface area consequently produces less active catalyst [8]. The optimum calcinations temperature obtained was 500 ºC.

Effect of Ca loading

The effect of Ca loading was carried out in order to investigate the optimum loading towards the performance of sulfur removal as shown in Figure 3. It clearly showed that an appropriate amount of Ca would increase the catalytic activity of the catalyst. The optimum calcium loading was 15 %. The excessive addition of Ca into the catalyst decreases the sulfur removal. It was due to the excess amount of Ca on the catalyst surface will cause the agglomeration to occur that reduced amount of active size.

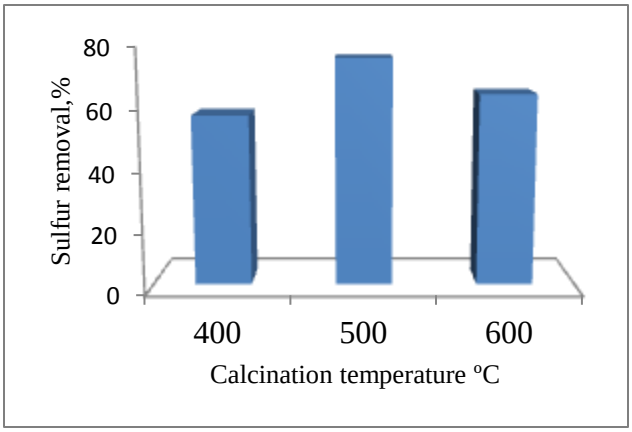

Figure 2. Effect of calcination temperature on Ca/MoO_3-PO_4/Al_2O_3 catalyst in the ODS reaction of commercial diesel

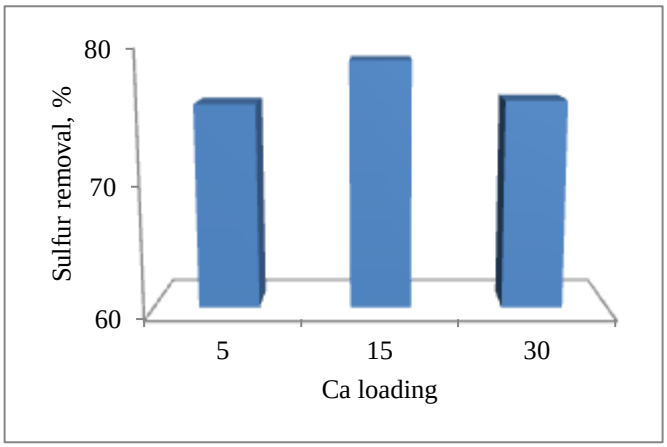

Figure 3. Effect of Ca loading on Ca/MoO_3-PO_4/Al_2O_3 catalyst calcined at 500 ºC for 5 h in the ODS reaction of commercial diesel

Characterization of Catalyst

Table 1 shows the textural properties of the bimetallic oxide catalysts, obtained by EDX analysis. EDX confirmed the presence of Mo, P, and Ca in the catalyst. It can be seen that by increasing the calcination temperatures from 400 to 600 ºC, the composition of Ca element was getting lower. It was probably due to the agglomeration of Mo which will hinder the Ca species, hence decrease the composition of this element and also diminished the catalytic activity. As shown in Figure 4, increase the calcination temperature from 400 to 600 ºC leads to the formation of aggregates and agglomerates with undefined shapes and mixture of larger and smaller particles size.

Table 1. Elemental analysis of the monometallic and bimetallic oxide catalysts

Catalysts	**Calcination T (°C)**	**Loading Mo (wt. %)**	**Loading P (wt.%)**	**Loading Ca (wt.%)**
MoO_3-PO_4/Al_2O_3	500	15	0.63	-
Ca/MoO_3-PO_4/Al_2O_3	400	16.30	2.16	0.5
Ca/MoO_3-PO_4/Al_2O_3	500	15	3.10	0.33
Ca/MoO_3-PO_4/Al_2O_3	600	16	3.3	0.14

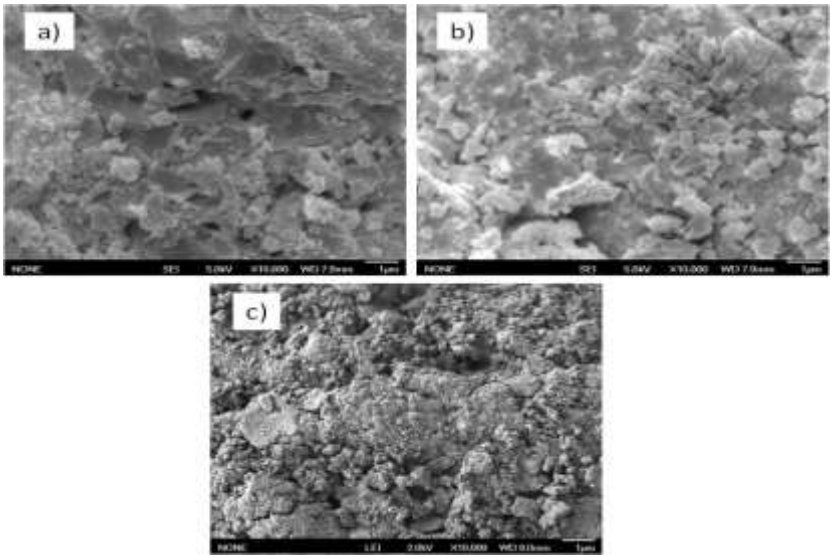

Figure 4. FESEM micrographs of Ca/MoO_3-PO_4 (15:85)/Al_2O_3 calcined at a) 400ºC b) 500ºC c) 600ºC. Magnification 10 k, scale bar 1µm

The XRD diffraction patterns of the Ca/MoO_3-PO_4/Al_2O_3 catalysts (Figure 5) indicate that the catalyst calcined at 500 °C and 700 °C possess amorphous structure which made the molybdenum phase undetectable suggesting the presence of high dispersion monolayer of Mo on the catalyst. This phenomenon could be the reason of higher catalytic activity of Ca/MoO_3-PO_4/Al_2O_3 (15:85) catalyst calcined at 500 ºC .The oxide peak does not appear in the diffractogram probably due to the small particle size of Ca (<4 nm) which is beyond XRD detection limit and low Ca loading in the catalyst as shown in EDX data.

Increasing the calcination temperature at 900 °C led to the formation of crystalline Mo_9O_{26} with new peaks obtained at 2θ value = 21.760° (I_{100}) and 25.85° (I_{60}) which attributed to base centered monoclinic phase. As shown in the diffractogram at 900 °C, the phase was dominated by alumina support which assigned as Al_2O_3 rhombohedral occurred at 2θ = 35.10° (I_{100}), 43.32° (I_{94}), 57.41° (I_{79}), 25.85º (I_{74}). It was claimed by Jones et al. [9] that catalysts calcined at temperatures above 500 °C showed high crystallinity. It was observed that the higher crystallinity and crystallize size of sample was observed at 900 °C than those treated at 500 °C and 700 °C suggesting that sample prepared at high temperature aggregate and agglomerate to form larger particle size with high crystallinity and also showed clear pattern of metal oxide. This results was agreement with our catalytic activity where the increased of calcinations temperature diminished the catalytic activity.

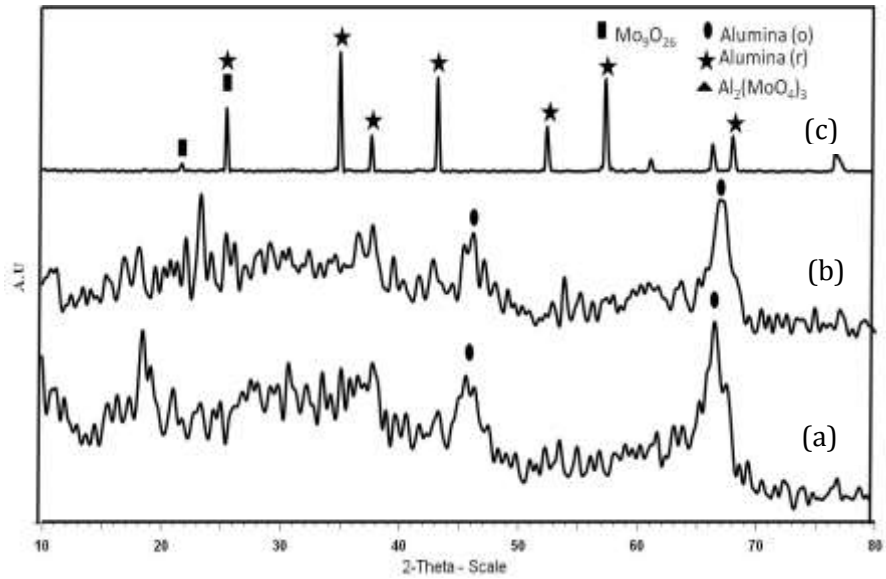

Figure 5. XRD diffractogram patterns of Ca/MoO_3-PO_4/Al_2O_3 calcined at (a) 500°C, (b) 700°C and (c) 900°C.

Mechanistic Study

The proposed peroxidic oxidation mechanism of DBT on Ca/MoO_3-PO_4/Al_2O_3 catalyst with TBHP is shown in Figure 6. The reaction pathway proceeded initially through the nucleophilic attack of TBHP on Ca/MoO_3-PO_4/Al_2O_3 to form species (1). The oxidation process must proceed by nucleophilic attack of the sulfur in the DBT (2) on the positively charged peroxometallic complex (1) to form DBT sulfoxide (3) and regenerated polymolybdate species, respectively. Subsequently, the sulfoxide (3) undergoes further oxidation to form DBT sulfone (4) [2].

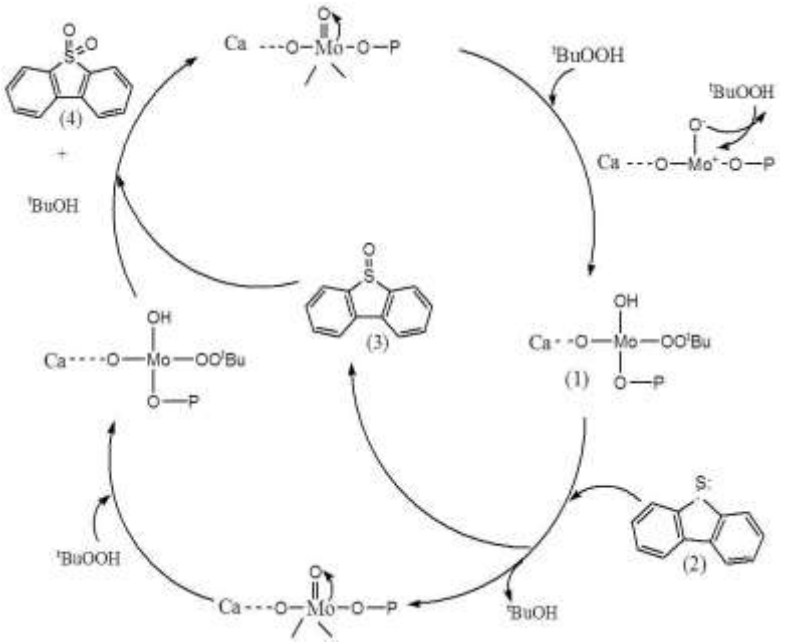

Figure 6. A proposed cyclic mechanism for the oxidation of dibenzothiophene by TBHP in the presence of Ca/MoO_3-PO_4/Al_2O_3 catalyst

Conclusion

Sulfur level in the Malaysia commercial diesel can be reduced from about 440 ppmw to 92 ppmw of sulfur at 45 ºC under mild condition using polymolybdate based catalyst with alkaline earth metal as dopant. Further improvement on MoO_3-PO_4/Al_2O_3 catalyst using different dopants indicated that oxidative desulfurization (ODS) for commercial diesel has been achieved over the Ca/MoO_3-PO_4/Al_2O_3 (15:85) calcined at 500 ºC. The catalyst had good activity in the oxidative desulfurization with TBHP in diesel fuel. These results may indicate that alumina supported polymolybdate based catalyst has the potential to be used as catalyst in Cat-ODS to meet the future regulation of sulfur in diesel fuel.

Abstract

Biohydrogen is a renewable source of clean fuel and energy which can be derived from biomass. One of the suitable candidate as a source of biomass is palm kernel shell (PKS). Our initial work shows that biohydrogen may be produced from PKS in the presence of zeolite supported catalysts. The potential of using cerium oxide (CeO_2) supported catalysts for the production of biohydrogen from PKS is explored in this work using 2.5 – 10 % Fe loading. The catalysts were prepared by incipient wetness impregnation method and calcined at 500 ^oC for 16 h. The physicochemical properties of these catalysts were characterized using BET and XRD. The catalysts were tested in dry and steam gasification of PKS at 700 ^oC using PKS feeding rate of 2 g h^{-1} under N_2 atmosphere with biomass to catalyst ratio of 3:1 (wt/wt). Steam to biomass ratio of 3.5:1 (wt/wt) was used in steam gasification reaction. The gaseous products were analyzed using an on-line gas chromatography equipped with thermal conductivity detectors (TCD) and fitted with Molsieve 5A and Hayesep Q columns. Result shows that 2.5 % Fe/CeO_2 gave the highest hydrogen production in both the dry and steam gasification of PKS.

Abstrak

Biohidrogen adalah sumber bahan api yang boleh diperbaharui daripada sumber biomas. Isirung kelapa sawit (PKS) merupakan salah satu sumber biomas yang sesuai digunakan umtuk tujuan ini. Kajian awal menunjukkan biohidrogen boleh dihasilkan daripada PKS dengan menggunakan mangkin berpenyokong zeolite. Dalam kajian ini, muatan mangkin 2.5 – 10 % logam Fe berpenyokong cerium oksida (CeO_2) digunakan untuk meningkatkan penghasilan biohydrogen daripada PKS. Pemangkin disediakan menggunakan kaedah pengisitepuan pembasahan permulaan dan dikalsinkan pada suhu 500 ^oC selama 16 jam. Sifat fizikal kimia pemangkin ini dianalisa menggunakan teknik BET dan XRD. Kereaktifan mangkin untuk penghasilan biohidrogen diuji dalam pengegasan kering dan berstim pada suhu 700 ^oC dengan PKS diperkenalkan pada kadar 2g h^{-1} dan nisbah PKS kepada pemangkin adalah 3:1 (wt/wt). Nisbah stim kepada PKS 3.5: 1 (wt/wt) telah ditetapkan dalam eksperimen pengegasan berstim. Gas yang telah dihasilkan telah dianalisa menggunakan kromatograf gas yang dilengkapi pengesan konduktiviti termal (TCD) serta tiub Molsieve 5A dan Hayesep Q. Keputusan kajian menunjukkan penghasilan hidrogen yang maksimum dicapai dengan kehadiran mangkin 2.5 % Fe / CeO_2.

Introduction

The hiking prices of petroleum fuel and growing issues on environmental impact, particularly emission of greenhouse gases draw world's attention to the biomass as an alternative energy. The possible utilization of biomass to produce bio-fuels such as bioethanol and biohydrogen makes biomass a critically important source of sustainable energy future. The production of hydrogen rich gas from renewable biomass is being promoted as the fuel for the future since it has higher engine efficiencies and zero emission.

Biomass can be reformed to hydrogen through gasification technology where it converts lignocellulosic biomass to gaseous products such as H_2, CO, CO_2, CH_4 and light hydrocarbons. Traces amount of char, ash and tar are also produced during biomass gasification. However, the formation of tar and char create severe problems in the operation of gas engine such as corrosion, burning difficulties and internal deposition.

Catalytic gasification of biomass helps to decompose tar and heavy hydrocarbon in the product gas streams at a lower temperature. In fact, the application of catalyst not only functions as tar abatement, but it also plays a significant role in promoting high content of product gases [1]. Despite of having significant activities as water gas shift (WGS) catalysts and in hydrocarbon reforming, Fe-based catalysts also facilitate in biomass steam gasification. This is explained by the capability of Fe to crack tar produced in the product stream which is similar to the capability of dolomite [2].

To avoid catalyst deactivation, different promoters or supports are added to the catalyst precursor. In our previous work, Zeolite Beta (BEA) supported catalysts were used as a catalyst and the result indicated a significant performance in producing H_2 from steam gasification of PKS [3]. This work presents further catalyst development using Cerium Oxide (CeO_2) as the catalyst support due to its redox properties and ability to promote metal-ceria interaction [4]. Tomishige and co-workers [5] investigated various oxide supports and supported metal catalysts for gasification of cellulose at 550 ^oC and reported that the highest yield of CO and H_2 were achieved using CeO_2 as support while the lowest conversion was found on Al_2O_3 and SiO_2. Thus, this work aims to study the effect of Fe loading on CeO_2 on the production of H_2 in dry and steam gasification of PKS.

Materials and Methods

Chemicals and raw materials

Palm kernel shell (PKS), the biomass feedstock for gasification reaction was collected from Felda Nasaruddin Plantation in Perak. The PKS was first dried at 110 ºC for 4 h before they were ground and sieved to 500 µm. The ultimate and proximate analyses of PKS are displayed in Table 1.

Table 1. Ultimate and Proximate analysis of PKS

Ultimate analysis (%)	
C	49.65
H	6.13
N	0.41
S	0.48
O	43.33
Proximate analysis (%wt wet basis)	
Volatile matter	81.03
Fixed carbon	14.52
Ash	4.44

Catalyst loading with range 2.5 – 10 wt% Fe/CeO_2 were prepared using incipient wetness impregnation method with Cerium oxide (CeO_2) as the catalyst support. CeO_2 (Sigma Aldrich, 99.9 %) was first calcined at 500 °C for 16 hr. Next, the required amount of $Fe(NO_3)_3.9H_2O$ (Merck, 98 %) was dissolved in sufficient amount of deionized water followed by addition of CeO_2 to the metal salt solution while stirring. The slurry formed was left for 4 hr and then dried at 120 °C for 16 hr. Finally, the prepared catalysts were calcined at 500 °C for 16 hr. The prepared catalysts were crushed and sieved to <250 µm. The catalysts are denoted as xFe/CeO_2, where x represents the amount of Fe loading e.g. $2.5Fe/CeO_2$ is 2.5wt % of Fe was loaded on cerium oxide.

Characterization of catalysts

N_2 adsorption-desorption isotherm (Micromeritics ASAP 2020) was used to determine the surface area, pore size and pore volume of the catalyst. The samples were degassed in vacuum at 200 °C for 4 hr prior to the measurement. Powder X-Ray Diffraction (XRD) pattern of the catalysts was obtained using a Bruker D8 Advance diffractometer with a radiation sources of Cu-Kα to identify their crystal structures. The reducibility measurement of the catalysts was conducted on a Thermo Electron TPDRO 1100 analyser. The sample was reduced in a stream of 5 $\%H_2/N_2$ at a heating rate of 20 °C to reach a final temperature of 1000 °C.

Gasification of PKS

Both dry and steam gasification reaction of PKS were performed at 700 °C in a two staged reactors. The biomass samples were placed in the first reactor and a catalyst sample was held in placed by quartz wool in the second reactor with biomass to catalyst mass ratio of 3:1. The reactor system was purged with N_2 at 100 ml min^{-1} before both reactors were heated to 700 °C at a heating rate of 150 °C/hr. Then, the PKS was introduced at feeding rate of 2 g hr^{-1} under N_2 atmosphere. Water was introduced by liquid pump when the temperature of the first reactor reached 700 °C, where it was instantly evaporated at the elevated temperature and then carried to the reactor by N_2 flow. The steam to biomass (S/B) ratio was 3.5. The outlet gases passed through a condenser prior to analysis with online gas chromatography (Agilent 7890A) equipped with two thermal conductivity detectors (TCD) and a flame ionization detector (FID). H_2, CO and CO_2 were measured using TCD detectors fitted with Molsieve 5A and Hayesep Q column, while CH_4 and C_2 hydrocarbons were analyzed using FID detector fitted with HP-AL/S and DB-1 columns.

Results and Discussion

Catalysts characterization

The N_2 adsorption- desorption isotherms of the CeO_2 support shows a Type III isotherm according to IUPAC classification system which indicates that the CeO_2 is a non-porous materials. Table 2 shows the BET surface area of the CeO_2 based catalysts. The surface area increases with increasing of Fe loading. This shows that the loading of Fe metal provides additional nucleation sites which contribute to the higher surface area [6].

Table 2. The surface area of Fe/CeO_2 catalysts

Catalysts	**CeO_2**	**$2.5Fe/CeO_2$**	**$5Fe/CeO_2$**	**$7.5Fe/CeO_2$**	**$10Fe/CeO_2$**
Surface area (m^2/g)	4.2	5.0	5.2	5.6	6.4

The X-ray diffractograms of CeO_2 based catalysts are shown in Figure 1. All samples show four significant diffraction peaks at 2θ= 28.6°, 33.1°, 47.6°, 56.4° which correspond to the (111), (200), (220) and (311) planes of cubic CeO_2 (81-0792 JCPDS file). It is observed that the peak heights slightly decrease with increasing loading of Fe on the CeO_2 support. Appearance of a small peak corresponding to the hexagonal hematite iron oxide, Fe_2O_3 (02-0919 JCPDS file) is only detected in $10Fe/CeO_2$ catalyst which indicates that the Fe_2O_3 are finely dispersed on the surface of CeO_2 at lower loading of Fe. However, the absence of diffraction peaks has been suggested to be attributed to the Fe_2O_3 phase where Fe was substituted in the CeO_2 lattice leading to formation of a solid solution of iron-cerium oxide [7].

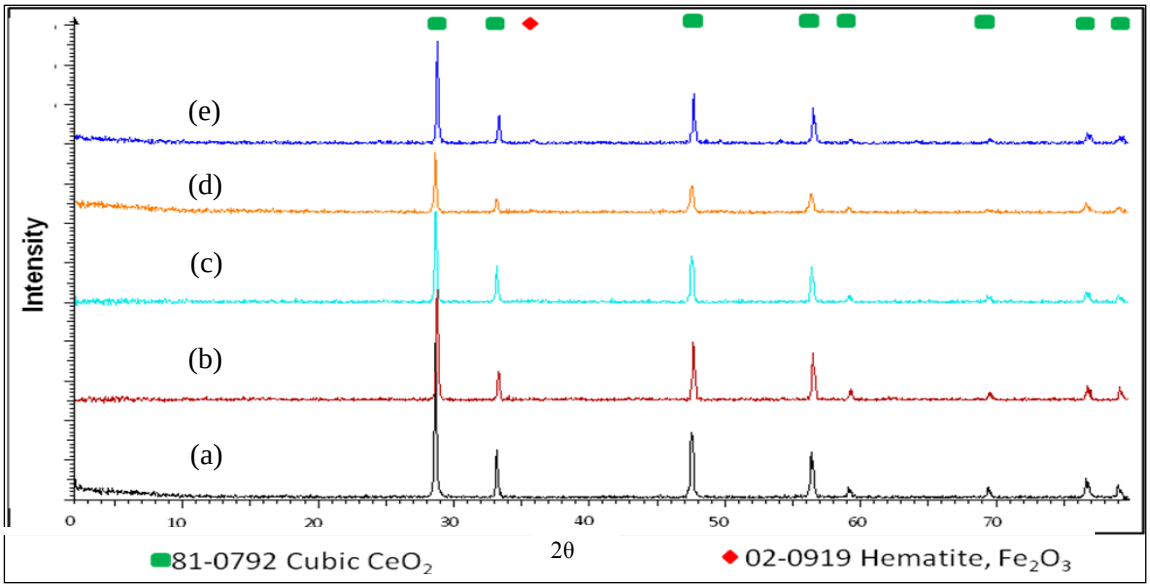

Figure 1. X-Ray diffraction patterns of (a) CeO_2 support, (b) 2.5Fe/CeO_2, (c) 5Fe/CeO_2, (d) 7.5Fe/CeO_2 and (e) 10Fe/CeO_2

Catalytic activity

Figure 2 shows the distribution of gaseous products from dry gasification of PKS in the presence of Fe/CeO_2 catalysts with H_2 as the main products followed by CO_2 and CO while only trace amount of CH_4 was detected. Figure 2 shows that H_2 production is significantly improved when CeO_2 was used as catalyst. Incorporation of 2.5 wt% Fe to the CeO_2 support slightly increased the H_2 production but further increased in Fe loading resulted in reduction in H_2 production. However, it is also observed that increased loading of Fe resulted in an increment in CO_2 and CO produced, which indicates that the PKS undergo oxidation. In addition, the enhanced CO_2 concentration may also contribute from the oxidation of CO to produce CO_2, with reaction path as shown in Eq (1)[8].

$$CO_{ad} + O_{lattice} \rightarrow CO_2 \quad (1)$$

The maximum H_2 yield with the least formation of CO_2 and CO is obtained in the presence of 2.5 wt% Fe for both dry and steam gasification. This result may be explained in term of the formation of cubic ceria-like solid solution as corroborated in XRD pattern. The Fe-O-Ce interaction enables the formation and stabilization of small particles of mixed oxides. As this catalyst reacts, it may provide a larger number of exposed actives sites and result in higher catalytic activity [9]. It is concluded that the interaction between well dispersed Fe species and the good oxygen mobility in the Ce-Fe solid solution promotes the formation of synthesis gas. Therefore, it can be expected that the production of H_2 decreses with increasing of Fe loading.

Both Figures 2 and 3 show that Fe loading higher than 2.5 wt% resulted in a decreased in H_2 production which could be attributed to the lack of Fe-O-Ce interactions. This trend is in agreement with those reported earlier where they proposed that lower catalytic activity of Fe-CeO_2 is due to the diffusion of Fe^{3+} into the lattice structure of Ce^{4+}, resulting in less active sites available for reaction to take place [10].

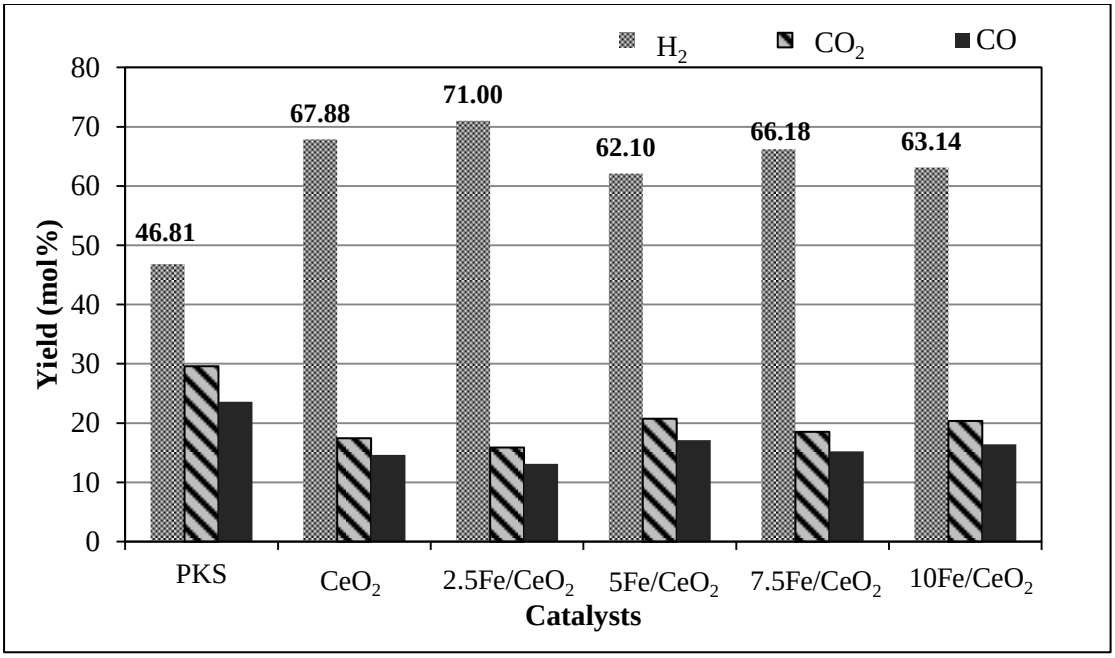

Figure 2. Distribution of gaseous products from dry gasification of PKS

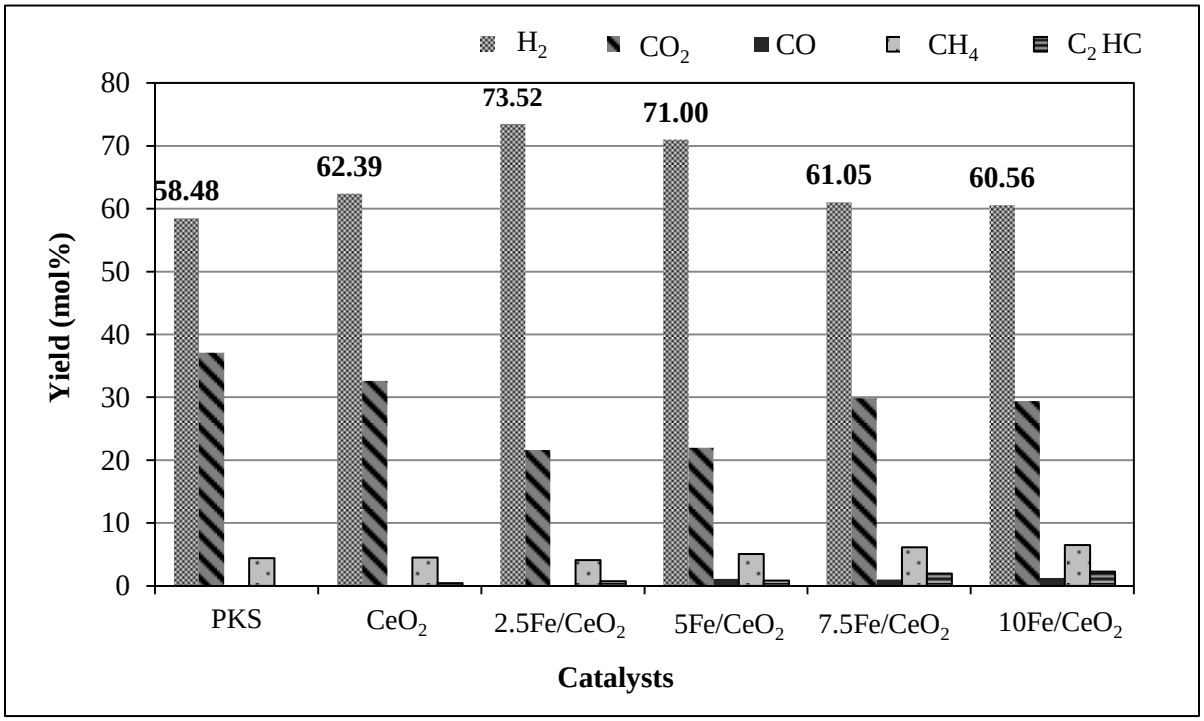

Figure 3. Distribution of gaseous products from steam gasification of PKS

The introduction of steam facilitates further water gas shift reactions to occur in the gasification. It has been suggested that the interaction between carbon deposits from PKS decomposition and the lattice oxygen of CeO_2 would lead to the formation of CO [11] as shown in Eq (2) which then reacts with steam to produce H_2 and CO_2, following the WGS reaction (Eq3).

$$C + O_{lattice} \rightarrow CO \quad (2)$$
$$CO + H_2O \rightarrow H_2 + CO_2 \quad (3)$$

Conclusion

Fe/CeO_2 catalysts with Fe loading of 2.5-10 wt% were successfully prepared and tested in PKS gasification for production of biohydrogen. Nitrogen adsorption-desorption isotherms of these catalysts show that they are Type III materials indicating that the catalysts are nonporous materials. XRD results confirmed the presence of four strong peaks of cubic Ceria and a weak peak of hexagonal hematite iron oxide, Fe_2O_3. The 2.5 wt% Fe/CeO_2 catalyst produced the maximum H_2 yield, 70% with the least formation of CO_2 and CH_4. The H_2 yield increased to 73% in steam gasification of PKS as compared to dry gasification. The favourable catalytic activity in gasification reactions may be correlated to the metal support interaction between iron species and the cubic CeO_2 solid solution. It is concluded that the H_2 yield decreases with increasing of Fe loading.

Abstract

This research mainly focuses on developing a natural cellulose nanofibre (CNF) from kenaf bast fibre and its potential for enzyme immobilization support. CNF was isolated by using a combination between chemical and mechanical treatments such as alkaline process and high-intensity ultrasonication process to increase the efficiency of hemicellulose and lignin removal, and to reduce its size into nano-order. The morphological study was carried out by using scanning electron microscope (SEM), indicating most of CNF diameter in range of 50-90 nm was obtained. The result of chemical analysis shows that cellulose content of raw bast fibre, bleached pulp fibre and CNF are 66.4 %, 83.7 % and 90.0 %, respectively. By decreasing the size of cellulose fibre, it increases the number of (O–H) group on the surface that plays as important role in enzyme immobilization. Covalent immobilization of cyclodextrin glucanotransferase (CGTase) onto CNF support resulted in about 95.0 % of protein loading with 69.48 % of enzyme activity, indicating high immobilization yield of enzyme. The enzymatic reaction of immobilized CGTase was able to produce more than 40 % yield of α-CD. Reusability profile of immobilized CGTase resulted in more than 60 % of retained activity up to 7 cycles. Therefore, the CNF is highly potential to be applied as enzyme immobilization support.

Abstrak

Kajian ini memberi tumpuan terutamanya kepada penghasilan nano-gentian selulosa (CNF) semulajadi daripada gentian lapisan kulit kenaf dan potensinya sebagai penyokong pemegunan enzim. CNF dihasilkan dengan menggunakan gabungan antara rawatan kimia dan mekanikal seperti proses alkali dan proses ultrasonikasi berintensiti tinggi untuk meningkatkan kadar kecekapan penyingkiran hemiselulosa dan lignin, dan pengurangan saiz kepada nano. Kajian morfologi menggunakan mikroskop imbasan elektron (SEM), menunjukkan sebahagian besar daripada saiz diameter CNF diperolehi dalam julat 50-90 nm. Hasil kajian analisis kimia menunjukkan bahawa kandungan selulosa daripada gentian mentah, gentian pulpa dan CNF masing-masingnya adalah 66.4 %, 83.7 % dan 90.0 %. Dengan mengurangkan saiz diameter gentian selulosa, ia meningkatkan bilangan kumpulan (O-H) di permukaan sokongan yang mana memainkan peranan yang penting dalam pemegunan enzim. Pemegunan

Siklodektrin Glukanotransferase (CGTase) secara kovalen pada CNF menunjukkan kira-kira 95.0 % muatan protein dengan 69.48 % aktiviti enzim, menunjukkan pemegunan enzim yang tinggi terhasil. Tindak balas berenzim CGTase terpegun juga mampu menghasilkan lebih daripada 40 % pengeluaran α-CD. Kitaran kebolehulangan enzim terpegun menunjukkan lebih daripada 60 % daripada aktivitinya dapat dikekalkan selama 7 kitaran. Oleh itu, CNF sangat berpotensi untuk digunakan sebagai penyokong pemegunan enzim.

Kata kunci: gentian-nano selulosa (CNF), kenaf, pemegunan enzim, siklodektrin glukanotransferase (CGTase), rawatan kimia dan mekanikal

Introduction

Nowadays, billions of tons of natural fibre around the world are considered abundant, inexpensive and readily available. Thus, it becomes more interesting to deal with green environment, energy demand, and financial problems. Kenaf (*Hibiscus cannabinus L.)* is one of the feasible resources of cellulose with economic and ecological advantages. Kenaf consists of two types of fibre, bast and core fibre. Bast refers to outer layer of plant fibre (30 % of dry weight), meanwhile core represents the inner layer of fibre (70 % of dry weight). Bast fibre has been reported possess an excellent mechanical characteristic, which can be an excellent support for enzyme immobilization, as well as alternative to current used of polymer-grafting material support [1]. Bast fibre is one of non-wood lignocellulosic fibres comprises of three major components such as lignin, hemicellulose and cellulose [2]. In fact, cell walls of lignocellulosic fibres consist of basic structural, called as microfibrils. As a result, cellulose microfibrils can actually be considered to be nanofibers, since the definition of a nanofiber is a size <100 nm in one dimension [3]. Cellulose is defined as a linear polymer that consists of both crystalline and amorphous region, while hemicellulose and lignin display a complete amorphous structure [4]. Cellulose chain was bound together by hydrogen bonding, whereas lignin and hemicellulose form a matrix surrounding the CNF. Removal of these matrix by top-down approach techniques (chemical-mechanical treatment) is essential to obtain CNF, as well as to improve the surface morphology for enzyme immobilization [5].

The use of CNF in enzyme immobilization is not only to enhance the performance of enzymatic synthesis, but also to minimize the loss of enzyme activity caused by immobilization due to the presence of large surface area per volume ratio [6]. Large surface area also provides a high number of surface functional group especially (O–H) group on the surface of CNF, which increase the number of the interaction of enzyme onto the CNF support [7]. Covalent interaction is the most stable interaction of enzyme molecules to the support; it can minimize the enzyme leakage from its support into the reaction medium compared to other immobilization techniques [8]. The objective of this work is to study the potential application of CNF from kenaf bast fibre in enzyme immobilization *via* covalent binding.

Materials and Methods

Raw material and chemicals

Kenaf raw bast fibre was a gift from Lembaga Kenaf dan Tembakau Negara (LKTN), Malaysia. All chemicals are technical grade such as sodium hydroxide (NaOH), sodium chlorite ($NaClO_2$), acetic acid (CH_3COOH), aqueous hydrogen peroxide (H_2O_2), anthraquinone (AQ), Bradford reagent (coomasive blue), glutaraldehyde (GA), 1,12-diaminododecane and bovine serum albumin (BSA) (Merck Chemicals and R&M Chemicals, Malaysia). Cyclodextrin glucanotransferase from *B. macerans* (CGTase, EC 2.4.1.19) with activity of 600 U/ml was purchased from Amano Enzyme Inc., Japan. Water soluble potato starch was purchased from Sigma, Malaysia.

Isolation of CNF support

The isolation process of CNF consists of several steps of alkaline process and high-intensity ultrasonication. Kenaf bast fibre was retted by using water and then it was oven-dried overnight. Kenaf bast fibre was then cut into shorter, about 1-2 cm in length. About 20 g of short bast fibre was heated in aqueous solution containing of 15 wt % of NaOH and 0.1 wt % of AQ, using non-stirred pressure vessel (MOC: SS316, Equipment no: 2311, AMAR Equipments PVT. LTD., Mumbai, India), and the process was called as delignification process. The ratio of fibre to liquid was 1:9 and the process was carried out at 180 ^{0}C (40 ± 3 bar) for 30 min. AQ was added in the solution to increase the delignification rate, as well as to preserve the fibres from alkaline degradation [9]. In fact, delignification process is mainly to remove the lignin content in the fibre. The obtained pulp was rinsed using distilled water several times to remove any residual chemical from it. Bleaching process was performed to remove

the residual lignin and hemicellulose, which it involved with three stages of different chemical processes (e.g. $NaClO_2$, CH_3COOH, NaOH, and H_2O_2), according to method disclosed by Jonoobi et al. [10]. After a series of bleaching process, bleached pulp fibre was filtered and rinsed with distilled water until it became neutralized pH. The process was repeated five times until the fibre became white, and kept in a water-swollen condition. In preparation of mechanical treatment, the bleached pulp fibre was soaked in distilled water and sonicated by using high-intensity ultrasonic dismembrator (FB705, Fisher Scientific (M) Sdn. Bhd., Malaysia) at 20 kHz of operating frequency, which equipped with 12.7 mm in diameter size of cylindrical titanium alloy probe. The subsequent ultrasonication was conducted for 30 min to isolate CNF from bleached pulp fibre. The ultrasonic treatment was carried out in an ice/water bath. Ice was maintained throughout the ultrasonication process to avoid overheating [11].

Functionalized support *via* chemical coupling reaction

CNF suspension was freeze-dried. Dried CNF support, about 1 g was coupled with 1 g of 1,12-dodecanediamine in 50 ml of methanol containing 5 g sodium methoxide in a round bottom flask. The reaction mixture was refluxed for 6 hours in a water bath at 80 °C. Then, it was filtered after cooling and washed with distilled water several times to remove any excess chemicals. The CNF–1,12-dodecanediamine derivative was stirred in 40 ml of 0.1 M potassium phosphate buffer (pH 8.0), containing 2.5% (v/v) of GA at 25 °C for 2 hours. The CNF–1,12-dodecanediamine–GA derivative was filtered and washed with the same phosphate buffer to remove the excess GA.

Covalent immobilization of CGTase onto functionalized CNF support

The functionalized support (CNF–1,12-dodecanediamine–GA derivative) was suspended in 2.5 ml of enzyme solution, containing 227.48 U/ml CGTase enzyme and 0.05 M potassium phosphate buffer (pH 6.0). The mixture was gently stirred overnight at 4°C. The unbound enzyme was removed by washing with the same phosphate buffer until there is no enzyme activity detected in the filtrates.

Scanning electron microscopy (SEM)

SEM (S-3400N, Hitachi, Japan) was used to observe the surface morphology of fibre based on the effect of process treatment. The acceleration voltage was set up in range of 5-20kV, and samples were sputter-coated with gold to avoid charging effect during SEM observations. The fibre diameter was measured by using image analyser software. The results were reported as the average values of the data for each set of measurements.

Chemical analysis

The cellulose, hemicellulose and lignin contents of CNF were determined by using Fibertec™2010 Auto Fibre Analysis System (FOSS Analytical AB, Sweden). The analysis was carried out according to its standard procedure based on FOSS manufacturer's manual. Cellulose, hemicellulose and lignin content were determined by using Acid Detergent Fibre (ADF), Neutral Detergent Fibre (NDF) and Acid Detergent Lignin (ADL). The chemical analysis of sample can be calculated by following formula: (a) Hemicellulose = NDF (hemicellulose, cellulose and lignin) – ADF (cellulose and lignin); (b) Cellulose = ADF – ADL (lignin); (c) Lignin = ADL [12].

Protein loading determination

Bradford method is approximately four times more sensitive compared to Lowry assay [13]. Thus, modified Bradford assay was used to determine the amount of protein loaded onto the functionalized CNF [13]. The quantity of immobilized enzyme was measured after the end of the all washing steps at 595 nm. Bovine serum albumin (BSA) was used as a standard protein. The amount of protein content of immobilized enzyme onto support was calculated by using the following formula: amount of protein after immobilization = (amount of protein added) – (amount of unbound protein) [14].

Enzyme activity assay (α-cyclodextrin production and enzyme reusability)

The formation of α-cyclodextrin (α-CD) from soluble starch was determined as follows: 30 mg of immobilized CGTase-CNF support was incubated at 60°C in a shaking water bath with 20 ml 0.05 M phosphate buffer, pH 6.0 (containing with 5 w/v% of water-soluble starch). There were eight samples were incubated for different reaction times (1-8 hours). The enzymatic reaction was stopped by placing each sample in a boiling water bath for 15 min. The supernatant was collected by centrifugation for 10 min (10,000 rpm) and passed through a Millipore filter 0.22

μm. The reaction product of α-CD formation was analysed by using Shimadzu HPLC system (Liquid Chromatograph LC-10AT, Diode Array SPD-M10A, and RID 6A), equipped with a Zorbax Carbohydrate column (L: 150 mm, I.D: 4.6 mm, YMC Co. Ltd., Japan) at 30°C. With injection volume of 20 μl, the sample of α-CD was eluted isocratically with acetonitrile-water (75:25) at a flow rate of 1.0 mL min^{-1}. To measure CGTase activity, the enzymatic reaction was run for 5 min. One enzyme activity unit (U) was defined as the amount of enzyme that liberates 1 μmol/min of α-CD under the assay conditions.

For the reusability analysis, 30 mg of immobilized CGTase-CNF support was incubated with 20 ml of 5% (w/v) water-soluble starch in phosphate buffer (0.05 M, pH 6.0). The reaction process was repeated up to 7 cycles at 60°C for every 1 hour. At the end of each reaction, the supernatant was collected by centrifugation (10,000 rpm) for 5 min and the content of α-CD was analysed as described above. Whereas, the precipitate (immobilized CGTase on CNF) was washed with distilled water. Then, it was re-suspended in 20 ml of freshly prepared substrate to start a new cycle. All results reported are the means of at least three separated experiments.

Results and Discussion

Scanning electron microscopy (SEM) analysis

The aqueous suspensions of the raw bast fibre, bleached pulp fibre and CNF after chemo-mechanical treatments are shown in Figure 1. After the chemical treatments, raw bast fibre turned from brown colour into yellowish colour as bleached pulp fibre, indicating a significant amount of lignin and hemicellulose were removed [11]. After the ultrasonication process, CNF suspension turned white colour and homogenously dispersed in water, indicating the nano-sized fibre was sufficiently dispersed and converted to the highly viscous suspension [15].

The surface morphological of raw bast fibre, bleached pulp fibre and CNF were visualized by using SEM, which images of these samples are also depicted in Figure 1. This study reveals that the surface structure of treated fibre was improved in term of its smoothness, roughness and diameter size. Figure 1(a) shows raw bast fibre composed of microfibre bundle and its surface was covered with other impurities (e.g. hemicellulose, lignin, pectin and waxy substances). The average diameter size of raw bast fibre is in a range of 30-70 μm. After a series of chemical process, raw bast fibre was separated into individual micro-sized cellulose fibre, representing as bleached pulp fibre as shown in Figure 1(b). The average diameter size of bleached pulp fibre was reduced to 5-20 μm. The surface of bleached pulp fibre also found smoother than raw bast fibre and it was reported to be composed of strong hydrogen bonding between cellulosic fibril [16]. Thus, removal the impurities such as lignin and hemicellulose by delignification and bleaching processes could reduce the diameter of fibres, as well as disintegrated the single sized into individual micro-sized cellulose fibres. Figure 1(c) represents the SEM of CNF after passing through the ultrasonication process, display as a cellulosic filament like a long entangled classical web structure. CNF support also represents the combination of chemical and mechanical treatments could strip down the individual micro-sized cellulose fibre from bleached pulp into nano-sized cellulose fibre (average diameter size: 50-90 nm). Thus, further study on the optimization of preparation factors (e.g. concentration of the chemical used, treatment process time and output power of ultrasonication process) is important to increase the yield of nano-sized cellulose fibre as well as to reduce its diameter size.

Chemical composition

Highly cellulose content can be extracted by removal of lignin, hemicellulose and other impurities from raw bast fibre using a series of conventional methods. The changes of chemical composition of raw bast fibre, bleached pulp fibre and CNF were presented in Table 1. Initially, raw bast fibre consisted of around 66.4 %, 18.0 % and 12.6 % of cellulose, hemicellulose and lignin, respectively. During the delignification and bleaching steps, the cellulose content increased up to 83.7 % from raw bast fibre, whereas hemicellulose and lignin decreased to 10.3 % and 5.1 %, respectively. Thus, these major changes were attributed to the chemicals used that employed in process treatment. NaOH, $NaClO_2$, H_2O_2 and CH_3COOH were found efficiently in removing most of lignin and hemicellulose in the fibre [10]. In fact, AQ was added during delignification is to enhance the delignification rate and also to protect the fibers from alkali. Delignification was also carried out under pressure, which contributed to loosen the lignin structure from cellulosic fibre, as well as to increase the degradation rate of lignin in a short period of time. This is because, hemicellulose and lignin formed a matrix surrounding cellulose structure [17]. Removal of hemicellulose and lignin is essential to isolate fibre with high cellulose content. After

ultrasonication, cellulose content in CNF increased up to 90.0 %. Hemicellulose and lignin contents decreased to 6.8 % and 2.4 % respectively. High-intensity of ultrasonication process was able to increase the cellulose content as well as the diameter size of fibre, due to the vibration of water molecules that encourage the dispersion effect of micro-fibre bundles into individual nano-sized cellulose fibres. Nano-order fibre is not only to attribute the increasing of cellulose content on the surface fibre, but also to provide a large surface area per volume ratio. However, variations of these results are corresponding to the result of morphological structure and size of fibres.

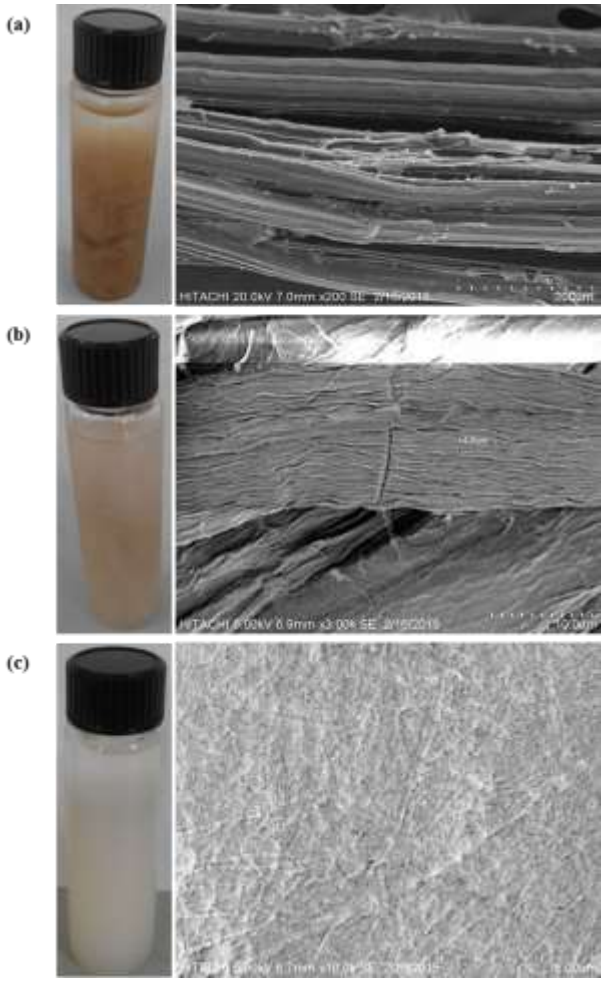

Figure 1. Dispersion states (left) and SEM micrograph (right) of the (a) raw bast fibre (200x), (b) bleached pulp fibre (3000x), (c) CNF.

Table 1. Chemical composition of kenaf bast fibre (based on dry-weight)

Materials	**Cellulose (%)**	**Hemicellulose (%)**	**Lignin (%)**	**Extractive (%)**	**Ash (%)**
Raw bast fibre	66.4 ± 1.1	18.0 ± 1.4	12.6 ± 0.1	1.7 ± 0.2	1.4 ± 0.0
Bleached pulp fibre	83.7 ± 0.3	10.3 ± 0.9	5.1 ± 1.2	0.7 ± 0.3	0.2 ± 0.1
CNF	90.0 ± 0.3	6.8 ± 0.4	2.4 ± 0.2	0.5 + 0.1	0.0 ± 0.0

CGTase immobilization

In this study, CGTase enzyme was immobilized onto CNF support through covalent binding technique. In detail, covalent binding technique represents the CGTase was covalently immobilized *via* chemical coupling agents such as 1,12-dodecanediamine (as spacer arm) and GA (as ligand), representing as one of chemical modification techniques. This technique required two mutual reactive functional groups on CNF support surface and enzyme side to perform essential interaction between functional groups [18]. Chemical coupling agents function as specific linkage or anchor from one side of functional group to other side of functional group, representing as [CGTase enzyme–(ligand–spacer arm)–CNF support], which forms a thin layer on surface CNF support. Chemical coupling agents also permit a very strong binding between target enzyme molecules and CNF support at a specific point of reactive group, as promising the accessibility and flexibility of the interaction [18]. Reactive functional group acts as a platform for the interaction between two end-terminals of the chemical coupling, providing the highest chance to create bio-functionalized linkage with the amino group of enzyme [19].

According to the previous research studies, CNF was reported that consists of mainly (O–H) group on its surface [9–11, 15, 20]. The percentage of immobilization yield is correlated to the interaction of chemical coupling agent onto the surface of CNF. As depicted in Table 2, about 95.0% of immobilization yield of protein binding with 69.48% retained enzyme activity were obtained. The results show high percentage of immobilization yield indicates the successfully of interaction between CGTase molecules and CNF support [18]. High percentage of enzyme activity also contributes to the better performance of enzymatic reaction [14, 21–23].

Table 2. CGTase immobilization onto CNF support

Enzyme added		**Unbound enzyme**		**Immobilized enzyme**		**Immobilization yield**	
Protein(Po) (mg/g support)	**Activity(A) (U/g support)**	**Protein (mg/g support)**	**Activity(U) (U/g support)**	**Protein(P) (mg/g support)**	**Activity(I) (U/g support)**	**Binding (%) (P/Po) x 100**	**Activity (%) I/(A-U) x 100**
30.0	568.7	1.49	119.22	28.51	312.28	95.0%	69.48%

The cyclization activity of immobilized CGTase on CNF support was investigated at temperature of 60 °C, in phosphate buffer (pH 6.0, 0.05 M). The enzymatic reaction of immobilized CGTase converted the soluble starch into mainly α–CD compound. The percentage of α-CD forming for 1 hour shows drastically increased up to 28 % of production yield and gradually increases up to 48 % after 8 hours of reaction time, as presented in Figure 2. Substrate limitation and product inhibition probably effected to the enzymatic reaction of CGTase, indicating stationary line when the reaction process time was extended [24]. Fig. 3 shows the reusability of the 7 cycles of repeated batch process of immobilized CGTase. The result indicated that the residual activity has gradually decreased until 7 cycles. The reusability profile of immobilized CGTase describes the residual activity reduced gradually from cycle 1 to cycle 7, which from 100 % to 66 %. After the fifth cycle, the immobilized enzyme shows a little decreasing on its residual activity. Therefore, the immobilized enzyme is able to maintain in a good yield of forming α–CD even though after 7 cycles. However, both of these results show a good in enzymatic activity either in production of α–CD or reusability of immobilized CGTase on CNF support through covalent interaction. Thus, the CNF support can be applied as a good support structure for enzyme immobilization.

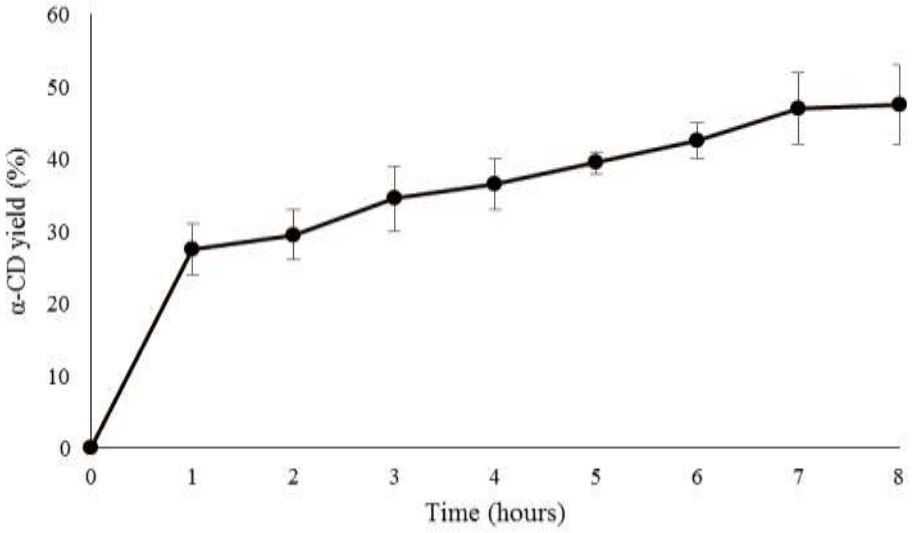

Figure 2. α-CD formation by immobilized CGTase. The immobilized CGTase was reacted in a phosphate buffer (0.05 M, pH 6.0), at temperatures 60 ^{0}C.

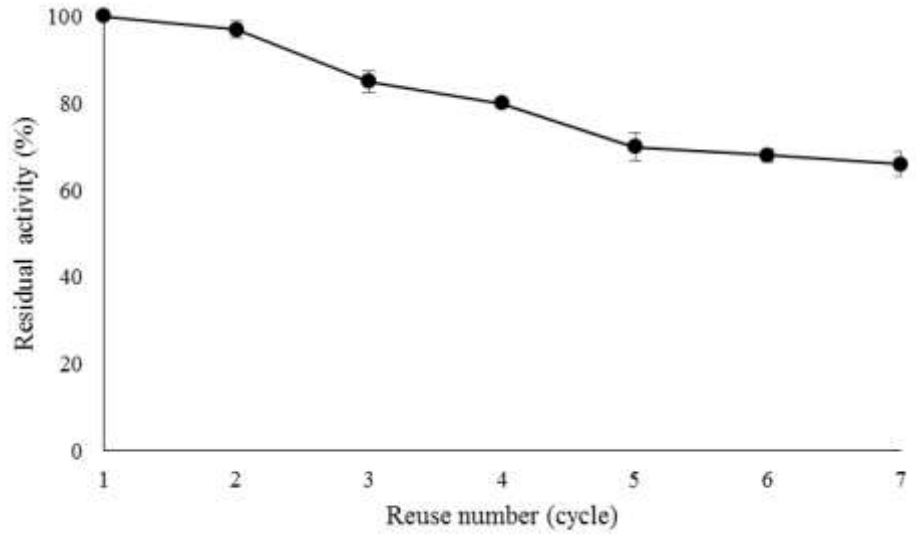

Figure 3. Reusability (repeated batch) of immobilized CGTase. The immobilized CGTase was reacted in a phosphate buffer (0.05 M, pH 6.0), at temperatures 60 ^{0}C.

Conclusion

CNF was successfully isolated from kenaf bast fibres by chemical and mechanical treatments. SEM analysis reveals that CNF has different surface morphology and diameter size which reduction of level roughness and size; attributed to each stage of the treatment processes. Chemical analysis of fibre after each chemical process and high-intensity ultrasonication indicated to the increasing in cellulose content by the decreasing of lignin and hemicellulose contents, also indicated the successfully removal of these impurities. Covalent immobilization of CGTase onto CNF support also reveals a good result in the enzyme assay, which promotes a highly α–CD production and reusability of

enzyme. Thus, CNF support was potential to be applied in enzyme immobilization due to high exposed surface area as well as to provide high cellulose content (e.g. it increases the number of (O–H) group on the surface of CNF for the covalent interaction). Developing of nanobiocatalyst system would benefit for both enzyme and nano-sized support, since the enzyme molecule itself is already in the nano-sized.

Abstract

Our previous studies on Malaysian *Uncaria* (Rubiaceae) have yielded over 20 compounds including alkaloids and flavonoids with some compounds showing interesting biological activities. In the search of new bioactive compounds from the genus, a phytochemical investigation on *Uncaria lanosa* (Wall.) locally known as “gegambir paya” or “gegambir hitam” was carried out via metabolite profiling. The plant is reported to be used as an infusion for intestine inflammation and a decoction for cleaning wounds and ulcers. Metabolite profiling was carried out using ultrahigh-performance liquid chromatography coupled with orbitrap mass spectrometry detectors (UHPLC-Orbitrap MS). Ten alkaloids and six flavonoids previously isolated from other *Uncaria* species were used as reference compounds. Phytochemical analysis of the stem extracts of the plant found the presence of a flavonoid and three alkaloids whose identities were obtained through the comparison of their mass and fragmentation pattern as well as the retention times of the reference compounds. The developed LC-MS method is expected to lead to a more rapid and reliable approach in discovery of new or novel compounds in *Uncaria* genus. The development of the MS database will also aid in the metabolite profiling of other medicinal plants in natural product research.

Abstrak

Kajian kami sebelum ini ke atas *Uncaria* (Rubiaceae) Malaysia telah menghasilkan lebih 20 sebatian termasuk alkaloid dan flavonoid dengan beberapa sebatian yang menunjukkan aktiviti biologi yang menarik. Dalam usaha mencari sebatian bioaktif baru dari genus ini, siasatan fitokimia ke atas *Uncaria lanosa* (Wall.) yang dikenali sebagai "gegambir paya" atau "gegambir hitam" telah dijalankan melalui profil metabolit. Tumbuhan ini dilapor digunakan sebagai infusi untuk radang usus dan sebagai rebusan untuk membersihkan luka dan ulser. Pemprofilan metabolit telah dijalankan dengan menggunakan kromatografi cecair ultra tinggi dengan pengesan spektrometri jisim orbitrap (UHPLC-Orbitrap MS). Sepuluh alkaloid dan enam flavonoid yang sebelum ini diasingkan daripada spesies *Uncaria* lain telah digunakan sebagai bahan rujukan. Analisis fitokimia ekstrak daripada batang tumbuhan tersebut menemui satu flavonoid dan tiga alkaloid yang dikenalpasti melalui perbandingan jisim, corak fragmentasi serta masa tahanan berbanding sebatian rujukan. Kaedah LC-MS yang dibangunkan dijangka membawa kepada pendekatan yang lebih pantas dan boleh dipercayai dalam penemuan sebatian baru atau novel dalam genus *Uncaria.* Pembangunan pangkalan data MS juga akan membantu pemprofilan tumbuhan ubatan lain dalam penyelidikan produk semulajadi.

Kata kunci: *Uncaria*, *Uncaria lanosa*, profil metabolit, UHPLC-Orbitrap MS

Introduction

Uncaria genus (Rubiaceae) which comprises 34 species worldwide has been used to treat various diseases including treatment of cancer, Parkinson's disease, Alzheimer's disease, chirrhosis, dizziness, hypertension, convulsion, asthma, rheumatism and many other diseases [1, 2]. Fourteen species are available in Malaysia. In our previous studies on Malaysian *Uncaria*, over 20 compounds including alkaloids and flavonoids have been isolated [3]. Some of the tested compounds have shown interesting biological activities. However, isolation of compounds using conventional chromatographic techniques can be tedious and time-consuming and may yield uninteresting or known compounds. In the search of new compounds from the genus, we have carried out a phytochemical investigation on *Uncaria lanosa* Wall which is locally known as "gegambir paya" or "gegambir hitam". The plant is reported to be used as an infusion for intestine inflammation and a decoction for cleaning wounds and ulcers [4]. According to Kam et al. [5], there are 14 species of *Uncaria* identified in Peninsular Malaysia and for Malaysian *Uncaria lanosa* var. *ferrea*, only two alkaloids, isopteropodine and pteropodine have been recorded.

Materials and Methods

Chemicals and raw materials

Stems of *U. lanosa var. ferrea* (Blume) Ridsd. with voucher specimen number HTBP4324 were collected from Pahang, Malaysia and standards were previously isolated from other *Uncaria* species. Ultrapure water was obtained from a PURELAB Ultra Laboratory Water Purification Systems and HPLC grade acetonitrile and methanol were purchased from Merck. Solvents used for fractionation and isolation were of industrial grade and were distilled prior to use.

Sample preparation

Pure compounds previously isolated from *Uncaria* extracts were dissolved separately in methanol. For sample preparation, dried and ground stems of *Uncaria lanosa* was extracted through 3-days maceration with methanol. The mixture was filtered and evaporated off under reduced pressure. The crude extract was further extracted by liquid–liquid extraction using two types of solvents; non-polar solvent (hexane) and medium polar solvent (dichloromethane, DCM). Each mixture was filtered separately and evaporated off under reduced pressure. 1 mg of DCM extract was weighed accurately and dissolved in 1 mL of methanol: water (30:70, v/v). Samples were filtered through a 0.22 µm PTFE filter into 2 ml screw cap vials prior to LC-MS analysis.

Instrumentation

UHPLC-Orbitrap MS was conducted using Thermo Scientific Q Exactive Hybrid Quadrupole – Orbitap Mass Spectrometer with ESI source system, a dual pump, an automatic injector (20 µL loop), a degasser unit and column heater. Data processing was performed using Xcalibur software.

High performance liquid chromatography

Samples were separated using GL Sciences - Inertsil Column C-18 (250 mm x 4.6 mm, i.d., 5µm) at a column temperature 40 °C. Flowrate was 0.6 ml/min and injection volume was 5 µl. After each injection the needle was washed with 100 % ACN. The mobile phase consisted of water containing 0.01 % formic acid (A) and acetonitrile (B). A gradient elution program was used as follows: 5 – 55 % B (0.00 – 30 min) and 55 – 95 % B (30 – 50 min).

Mass spectrometry condition for LC-MS

The LC/MS profiling of the extract and standards were identified using UHPLC-Orbitrap MS. Nitrogen was used as the sheath and auxiliary gas at flow rate of 45 and 25 ml/min, respectively. The optimum source (ESI) condition were: spray voltage 4.5 and 3.7kV for positive and negative respectively, S-Lens RF Level at 55.00, ESI capillary temperature 320 °C and probe heater temperature 30 °C.

Results and Discussion

Four chemical structures of compounds identified in DCM extract of *U. lanosa* var. *ferrea* was illustrated in Figure 1.

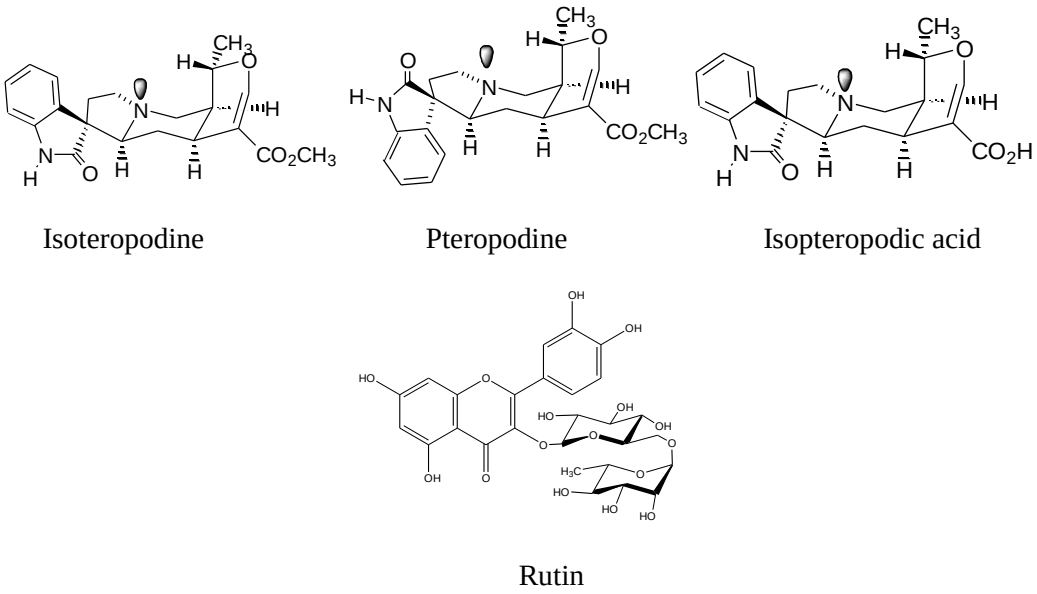

Figure 1. Chemical structures of compounds identified in DCM extract of *U. lanosa* var. *ferrea*

Development of database

The LC-ESI-MS profiles of previously isolated compounds from *Uncaria* species was added into MS database and percent error (ppm) were calculated. The LC-MS spectra of each compound was stored in the MS libary and to be used as reference for the identification of compounds from LC-MS analysis of crude extracts and fractions of *Uncaria* species. The LC-MS profiles are shown in Table 1 and Table 2, respectively.

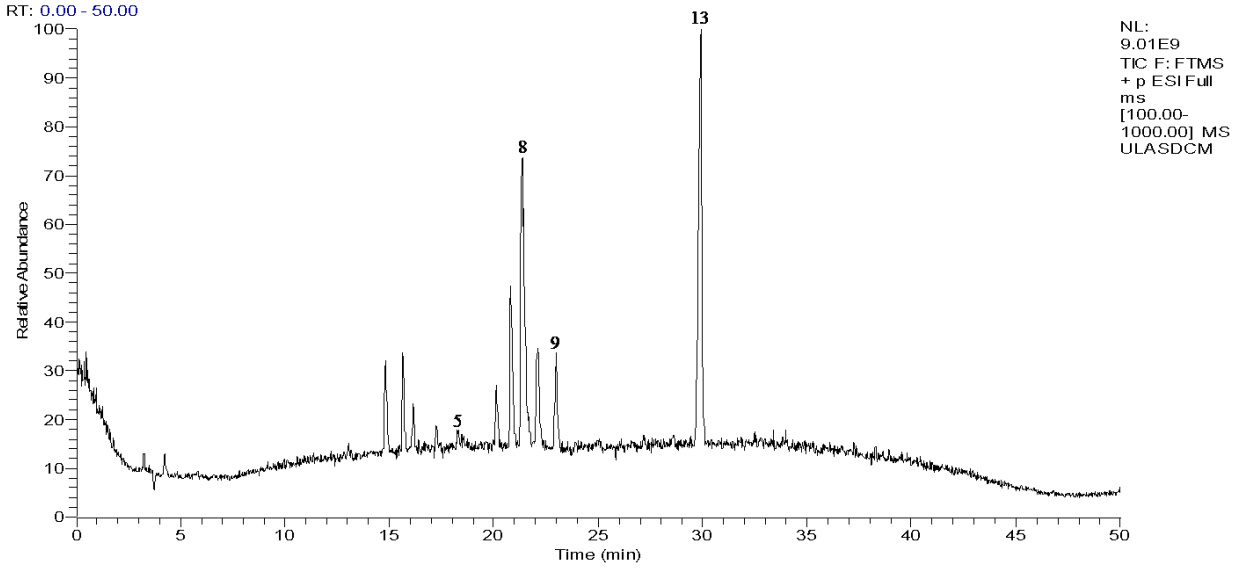

Figure 2**.** Chromatogram of DCM extract of *U. lanosa*; the total ion chromatogram (TIC) in positive mode; the number assigned to the identified peak is according to the number of the reference compound as shown in Table 1

Qualitative analysis of compounds in *Uncaria lanosa* extract

The UHPLC-Orbitrap MS method was employed for the metabolite profiling and identification of the chromatographic peaks of the DCM stem extract of *Uncaria lanosa*. From the analysis, the positive mode affords higher sensitivity for most of the peaks compared to the negative mode. All of the reference compounds can be detected in positive mode but two of the reference compounds cannot be detected in negative mode. Therefore this mode was chosen and applied in the analysis. By comparing the retention time and *m/z* value with the reference compounds, four peaks have been identified, including one flavonoid and three alkaloids which were unambiguously identified as rutin (5), pteropodine (8), isopteropodic acid (9) and isopteropodine (13). The structures of the identified compounds are shown in Figure 1. As shown in Figure 2, peak (5) shows a $[M+H]^+$ ion at 611.16058, peak (8) shows a $[M+H]^+$ ion at 369.18097, peak (9) shows a $[M+H]^+$ ion at 355.16537 and peak (13) shows a $[M+H]^+$ ion at 369.18109. It was found that the Orbitrap MS detection provided accurate molecular weight (±7 ppm). To date, metabolite profiling using mass spectrometry has only been reported for *Uncaria tomentosa* (cat's claw), *Uncaria rhynchophylla* and *Uncaria sinensis* [6 - 9].

Conclusion

In this paper, the proposed UHPLC-Orbitrap MS method was used for the qualitative analysis of alkaloids and flavonoids in *Uncaria lanosa*. Sixteen previously isolated compounds comprising six flavonoids and ten alkaloids were used as standards and were characterized by their retention time and *m/z* values. Four peaks in the extract of *U. lanosa* were identified as rutin, pteropodine, isopteropodic acid and isopteropodine. The developed LC-MS method is expected to lead to a more rapid and reliable approach in the discovery of new or novel compounds from the *Uncaria* genus.

Abstract

The effect of palm oil fiber-TiO_2 ratio in the composite on the reduction of benzene, toluene, xylene and formaldehyde in the air is studied. The ratio was set at 1:0, 1:9 and 5:5. The combination of adsorption process by palm oil fiber and photooxidation of volatile organic compounds by titanium dioxide was revealed. The composite were prepared by using mechanical milling technique. The performance of the composite was characterized in terms of percentage of recovery of benzene, toluene and xylene (BTX) using GC/FID and formaldehyde concentration reduction using formaldehyde meter. The results of recovery of the BTX by palm oil fiber/titanium dioxide composite were more than 90%. The palm oil fiber/titanium dioxide composite has successfully reduced the concentration of formaldehyde by up to 66.7%. Therefore, the palm oil mesocarp fiber/titanium dioxide composite produced is able to reduce the concentration of volatile organic compounds.

Keywords: mesocarp fiber, palm oil fiber, titanium dioxide, photocatalyst, photo oxidation, volatile organic compunds

Abstrak

Kesan nisbah serat kelapa sawit-titanium dioksida dalam komposit bagi pengurangan kandungan BTX dan formaldihid dalam udara telah dikaji. Nisbah telah ditetapkan sebagai 1:0, 1:9 dan 5:5. Kombinasi proses penjerapan oleh serat kelapa sawit dan proses oksidasi cahaya sebatian organik meruap oleh titanium dioksida telah dijelaskan. Serbuk komposit serat kelapa sawit-titanium dioksida telah disediakan menggunakan kaedah kisaran mekanikal untuk mendapatkan serbuk komposit. Prestasi komposit telah diuji dari segi nilai peratusan ujian pemulihan benzena, toluena dan xilena (BTX) menggunakan kromatografi gas dengan pengesan pengionan api (GC/FID) dan peratusan pengurangan kepekatan formaldehid menggunakan meter formaldehid. Nilai peratusan ujian pemulihan BTX yang diberikan oleh serbuk komposit melebihi 90%. Serbuk komposit dari serat kelapa sawit dan titanium dioksida telah berjaya mengurangkan kepekatan formaldehid sebanyak 66.7%. Oleh itu, komposit yang dihasilkan dari serat kelapa sawit dan TiO_2 boleh mengurangkan kepekatan sebatian organic meruap dalam udara.

Kata kunci: serat mesokap kelapa sawit, serat kelapa sawit, titanium dioksida, pemangkin cahaya, sebatian organik meruap

Introduction

Indoor air pollution can contribute to many health issues such as headache, dizziness, irritation, cancer and respiratory difficulties [1-4]. The common volatile organic compounds (VOCs) that usually exist in indoor air or a

building are benzene, toluene, isomeric xylene and formaldehyde. These pollutants were from different sources such as incomplete combustion of by-product, construction materials and exhaust emission [2, 5]. In addition to the nature of a new or old building that utilized furniture, paint, adhesive sealants, building materials and floor panels that are recognized as the source of these VOCs [6].

VOCs which can cause various side effects can be trapped and reduced by using adsorbent materials. There are numbers of adsorbent that has been used to treat air pollutants. Local raw minerals such as aluminum oxide (Al_2O_3), silicon dioxide (SiO_2) and titanium dioxide (TiO_2) had been used to remove dimethyl benzene, one of the volatile organic compounds [7]. Whereas nanosilica was used to remove formaldehyde from polluted air [8].

Traditionally, the air pollutants were reduced by increasing the air exchange and controlling the pollutant sources [9]. Recently, photocatalytic oxidation process has been used to remove trace-level organic contaminants in air and has received considerable attention because this technology can be potentially applied in office buildings, factories, labs, homes and cars [10]. TiO_2 is a well-known decomposing agent that has high photo stability, commercial availability, low cost and relatively good activity that uses photocatalytic oxidation process to degrade organic pollutants [11]. In this study, palm oil fiber/TiO_2 composite with different ratio are fabricated to act as adsorbing material using passive sampling technique. The result of percentage of recovery of the prepared composite was compared with the standard percentage value set by National Institute of Occupational Safety and Health (NIOSH). The effect of photocatalyst activity by adding TiO_2 to palm oil fiber was discussed in terms of formaldehyde concentration reduction percentage.

Materials and Methods

Titanium (IV) oxide powder (99.8 % trace metal basis) from Sigma Aldrich, the standard solution of benzene, toluene, pm-xylene and o-xylene were analytical grade with >99% purity, brand Dr Ehrenstorfer. Carbon disulfide with ≤0.001% benzene was purchased from MERCK. Commercial activated charcoal made from coconut shell was purchased from SKC, 1.8 ml glass vial with PTFE lined caps were purchased from Agilent for gas chromatography analysis.

Preparation of composite powder material

Palm oil fibers were washed with distilled water to remove dirt and contaminants. It was dried in the oven at 105 ˚C for 24 hours. Then the palm oil fibers were undergo a series of grinding process; started with grinder (Model, Rocklab grinder TC 40) for 10 minutes and were sieved using rotary sieve (38 micron). It was then ball milled at 600 rpm for 30 minutes. TiO_2 powder together with the palm oil fiber mixture was ball milled at 600 rpm for 30 minutes. Samples were labelled as POFN for 100% palm oil fiber, R1 for 10% titanium dioxide and R5 for 50% titanium dioxide.

Preparation of stock and standard solution

Stock standard solution of toluene, pm-xylene and o-xylene were prepared by adding 1 ml of each standard into 25 ml volumetric flask. Stock standard solution of benzene was done by adding 0.1 ml of standard benzene to 20 ml volumetric flask. Stock solution of formaldehyde was prepared by adding 50 mg of formaldehyde into 100 ml volumetric flask. Then, 5 ml of the stock solution was taken and added into 100 ml volumetric flask to prepare formaldehyde standard solution of 10 ppm.

Recovery test

Carbon disulfide was added into each stock solution to make it either 25 ml or 20 ml solution. Different concentration of standard solution i.e. 8 ppm, 10 ppm and 12 ppm were prepared from stock standard solution. Standard calibration curves for each parameter are performed in Chemstation as stated in instrument manual. 150 mg sample powders with particle size ranges from 47nm to 94.8 nm for palm oil fiber and 62 nm to 111 nm for titanium dioxide were placed in screw cap glass vials and spiked with known amount of benzene, toluene, pm-xylene and o-xylene (BTX) from the standard solution and left in a refrigerator at 4˚C for 24 hours. 1 ml carbon disulfide was added to each vial and immediately closed up. The vials were agitated for 30 minutes and then analysed using gas chromatography with flame ionization detector. A bar chart of recovery percentage was drawn

for comparison purposes. The percentage of recovery was calculated by dividing recovered value with spiked value times by 100.

Formaldehyde test

Stock standard solution and a standard solution of formaldehyde were prepared as above. The formaldehyde solution was heated on a hotplate at 50 ˚C. 10 ml of the standard solution was pipetted into a petri dish and placed inside a 457 x 305 x 305 mm test chamber. The test chamber with 55% relative humidity was set up with a 220-240 V ~ 50/60 Hz 27 Watt lamps. The concentration of formaldehyde was measured by MultiRAE Lite formaldehyde meter. The composite sample was placed inside the test chamber when the formaldehyde meter gave 1 ppm reading on the screen. The light intensity and relative humidity in test chamber maintained as constant.

Results and Discussion

Volatile organic compounds used in this study were toluene, and xylene with three isomers; ortho-, meta-, para-substitution. A good sorbent should be able to desorb all the absorbed analytes [12]. Figure 1 shows that the composite adsorbed all the hazardous VOCs because the obtained value of the percentage of recovery more than 100%. The percentage of recovery for palm oil fiber/titanium dioxide composite powder was calculated using Equation 1 which is given by the area under peak of chromatogram. The amount recovered is the value given by area under peak by gas chromatography as expressed in equation 1 below.

$$\text{Percentage of recovery} = (\text{amount recovered}/\text{amount spiked}) \times 100 \quad (1)$$

As shown in Figure 1(a – c) sample with 100 %, 90 % and 50 % palm oil fiber have more than 100 % recovery of toluene, pm-xylene and o-xylene. For composite powder that was spiked with 8 ppm and 10 ppm of selected analytes, the percentage of recovery ranges from 97 % to 121 %. The increasing number of analytes available that react with the chemical structure and functional group of palm oil fiber gave the highest percentage of recovery, i.e. 203 %. It was found that, the percentage of recovery is very much depending on the heating rate, the gas flow rate and purging time of the gas chromatography [13]. In this study the optimum heating rate and gas flow rate for maximum percentage of recovery was 10 ml/min and 2.0 ml/min, respectively. This finding is in agreement with result studied by Thammakhet and Muneesawang [13] where the optimum heating rate is needed to provide a high percentage of recovery without lowering the adsorption performance of the adsorbent and minimizes the analytes loss. Another possible reason for this observation is contributed by carbon disulfide. Carbon disulfide was used as eluent to elute the compound during the early stage of recovery analysis. When the gaps between double-bonded carbon atoms are similar or greater than Van der Waals separation, direct benzene-benzene polymerization is expected to occur. Due to the carbon disulfide assisted polymerization of the benzene ring in toluene and xylene, high percentage of recovery is obtained similar as reported by Ciabini et al. [14]. In Malaysia, the National Institute of Occupational Safety and Health has set a standard percentage of recovery value. All the adsorbent must meet the 75 % recovery criteria. Result below than 75 % is not accepted.

From the results of recovery for each of the analyte concentration, the palm oil fiber used was able to capture the hazardous volatile organic compounds. All the samples gave a value that exceeds the standard requirement set by NIOSH. The effect of TiO_2 added into the palm oil fiber in term of the formaldehyde reduction is shown in Figure 2. POFN, R1 and R5 samples have successfully reduced the formaldehyde concentration by 62 %, 63 % and 67 % respectively. Photocatalytic degradation by TiO_2 has contributes to better pollutant reducer property of the palm oil fiber composite powder. TiO_2 act as absorbent that absorbed a photon containing energy when it was irradiated by light. The energy that equal or larger than the band gap caused the electron to be excited from the valence band to a conduction band which created vacancy in the valence band. In this reaction, electron hole pair namely, h^+ and e^- are powerful oxidizing and reducing agents respectively [21]. Therefore, formaldehyde is oxidized to carbon dioxide and water according to Equation 2. As report by [15], formaldehyde decomposition rate is depends on humidity, UV light intensity and amount of photocatalyst. Other factors that affecting photocatalytic degradation are adsorption properties and photocatalytic activity of the catalysts [16].

$$HCHO + O_2 \rightarrow CO_2 + H_2O \quad (2)$$

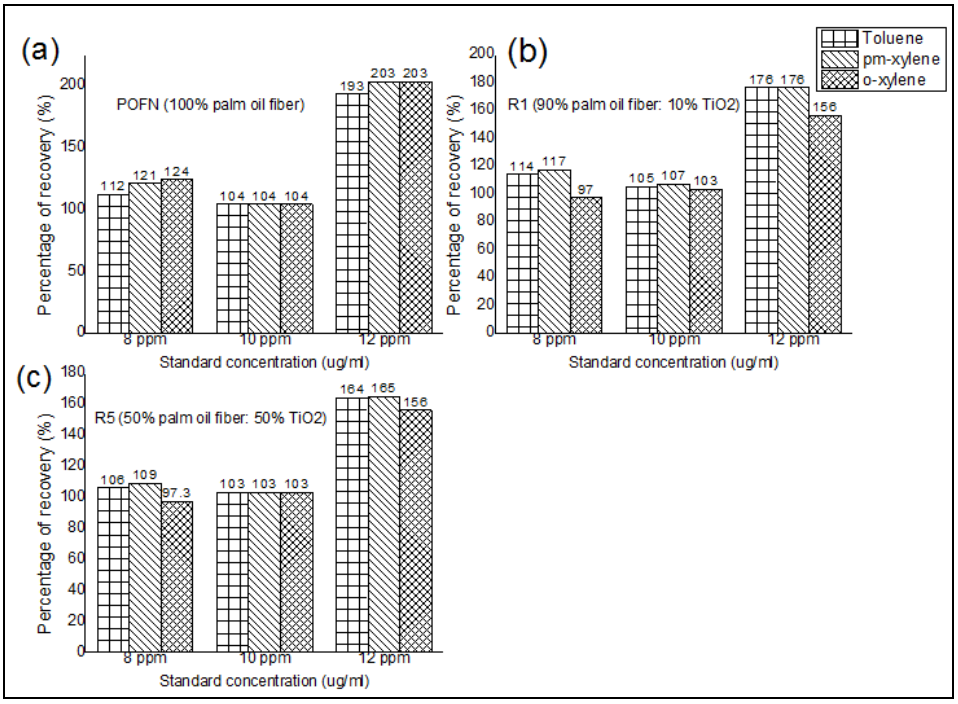

Figure 1. Percentage of recovery of pm-xylene, o-xylene and toluene in Standard 1, Standard 2 and Standard 3 (concentration of 8 ppm for Standard 1, 10 ppm for Standard 2 and 12 ppm for Standard 3) by sample (a) POFN, (b) R1 and (c) R5 after recovery test using carbon disulphide as eluent.

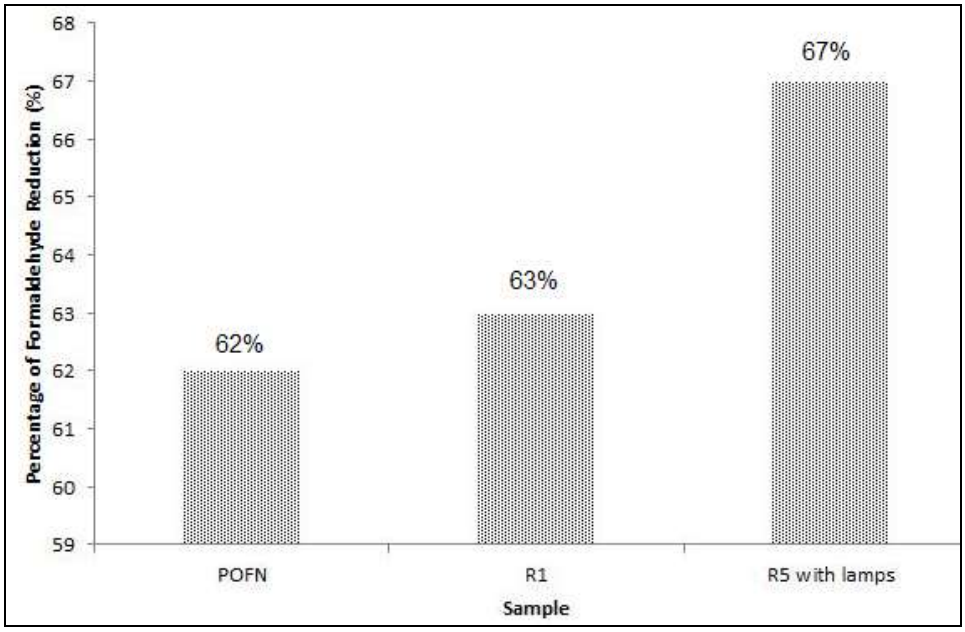

Figure 2. Percentage of formaldehyde concentration reduction by POFN (100% palm oil fiber), R1 (90% palm oil fiber: 10% titanium dioxide and R5 (50% palm oil fiber: 50% titanium dioxide). Only R5 was tested using reading lamps as source of light in the test chamber.

Conclusion

Palm oil fiber/titanium dioxide composite powder has successfully act like commercial activated carbon with percentage of recovery obtained more than 90% as required by the standard method used by NIOSH Malaysia. From the results obtained, a combination between adsorption and photocatalytic process is a promising solution to act as adsorbent and air pollutant reducer. The palm oil fiber/titanium dioxide composite acts as a photocatalyst that oxidized formaldehyde into carbon dioxide and also reduced the concentration of formaldehyde. The capability of the palm oil fiber composite enhance by the amount of the TiO_2 added therefore, the produced palm oil fiber/TiO_2 composite is capable to act as adsorbent and air pollutant reducer, simultaneously.

Abstract

Hemicelluloses were extracted from rice straw using alkaline extraction and ethanol precipitation. The effects of different extraction conditions; temperature (45 – 65 °C), pH (4.5 – 6.5), and concentrations of NaOH (0.25 – 1 M) on the hemicellulose yield were investigated. Two hemicelllulosic fractions namely Ha_1 and Ha_2 were obtained by precipitation of alkaline soluble hemicellulose in 0.2 volumes and 4 volumes ethanol, respectively. The Ha_1 and Ha_2 were further characterized to obtain total sugar, monosaccharides and Klason Lignin content. The highest hemicellulose yield for Ha_1 was 4.00 % obtained at 55 °C and pH 5.5 with 0.25 M of NaOH, whereas the highest hemicellulose yield for Ha_2 was 19.88 % obtained at 55 °C and pH 5.5 with 0.5 M of NaOH. This study revealed that hemicellulose yield is dependent on the pH, temperature and concentration of NaOH in the alkaline extraction.

Keywords: hemicelluloses, rice straw, alkaline extraction, ethanol precipitation

Abstrak

Hemiselulosa daripada hampas batang padi telah diekstrak melalui pengekstrakan beralkali dan pemendakan etanol. Kesan perbezaan kondisi pengekstrakan; suhu (45 – 65 °C), pH (4.5 – 6.5), dan kepekatan NaOH (0.25 – 1 M) ke atas hasil hemiselulosa dikaji. Dua pecahan hemiselulosa, Ha_1 and Ha_2 telah diperolehi melalui pemendakan hemisellulosa larut alkali dalam isipadu etanol 0.2 dan 4 masing-masing. Ha_1 and Ha_2 dicirikan oleh jumlah gula, kandungan monosakarida dan Klason Lignin. Hasil hemiselulosa tertinggi untuk Ha_1 adalah 4.00 % yang diperolehi pada suhu 55 °C, pH 5.5 and 0.25 M NaOH, manakala untuk Ha_2 adalah 19.88 % diperolehi pada suhu 55 °C, pH 5.5 and kepekatan 0.5 M NaOH. Kajian ini membuktikan hasil hemisellulosa bergantung kepada pH, suhu dan kepekatan NaOH dalam pengekstrakan beralkali.

Introduction

The main cereal crop in the whole wide world is rice, which is being produced in more than 148 million hectares with huge range of ecosystem. The scientific name of paddy is *Oryza sativa*. It is an important cereal crop that produce a lot of residues which is rice straw [1]. Rice straw is the rice plant stalk that is left as waste product on the field after harvesting of the rice grain [2]. A lot of rice straw are disposed by biomass burning that leads to air pollution.Therefore, a lot of research work has been performed to find ways of utilizing these agricultural waste. Hemicellulose is the second most abundant polysaccharide in nature, representing approximately 20-30% of

lignocellulosic biomass [3]. Hemicellulose polymers are complex components in the plants cell wall. With cellulose and lignin, hemicellulose form hydrogen bonds and covalent bond respectively.

The hemicelluloses are used in various industrial applications such as food additives, biodegradable films and in medicinal applications [4]. Various methods were used to isolate hemicellulose from the agricultural waste. Among these methods, alkaline extraction is most widely used. Alkaline solution hydrolyzes the ester linkage between hemicellulose and other components, resulted in isolating hemicellulose in the aqueous media. Usually the isolation of hemicellulose is done by using alkaline solution such as NaOH for softwood and KOH for hardwood [5]. The aim of this study was to optimize the alkaline extraction conditions and ethanol precipitation of hemicelluloses from rice straw. The effects of the concentration of NaOH, temperature and pH on hemicellulose percentage yield were investigated.

Materials and Methods

Materials

Rice straw was obtained from local sources (Perlis, Malaysia). It was dried and cut into small pieces. The straw was ground to pass a 0.08 mm size screen and stored at room temperature. All other chemicals used were of analytical grade unless otherwise stated.

Extraction of hemicelluloses

Extraction of hemicellulose was carried out by mixing the rice straw with 0.25 M sodium hydroxide (NaOH) with ratio of 1:25 (w/v). The mixture was stirred at 400 rpm and heated at constant temperature of 55 °C for 2 hours. After filtration, the pH of the solution was adjusted to pH 5.5 by adding 6 M hydrochloric acid (HCl). Then the mixtures were kept at 4.0 °C for 24 hours. The mixture was then centrifuged at 3500 rpm for 15 minutes. Ethanol 0.2 volumes and 4 volumes containing 10 % of acetic acid were added to the liquid fraction to precipitate Ha_1 and Ha_2 respectively. Both hemicellulose fractions (Ha_1 and Ha_2) were obtained and dried at 40.0 °C for 24 hours. In order to optimize the alkaline extraction conditions, the extraction was carried out at various concentration of NaOH (0.25 M, 0.5 M and 1 M) temperature (45 °C, 55 °C, and 65 °C) and pH (4.5, 5.5 and 6.5).

Analytical method

Total sugar content was measured according to phenol-sulphuric acid method [6]. The hemicellulose fraction with unknown concentration was added with 0.5 mL of 5.0 % phenol solution and the mixture was shaken. A volume of 2.5 mL concentrated H_2SO_4 was quickly added to the mixture (phenol-hemicellulose) and shaken once again. These solutions were then analysed where the absorbance of the mixtures were recorded at 480 nm using UV-Visible spectrophotometer. The hemicelluloses yield (%) was calculated based on total sugar content in the hemicelluloses fraction. The monosaccharides sugar was determined by using a high performance liquid chromatography (HPLC) (Agilent Technologies 1200 Series, Germany) using Aminex HPX 87P column (300 mm x 7.8 mm). The HPLC was equipped with a refractive index detector (G 1362A, Agilent Technologies 1200 Series, Germany) and column oven (Agilent Technologies 1200 Series, Germany). The hemicellulose fraction was filtered through a 0.20 µm nylon syringe filter (Minisart, Sartorius AG, Germany) prior directly injected to the HPLC system. The hemicellulose fractions were eluted using deionised water as the mobile phase at column temperature of 80 °C and a flow rate of 0.5 mL/min. Klason lignin content was determined following TAPPI method T222. The FTIR spectra of the hemicellulose fractions were obtained on a FT-IR spectroscopy (Nicolet 500) using a KBr disc containing 1% finely ground samples. Spectra were recorded between 4000 and 400 cm^{-1} at a resolution of 4 cm^{-1}.

Statistical analysis

ANOVA was used to analyse the data of experiment and Duncan's multiple range test was applied in order to determine the significant difference ($P<0.05$) of samples using Statistical Package for Social Science, Version 10 (SPSS Inc., Illinois). The result was expressed as mean ± SD (standard deviation).

Results and Discussion

Effect of NaOH concentration

Alkaline extraction was carried out to investigate the effects of NaOH concentrations; 0.25 M, 0.5 M and 1 M on hemicellulose yield, while other parameters were fixed as followed : pH 5.5 and temperature 55 °C. As shown in

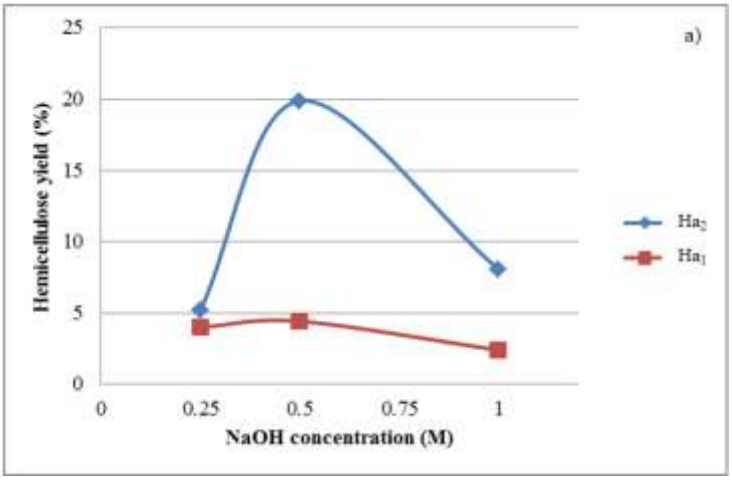

Figure 1 (a), hemicellulose yield for both Ha_1 and Ha_2 increased as NaOH concentration increased from 0.25 M to 0.5 M but then decreased tremendously when the NaOH concentration was increased to 1 M. This indicates that hemicellulose extraction was best performed at mild conditions. Hemicellulose yield for both, Ha_1 and Ha_2 were highest at 0.5 M NaOH concentration. Statistical analysis for Ha_1 showed that there were no significant differences between 0.25 M NaOH and 0.5 M NaOH ($P > 0.05$), while there were significant differences among 0.25 M NaOH and 1 M NaOH. Thus 0.25 M NaOH concentration was chosen for further analysis for Ha_1. On the other hand, the statistical analysis for Ha_2 showed that there were significant differences between 0.25 M, 0.5 M and 1 M NaOH ($P < 0.05$).Therefore, 0.5 M NaOH concentration was chosen for further analysis for Ha_2.

Effect of temperature

The effects of different temperatures (45 – 65 °C) on the yield of hemicellulosic fractions; Ha_1 and Ha_2 were studied while the other parameters were fixed; pH 5.5 with 0.25 M NaOH for Ha_1 and pH 5.5 with 0.5 M NaOH for Ha_2. Statiscal analysis of hemicellulose yield, Ha_1 and Ha_2 showed that the significant difference existence between temperature of 45 °C and 55 °C and among hemicellulose extracted at 55 °C and 65 °C ($P < 0.05$), however there is no significant difference between hemicellulose yield extracted at 45 °C and 65 °C ($P > 0.05$). Based on Figure 1 (b), the best temperature for alkaline extraction was at 55°C which gave the highest hemicellulose yield. The presence of high lignin content hindered the yield of hemicellulose in Ha_1 resulted in lower hemicellulose yield than Ha_2. The hemicellulose yield for both Ha_1 and Ha_2 significantly increased from 45 °C to 55 °C and as temperature of extraction reached 65 °C, the yield of hemicelluloses significantly decreased. The yield of hemicellulose decreased at 65 °C due to less degradation of macromolecular hemicellulose.The minor degradation occurred mainly because of the linkages between glycosyl units were cleaved at high temperature [6].

Effect of pH

pH was another factor which affected the efficiency of hemicellulose extraction. The effect of pH for hemicellulosic fractions, Ha_1 and Ha_2 were studied at different pH (4.5 – 6.5) while the other parameters were fixed; 0.25 M NaOH and temperature of 55 °C for Ha_1 while 0.5 M NaOH and temperature of 55 °C for Ha_2. Statiscal analysis for Ha_1 and Ha_2 showed that the significant difference existence between pH of 4.5 and 5.5 and between pH 5.5 and 6.5, ($P < 0.05$), however there is no significant difference between pH 4.5 and 6.5 ($P > 0.05$). There was an increasing trend in hemicellulose yield from pH 4.5 to 5.5 and decreasing trend from pH 5.5 to 6.5 for both Ha_1 and Ha_2. This indicated that minor degradation occurred when the pH was slightly acidic (pH 4.5) and at neutral condition (pH 6.5). Figure 1 (c) showed that the suitable pH to yield the maximum concentration for both Ha_1 and Ha_2 was at pH 5.5. Thus, pH 5.5 was favorable to isolate hemicellulose from rice straw using alkaline extraction.

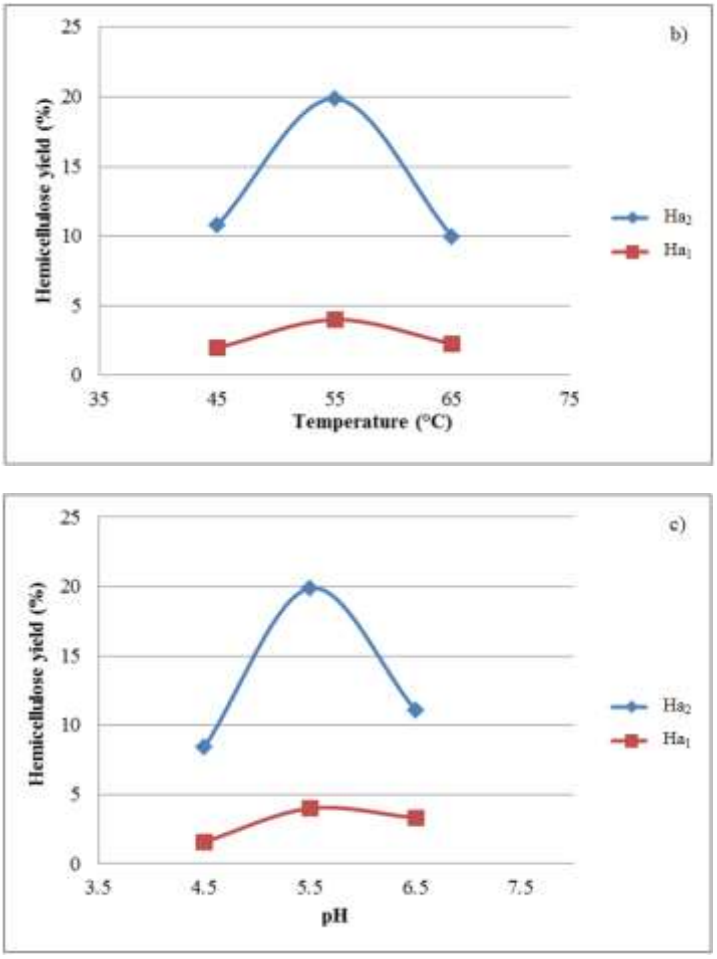

Figure 1. Effects of NaOH concentration (a), temperature (b), and pH (c) on hemicellulose yield (%) Ha_1 and Ha_2.

Klason Lignin content

The Klason lignin content for both hemicellulose fractions, Ha_1 and Ha_2 is shown in Table 1. The result showed that Ha_1 contain more lignin (11.72 %) than Ha_2 (4.22 %). Table 1 showed that as the volume of ethanol decreased (0.2 v) in Ha_1, the Klason lignin content increased and as the volume of ethanol increased (4v) in Ha_2, the Klason lignin content decreased. The increased volume of ethanol (4v) increased the polarity of plant cell wall in Ha_2 exposed it more to the solvent thus promote the lignin removal [7].

Table 1. Monosaccharide composition and Klason Lignin content for Ha_1 and Ha_2

	Glucose (mg/mL)	Arabinose (mg/mL)	Xylose (mg/mL)	Ara/Xyl ratio	Klason Lignin (%)
Ha_1	0.57 ± 0.44	0.10 ± 0.02	0.27 ± 0.02	0.36	11.72 ± 5.07
Ha_2	0.70 ± 0.18	0.96 ± 0.07	0.05 ± 0.05	21.08	4.22 ± 1.32

Data means and standard deviation n=3. Ha_1 represent hemicellulose high lignin prepared by alkaline extraction from rice straw with 0.2v ethanol precipitation. Ha_2 represent hemicellulose low lignin prepared by alkaline extraction from rice straw with 0.4v ethanol precipitation.

Monosaccharide analysis by HPLC

As shown in Table 1, both Ha_1 and Ha_2 composed of glucose, arabinose and xylose. The predominant sugar component for Ha_1 was glucose while for Ha_2 was arabinose. Ha_2 consisted of higher glucose concentration mainly because the presence of glucans which associated with xylans in primary cell wall, which were less associated with lignin. The xylose concentration higher in Ha_1 as compared to Ha_2. The lower amount of arabinose in Ha_1 suggested that the hemicellulose was closely assosiated to the cellulose surface [8]. Hemicellulose fraction, Ha_2 contained higher amount of Ara/Xyl (21.08) whereas Ha_1 showed lower Ara/Xyl ratio (0.36). Higher amount of Ara/Xyl means that the hemicellulose obtained more linear arabinoxylan while lower Ara/Xyl ratio consisted of branched arabinoxylan [9].

FTIR Spectra

Figure 2 shows the FTIR spectra of hemicellulosic fractions (Ha_1, Ha_2) and rice straw within the region of 500 – 4000 cm^{-1} including region 850 – 1200 cm^{-1} which is typical region for hemicellulose [10]. Both hemicellulose fractions show similar features. All of the spectra showed similarity as they all have hemicellulose band (850 –1200 cm^{-1}), which concluded that the alkaline extraction did not change the macromolecular structure of hemicellulose. Absorption band at 1610 cm^{-1} corresponded to the water bending mode presence for only Ha_1 and Ha_2 since hemicellulose have strong affinity towards water whereas, this band could not found in rice straw due to the presence of cellulose which hindered the water affinity [11]. Low intensity absorption band at region 850 – 1200 cm^{-1} in Ha_1 compared to Ha_2 shows low purity of hemicellulose fraction due to the higher lignin content for Ha_1 compared to Ha_2. The absoption band at region between 1126 – 1032 cm^{-1} is a typical band for lignin [12]. Higher intensity absorption band at region 1126 – 1032 cm^{-1} in Ha_1 compared to Ha_2, proved that lignin content was higher in Ha_1. The presence of absorption band at 1710 cm^{-1} in Ha_1 is due to the carboxyl groups as the hydroxyl groups in lignin undergo oxidation [13]. Absorption band at 3049 cm^{-1} is assigned to the C-H in an aromatic vibration as hemicellulose contained a small amount of lignin [10]. Absorption band at 1043 cm^{-1} is due to the C-O-C stretching glycosidic linkages in xylans. And the absorption band at 1740 cm^{-1} refer to acetyl carbonyl. As shown in Figure 2, broad absorption band at 3400 and 2400 cm^{-1} is due to the stretching vibrations of OH and CH respectively and absorption band at 1200 cm^{-1} refer to the stretching vibrations of C-O. The C-H bending vibration shows absoption bands at 1467 and 1427 cm^{-1} while the OH bending vibration shows absoption bands at 1340 cm^{-1} [14].

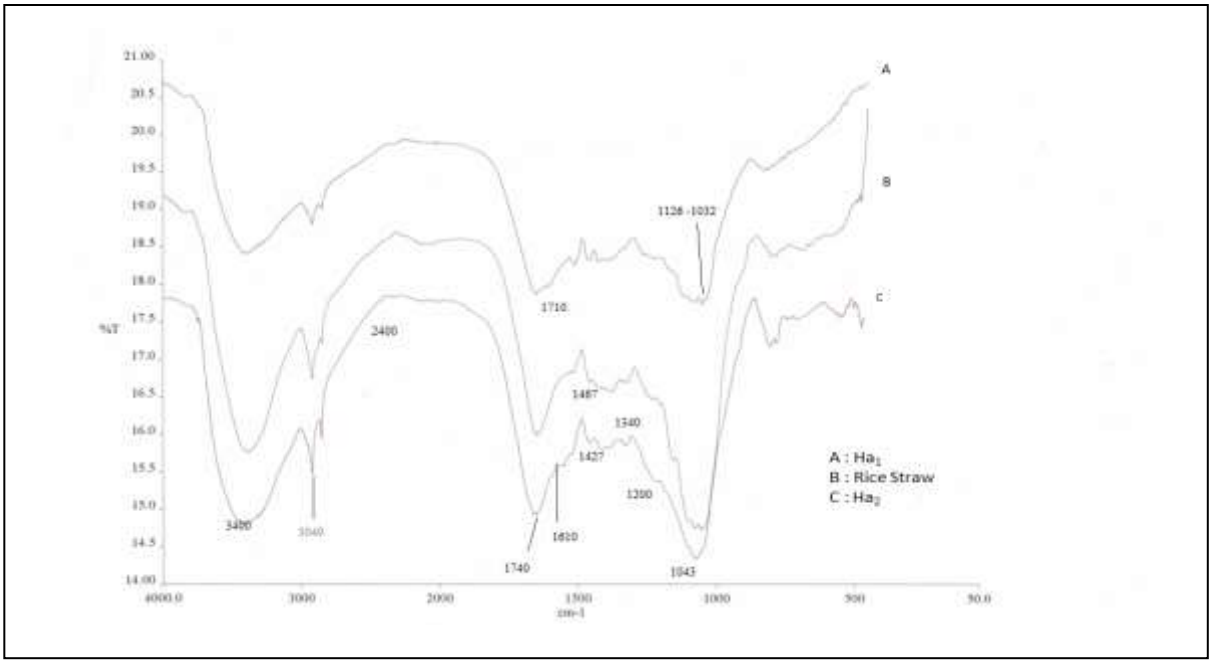

Figure 2. FTIR spectra of Ha_1, Ha_2 and rice straw

Conclusion

This study showed that the maximum hemicellulose percentage yield was obtained by alkaline extraction. The highest hemicellulose yield for Ha_1 was 4.00 % obtained at 55 °C and pH 5.5 with 0.25 M NaOH, whereas the highest hemicellulose percentage yield for Ha_2 was 19.88 % obtained at 55 °C and pH 5.5 with 0. 5M of NaOH. Hemicellulose yield Ha_2 was found to be higher than Ha_1, showing that lignin content affected the percentage yield of hemicellulose.

The role of surfactants in the formation of active Poly(vinylidene fluoride) (PVDF) ultrafiltration (AUF) membranes was studied. The effect combination of surfactants that are Sodium dodecyl sulfate (SDS)/Tween 80 and Tween 80/Triton X-100 formulations on performance and morphological structures were investigated for the first time. The influence of surfactants blends on the membrane pores was also examined. Experimental data showed that combination of Tween 80/Triton X-100 give the highest BSA permeation flux with a value of 285.51 $Lm^{-2}h^{-1}$. With combination of SDS/Tween 80, the AUF membrane showed the highest protein rejection up to 93 % and 79 % for Bovine Serum Albumin (BSA) and Egg Albumin (EA), respectively. Moreover, membranes characterization demonstrated that the addition of SDS/Tween 80 and Tween 80/Triton X-100 were found to affect the performance, surface morphologies and membrane pores of AUF PVDF membranes.

Keywords: poly(vinylidene fluoride), ultrafiltration, surfactant, protein rejection, morphology

Abstrak

Peranan surfaktan dalam pembentukan ultraturasan PVDF aktif (AUF) membran telah dikaji. Gabungan kesan surfaktan iaitu SDS/Tween 80 dan Tween 80/Triton X-100 formulasi terhadap prestasi dan struktur morfologi telah dikaji buat pertama kali. Pengaruh adunan surfaktan pada liang membran juga diperiksa. Data ujikaji menunjukkan bahawa gabungan Tween 80/Triton X-100 memberikan bacaan penyerapan fluks tertinggi iaitu 285.51 $Lm^{-2}h^{-1}$. Dengan kombinasi SDS/Tween 80, membran AUF menunjukkan protein penolakan tertinggi sehingga 93 % dan 79 % masing – masing untuk Albumin Serum Bovine (BSA) dan Albumin Telur (EA). Selain itu, membran pencirian menunjukkan bahawa penambahan SDS/Tween 80 dan Tween 80/Triton X-100 didapati memberi kesan kepada prestasi, morfologi permukaan dan liang membran AUF PVDF.

Introduction

Membrane technology has been found to be an alternative and attractive approach for separation or filtration because the process is faster, energy efficient and does not involve any phase change. Currently, the application of ultrafiltration (UF) in membrane technology is growing very rapidly in protein separations. The important goal in membrane technology is to control the membrane structure, which affects its performance. Hence, extensive

research has been conducted in attempting to improve the performance of the membrane [1]. Since Loeb and Sourirajan first introduced the phase inversion method, considerable progress has been made for understanding the formation mechanism of asymmetric membranes. The phase inversion process induced by immersion precipitation is a well-known technique to prepare asymmetric polymeric membranes. In that technique, a thin film of polymer solution is cast on to a suitable substrate and subsequently immersed into a coagulation bath. The diffusion exchange of solvent and non-solvent will results in the phase separation and also formation of membrane [2].

The UF membrane structure and performance can be controlled by the casting solution composition, casting condition and coagulation bath composition. Thus, in order to get the membrane with excellent structure and performance, introduction of a suitable additive to the casting solution is a convenient and efficient method [3]. Several researchers have reported on the role of additives in the membranes structure and performance. Some additives have the tendency to form macrovoids, others help in suppressing the macrovoids improving interconnectivity of the pores and resulting in higher porosity in the top layer and sub layer. In this study, Polyvinylpyrolidone (PVP) was used as an additive with combination of surfactants in order to control the membrane performance in the preparation of UF membranes. PVP is known as a non-toxic material which miscibility with membrane and solubility in water as well as solvents make PVP a suitable polymer additive. During the membrane formation process, PVP is added to the polymer solution to promote the formation of micropores [4]. It is assumed that the hydrophilic additive, PVP dissolve in water and the sites where PVP exist become micropores during the phase inversion process. Besides the formation of micropores, it has been generally accepted that the porosity increases and the macrovoid formation disappears as PVP was added to the casting solution [5]. For instance, Xu et al. [6] studied the effect of PVP for different MW on the morphology of polyetherimide hollow fiber and they found that the higher the MW of PVP added, bigger the pores were formed [6]. On the other hand, Wang et al. [7] also found similar finding that the decrease in the concentration of PVP resulted to lower water flux and higher rejection.

Although it appears that a number of works has been reported [5-7] using PVP as additives, there is yet no report regarding the effect of PVP additives with combination of surfactants on the morphology and performance of PVDF membranes. The surfactants need to be introduced in the casting solutions in order to prepare membranes either with good membrane structure (consisting of finger-like, dense top-layer and spongy sub-layer) or penetration properties because the addition of additive is still not versatile enough to prepare the appropriate membrane structure and properties. In this paper, the asymmetric membranes were prepared using polymeric solutions consisting of the PVDF, solvent N-methyl-2-pyrrolidon (NMP) and PVP by classical phase inversion method. By combining of surfactant to the polymeric solutions, the effect of anionic and non-ionic surfactants on morphological and performance of the asymmetric membranes such as pure water permeations and rejections were investigated and discussed.

Materials and Methods

Materials

Poly(vinylidene fluoride) (PVDF, Kynar® from Arkema, MW = 45.00 g/mol, d = 1.78 g/cm3) was obtained in pellet form, which is used as polymer in the preparation of membrane casting solution. N-methyl-2-pyrrolidone (NMP, >99%) (Merck, Darmstadt, Germany, d = 1.00 g/cm^3) was used as the solvent for PVDF. Polyvinylpyrolidone (PVP) (MW = 58000 g/mol, K29-32 from Acros Organics), was used as additive in the dope solution. Sodium dodecyl sulfate (SDS) (MW = 288.37g/mol, Merck Schuchardt OHG, Germany), Triton X-100 (MW = 646.86 g/mol, Fisher Chemical) and Tween 80 (d = 1.060 – 1.090 g/cm^3, Merck Schuchardt OHG, Germany) were used as surfactants in the casting solutions. Other solvents such as ethanol and n-hexane as well as distilled water were used as non-solvent in the coagulant bath. Bovine serum albumin (BSA), MW = 69 kDa and egg albumin (EA), MW = 45 kDa were purchased from Acros Organics, USA, used as the solute for filtration experiments. Disodium phosphate dehydrate ($Na_2HPO_4.2H_2O$) and sodium dihydrogen phosphate ($NaH_2PO_4.H_2O$) were used for the preparation of protein feed solution.

Preparation of membranes

Flat-sheet type PVDF membranes were prepared by the immersion precipitation method at room temperature. The casting solutions were prepared by blending of PVDF and PVP in the presence of different types of surfactant in

NMP under constant stirring for 8h at 60°C. A series of polymer solutions were prepared by various composition and type of surfactants, designated as M-P, M-PST and M-PTT as shown in Table 1. The obtained homogenous solution was allowed to stand for at least 2h to eliminate the air bubbles. Subsequently, the solution was spread uniformly on a glass plate, with the help of a casting knife maintaining a clearance between the knife and the plate. The polymer solutions were cast into thin film (100 µm thick) on glass sheets and then the resulting films were immersed into a water bath immediately and let the precipitation to complete (about 2-4 mins). The colour of the casted films changed from transparent to white immediately after immersion into the coagulation bath and separates out of the glass plate after some-time (3-5s). The formed membranes were immersed into tap water for 1 day. The dry membranes were obtained by soaking with ethanol and n-hexane for 24 hour and 1-3 hours respectively before drying at room temperature. Finally, the sheets were cut into the form of circular disk with diameter of 42 mm to be fitted in the membrane cell for filtration experiments. Two types of phase separation can be distinguished in the membrane preparation process. Firstly, the dry phase inversion takes place in the atmosphere by evaporation of the solvent. Secondly, the wet phase inversion is carried out by immersing the polymer solution film into a coagulation bath of a non-solvent, where an exchange of solvent and non-solvent takes place and the membrane is formed. Hence, in this study, we prepared membranes by a combination of both processes.

Table 1. The composition of dope formulation AUF membranes

Membrane	Total polymer (wt%)	Solvent (wt%)	Additive (wt%)	Surfactants (wt%)		
	PVDF	NMP	PVP	SDS	Triton X-100	Tween 80
M-P	17	80	3	-	-	-
M-PST	17	78	3	1	-	1
M-PTT	17	78	3	-	1	1

Pure water permeation (PWP)

Membranes after compaction were subjected to pure water permeation (PWP) within the range operating pressure of 50 – 300 kPa. The PWP was measured to ensure that the membranes used were stable. The permeability was measured under steady state flow. The PWP in the permeate side was measured at the ambient temperature of 25 ± 1°C. The pure water permeation, J_w was determined using Equation (1).

$$J_W = \frac{Q}{A \times t} \quad (1)$$

where J_w = pure water permeation ($Lm^{-2}h^{-1}$); Q = Volume of permeate (L); A = membrane area (m^2); t = time (h)

Protein rejection studies

Ultrafiltration experiment was conducted in the batch kit cell mentioned to study the influence of the addition of additives and surfactants on solute rejection of the prepared membranes. Bovine serum albumin (BSA, 69 kDa) and egg albumin (EA, 45 kDa) were chosen for the estimation solute rejectio n. The protein solutions was prepared at a concentration of 0.1 wt% in a phosphate buffer (0.5M, pH 7.2) using distilled water and was filtered through each of membranes. During the UF process, the permeate protein concentration were collected over measured time intervals in graduated tubes, and were analyzed for protein content by using UV-Visible spectrophotometer at a wavelength of 280 nm. The percentage rejection was calculated using Equation (2).

$$R(\%) = \left(1 - \frac{C_p}{C_f}\right) \times 100 \quad (2)$$

where R is percentage rejection of protein (%); C_p is concentration of protein in permeate (mg/mL); C_f is concentration of protein in feed (mg/mL).

Membrane Characterization by Morphological Studies

The morphology of the prepared membranes were investigated by microscopic observations which is carried out by a scanning electron microscope (SEM-JEOL JSM-6360LA) to provide the visual information of the top surface as well as cross-sectional morphology of the membranes. The top surface and cross-sectional views of the membranes should be broken in liquid nitrogen and coated with gold by using Auto Fine Coater (JFC-1600). All the SEM images were taken at various magnifications (X400-500). The top of the cross-section photographs presented in this article is the skin layer of the membrane.

Results and Discussion

Ultrafiltration test analysis

Ultrafiltration experiments were performed to explore the performance of PVDF/PVP additives membrane with addition of anionic/non-ionic and non-ionic/non-ionic surfactants. The water flux or pure water permeation (PWP), J_w of prepared membranes was measured to evaluate the influence of membrane composition on the membrane permeability. Figure 1 shows the pressure-dependent fluxes of pure water for the membranes prepared. PWP of all modified membranes were increases gradually with pressure increased up to 300 kPa.

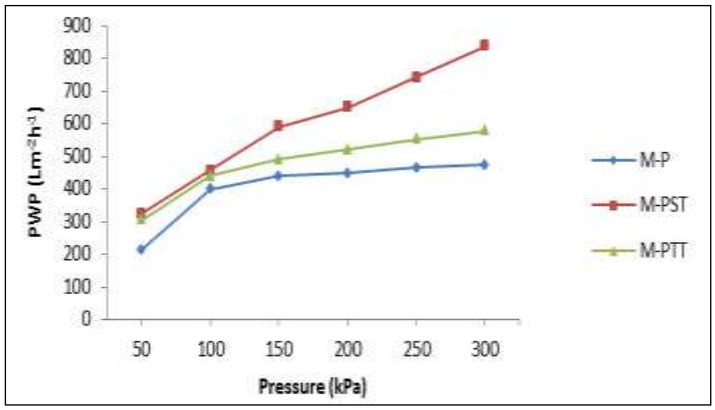

Figure 1. Effect of combination anionic/non-ionic and non-ionic/non-ionic surfactants on pure water permeation (PWP) of PVDF membranes

The combination of anionic and non-ionic surfactants, M-PST exhibited a higher PWP than that of the M-P and M-PTT membranes. From the result obtained, PWP of the M-PST attained a maximum value of 838.11 $Lm^{-2}h^{-1}$, while the minimum value was just 472.39 $Lm^{-2}h^{-1}$ for the M-P at 300 kPa. The water flux variation can be explained as the incorporation of combination anionic with non-ionic surfactants enhanced the hydrophilicity of the membranes which improved the water permeation to a certain extent. In the other hand, the value of PWP for M-PTT was found to be 577.37 $Lm^{-2}h^{-1}$, which is higher than M-P. This is correlates with the combination of both non-ionic surfactants resulted in high hydrophilicity compared to membranes without surfactant.

Protein permeate flux studies

The highest BSA permeate flux (PF) was 285.51 $Lm^{-2}h^{-1}$ for the M-PTT membrane and the minimum BSA-PF was 151.72 $Lm^{-2}h^{-1}$ for the M-P-without surfactant membrane (Figure 2). The highest PF is due to the formation of macrovoids in the sub-layer membrane which is faster rated leaching out during immersion process. Besides, for the combination non-ionic/non-ionic surfactants, interaction between hydrophobic chain and the non-polar sites of the membranes were observed which leading to hydrophilization of the membrane surface and pores [8]. As a result, higher PF for the non-ionic/non-ionic surfactants solution are obtained. In the other hand, the lowest PF may be due

to immiscible phase behaviour of blend composition without surfactant, which predominates due to lower molecular attractive forces between its blend components. During the filtration process, certain protein molecules can be deposited on the membrane surface, which caused an abrupt drop in flux. Additionally, protein molecules can be swept from the surface due to stirring, which resulted in equilibrium between depositions and sweeping [9].

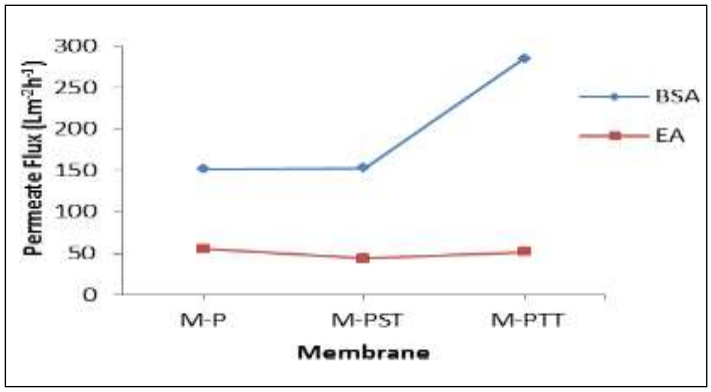

Figure 2. Effect of combination anionic/non-ionic and non-ionic/non-ionic surfactants on permeate flux (PF) of protein BSA and EA

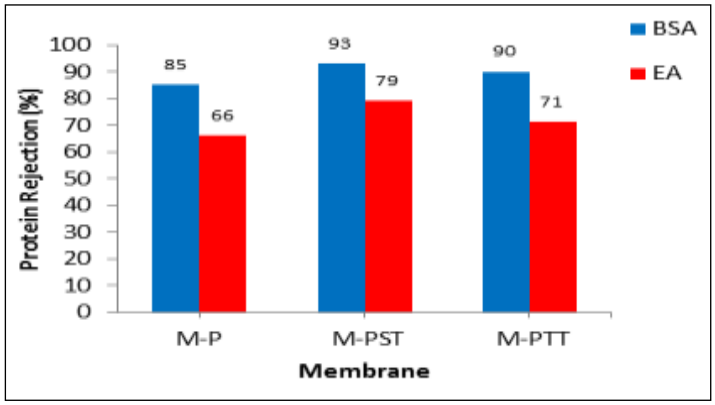
Protein rejection

The performance of the prepared UF membranes is also measured by investigating protein rejection during filtration experiment with macromolecular solute BSA (69kDa) and EA (45kDa) solution as feed. The protein rejection of BSA and EA are illustrated in Figure 3 for all the modified membranes when the feed solution is maintained at pH 7.2, since a change in pH may increase the adsorptive fouling of the membranes. In addition, if the pH of the proteins solution changes, intermolecular forces between protein molecules and membranes will predominate and affect the efficiency of membranes [10]. From the result obtained, the M-PST membrane exhibited higher rejection up to 93 % and 79 % for BSA and EA respectively, compared with other membranes. Higher rejection of BSA may be due to larger solute size of BSA compared with EA. Besides, the M-PTT membrane which combine non-ionic with non-ionic surfactants showed the BSA rejection 90 %, lower than membrane which combine ionic with non-ionic surfactants, may be because of homogeneity between the surfactants in the polymer solution. This will resulted in the formation of aggregate pores in membranes as discussed in SEM analysis.



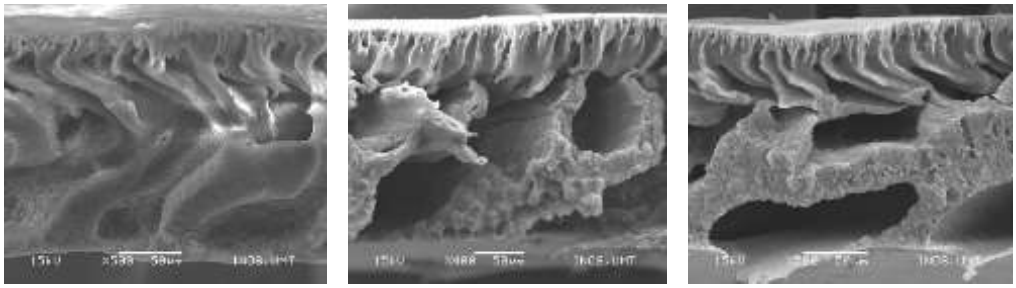


Figure 3. Effect of combination anionic/non-ionic and non-ionic/ non-ionic surfactants on proteins rejection

SEM analysis

Figure 4 shows the SEM images of the cross-section for different membranes prepared with combination of anionic/non-ionic and non-ionic/non-ionic surfactants. The SEM image of M-P membrane as presented in Figure 4 (a) shows the larger (open) finger-like pores formed were influenced by the exchange time between solvent and non-solvent in the coagulation bath [11]. It may be seen from the figures that membranes formed are having short and finger-like structures from the top layer to middle of sub-layer of the membrane. A dense spongy structure also formed beneath the skin layer and porous sub-layer of PVDF membrane. The casting solutions provided from hydrophobic polymers produced sponge-like structures due to delayed phase separation occurred during phase inversion process [12].

(a) M-P (b) M-PST (c) M-PTT

Figure 4. Cross-section SEM micrographs of morphological structure of PVDF membrane prepared withcombination anionic/non-ionic and non-ionic/non-ionic surfactants

The SEM images of M-PST and M-PTT in Figure 4(b) and (c) respectively show the existence of macrovoids in the presence of combination anionic and non-ionic surfactants in the PVDF/NMP blend membranes. Both of these membranes had asymmetric structure consisting of a fine porous selective barrier and a much thicker porous sub-layer. The SEM images in Figure 4(b) and (c) indicate that the combination of small amount SDS/Tween 80 and Triton X/tween 80 respectively in the casting solution can incite macrovoids formation.

A dense top layer and a porous sub-layer that is occupied by closed cell within polymer matrix and finger-like pore as well as interaction of anionic together non-ionic surfactants as shown clearly in Figure 4(b). Obviously, large pores are formed in the sub-layer of the membranes and therefore, it can be explained by miscibility between the added ionic, non-ionic surfactants and the coagulant. The miscibility between surfactant and coagulant plays an important role in the formation process of various sizes of pores. The macrovoids and finger-like pores in the sub-layer can be induced or suppressed by addition of appropriate surfactants, depending on their miscibility with coagulants. The addition of surfactants that have high miscibility with coagulants may be able to extend the formation of finger-like pores and macrovoids. On the other hand, the addition of surfactants with low miscibility with coagulants suppresses the macrovoids formation [13].

Conclusion

This study shows that all the membranes have asymmetric structure as observed from SEM images. It was found out that the combination of small amounts ionic surfactant (i.e. SDS) and non-ionic surfactants (i.e. Tween 80 and Triton X) to the casting solution increases formation of macrovoids and finger-like pores in the sub-layer of the membranes. With this little addition of surfactants to the casting solutions, the thickness of the prepared membranes significantly increases and hence, probably enhanced the PWP to a maximum value of 838.11 $Lm^{-2}h^{-1}$and 93% for BSA protein rejection.

Abstract

Pressurised liquid extraction (PLE) method was utilised to extract eurycomanone from Tongkat Ali root (*Eurycoma longifolia)* using water as extraction solvent. Optimisation of PLE operating parameters was conducted using three-factor response surface experimental design to evaluate the interactive effects of temperature (90 – 150 ºC), extraction time (10 – 30 min) and pressure (850 – 1700 psi) on the yield of eurycomanone. Online solid phase extraction – high performance liquid chromatography (SPE-HPLC) with a diode array detector (DAD) was used for the separation and detection of this compound. Extraction temperature was found significant in increasing the yield of eurycomanone. Based on maximum yield of eurycomanone, the optimum operating extraction conditions for PLE were set up at temperature (106 ºC), pressure (870 psi) and static time (30 min). The amount of eurycomanone from Tongkat Ali root samples of various sources was analysed using the optimised PLE conditions.

Abstrak

Kaedah pengekstrakan cecair tekanan tinggi (PLE) telah digunakan untuk mengekstrak eurikomanon daripada akar Tongkat Ali (*Eurycoma longifolia)* menggunakan air sebagai pelarut. Pengoptimuman parameter operasi PLE dijalankan dengan menggunakan reka bentuk eksperimen gerak balas permukaan tiga faktor untuk menilai kesan interaktif suhu (90 – 150 ºC), masa pengekstrakan (10 – 30 min) dan tekanan (850 – 1700 psi) ke atas hasil eurikomanon. Pengekstrakan fasa pepejal-kromatografi cecair tekanan tinggi (SPE-HPLC) dengan pengesan diod (DAD) telah digunakan untuk pemisahan dan pengesanan sebatian ini. Suhu pengekstrakan didapati penting dalam meningkatkan hasil eurikomanon. Berdasarkan hasil maksimum eurikomanon, pengkstrakan optimum untuk PLE, ialah suhu (106 ºC), tekanan (870 psi) dan masa static (30 minit). Amaun eurikomanon daripada pelbagai sampel akar Tongkat Ali telah dianalisis dengan menggunakan keadaan PLE yang telah dioptimumkan.

Introduction

Eurycoma longifolia or commonly known as Tongkat Ali or pasak bumi is a flowering plant in the family Simaroubaceae, native to Indonesia, Malaysia, Thailand, Vietnam, and Laos. The tree grows up to 12 meters in

height. Various bioactive constituents have been isolated and charaterised from *Eurycoma longifolia*, mostly from roots such as canthin-6-one alkaloids, β-carboline alkaloids, quassinoids, triterpenes, squalene derivatives, biphenylneolignans, eurycolactone, laurycolactone and eurycomalactone [1-5]. Quassinoids form the major bioactive constituents in this plant [6] and are mainly responsible for its bitter taste [1,7]. Eurycomanone (Figure 1), is found in the roots of *Eurycoma longifolia* have been traditionally used for its potential antimalarial, aphrodisiac, anti-diabetic and anti-microbial activities [8]. Among bioactive components of Tongkat Ali, eurycomanone has the highest concentration [9]. Thus, this compound is more commonly used as the marker compound for Tongkat Ali extract quantification [10].

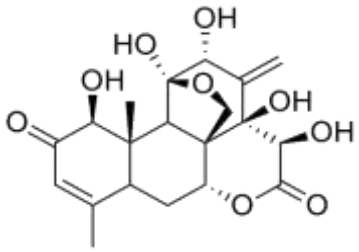

Figure 1. Chemical structure of eurycomanone

Typically, bioactive compounds are isolated using a series of processes beginning with extraction, which involves the transfer of solutes from a solid to a solvent. The ideal extraction system should be quantitative, non-destructive and time saving [11]. Several extraction techniques were reported such as Soxhlet extraction [12] and supercritical fluid extraction [13]. Soxhlet extraction is one of the oldest techniques for isolating metabolites from natural materials. It allows a high yield, but has a number of shortcomings, including long extraction time and large consumption of solvents, cooling water and electric energy. The disposal of waste solvents is also hazardous and very costly. Consequently, there is an increasing demand for new extraction techniques with possibilities for automation, shorter extraction time and lower solvent consumption. Pressurised liquid extraction (PLE), also known under the Dionex trade name accelerated solvent extraction (ASE), is currently attracting interest due to its rapid extraction time (5 – 30 min), a reasonable working temperature that can be optimised to achieve the desired extract, its simplicity, ability to be automated, low cost and its favourable environmental impact because of low solvent use [14]. The technique uses organic solvent or water at elevated temperature and pressure, which drastically improves the speed of the extraction process [15]. The high pressure allows maintaining the solvent in a liquid state at a high temperature. Under these conditions, the solvent has properties favouring the extraction process, and high solvent strength. Traditionally, the optimisation of factors affecting the extraction of active compounds can be achieved by studying each factor separately. However, through the application of chemometric, based on the use of central composite design (CCD) and multilinear regression analysis, an optimisation study that incorporates individual factors and also interactions of extraction temperature, pressure and static time can be obtained efficiently. The aim of this work is to determine an optimised pressurised liquid extraction method using experimental design for the extraction of eurycomanone from Tongkat Ali roots.

Materials and Methods

Plant Material

The roots of *Eurycoma longifolia* were provided by local suppliers. Samples were dried and ground before sieved into the size of 2.4 mm. The ground samples were stored at −20 °C until analysis.

Chemicals

Eurycomanone reference standard was purchased from Chromadex (Irvine, California). Stock standard solution containing 500 µg/mL of eurycomanone was prepared in methanol and kept in amber vials at -4 °C until use. Solvent used for PLE extraction was deionised water. For 2D-HPLC analysis, methanol, acetonitrile of HPLC grade were used, purchased from Merck (Germany).

Pressurised liquid extraction (PLE)

Extractions were done using ASE 350 accelerated solvent extractor (Thermo Scientific Ltd. Camberly, Surrey, UK). The dried and ground roots of *Eurycoma longifolia* (2 g) was accurately weighed into 34 mL extraction cells. The sample cells were then closed and placed into the carousel of the ASE 350 system. Extractions were done using water. The extraction conditions (temperature, pressure and extraction time) were optimised using an experimental design approach based on the marker compound (eurycomanone). The cell was rinsed with water (about 60 % of extraction cell volume). The extract was filtered and kept in a freezer at −20 °C prior to online SPE-HPLC analysis.

Experimental design

The experimental design was generated using Design-Expert version 6.0.4 (Stat Ease Software). The central composite design (CCD) with 5 coded levels; -α, -1, 0, +1 and +α was used. A total of 20 experiments (14 points of factorial design, and 6 center points) were carried out in randomised run order. The level of variables chosen for central composite design was assigned limits as shown in Table 1. The response variable (amount of eurycomanone) was evaluated by using response surface methodology (RSM).

Table 1. Central Composite Design used for the extraction of eurycomanone from Tongkat Ali roots

Coded level	Temperature (°C)	Pressure (Psi)	Extraction time (min)
-α	69.5	560	3
-1	90	850	10
0	120	1275	20
1	150	1700	30
+α	170.5	1990	37

SPE-HPLC separation

Chromatographic separation was performed on a Dionex Ultimate 3000 Liquid Chromatography System on Dionex Ion Pac AG14A (4 x 50 mm), Dionex C_{18} (5µm x 4.6 mm x 50 mm), and Acclaim Polar C18 (5µm x 4.6 mm x 250 mm) columns. The mobile phase comprised of pure water (A), methanol (B) and acetonitrile (C) (0 – 5.7 min: isocratic 70 % A: 30 % C; 5.7 – 8.5 min: gradient elution to 30 % A: 70 % C; 8.5 – 16 min: gradient elution 30 % A: 70 % B to 60 % A: 40 % B; 16 – 19 min: gradient elution 50 % B: 50 % C to 10 % B: 90 % C; 19 – 25 min: isocratic 10 % B: 90 % C), with flow rate kept at 1 mL/min. The column temperature was kept at 37 °C in an oven. Eluted compounds were monitored over a wavelength range of 200 – 400 nm. Figure 2 shows the chromatogram of standard eurycomanone separated using online SPE-HPLC.

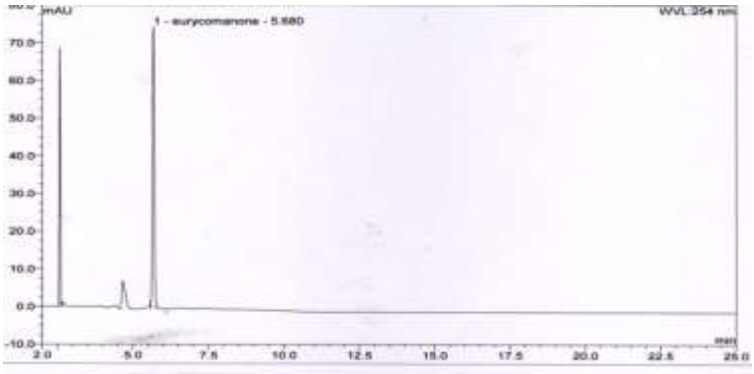

Figure 2. Chromatogram of standard eurycomanone (50 µg/mL)

Results and Discussion

Optimization of PLE operating parameters

Multilinear regression was applied to the results of the central composite design. The results were based on the amount of eurycomanone obtained from the extract as shown in Table 2. The effect of independent variables; extraction temperature (T), extraction time (t) and pressure (P) on the amount of eurycomanone was evaluated by second order (quadratic) and interactive effect (interaction between pairs of variables) (Table 3). The adequacy of the model were determined using model analysis, lack of fit test and coefficient of determination (R^2). ANOVA result showed that the model was significant, $p < 0.05$ ($p = 0.037$) with not significant lack of fit, $p > 0.05$ ($p = 0.0501$). The significance of the equation parameters for each response variable was also assessed by F-ratio at a probability (p) of 0.05. The closer the value of R^2 to unity, the better the empirical model fits the actual data. Criteria for a good fit of a model, the R^2 should be at least 0.80 [16]. In this study, the R^2 was 0.8923. The high value of R^2 (> 0.80) indicates the adequacy of the applied quadratic model.

Variation in extraction temperature (T^2) revealed that the increase in temperature resulted in a higher amount of eurycomanone extracted but reached a maximum value, with no significant further improvement thereafter as shown in Figure 3a and 3b. Pressure (P) and static time (t) were found not significant ($P > 0.05$) in the extraction of eurycomanone from Tongkat Ali root samples.

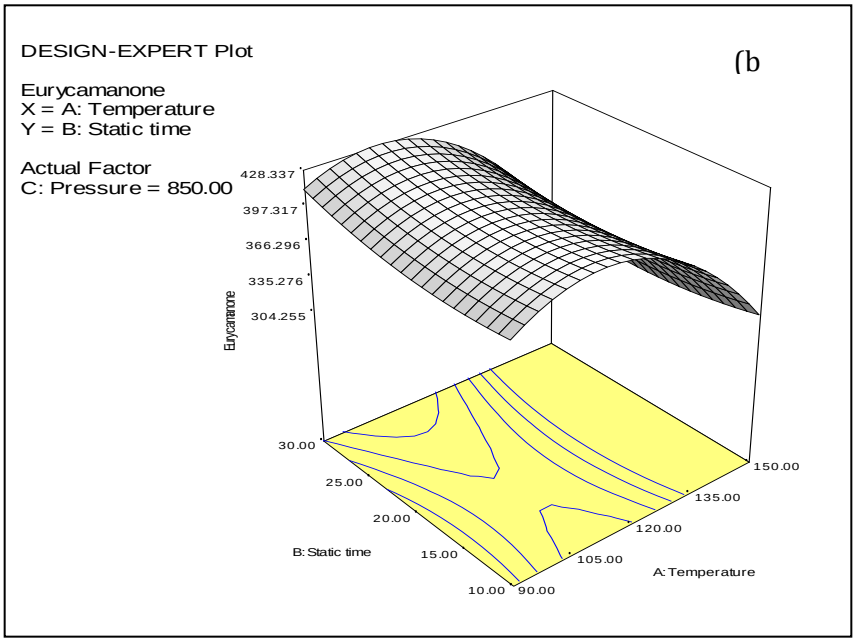

Figure 3. Contour and response surface plot of pressure against temperature (a) and static time against temperature (b) of eurycomanone obtained using Central Composite Design

Extraction temperature has a profound effect of the PLE process as reported by previous researcher [17]. Pressure is a minor variable for the resultant efficiency and it is only required to maintain the extractant in the liquid phase. The SPE-HPLC results obtained from this study indicate that the concentration of the eurycomanone increased significantly ($p < 0.05$) with temperature (Table 1). The results concurred with those reported by Gamiz-Gracia and de Castro [18]. In general, more components are extracted when the temperature is elevated, brought about by increasing solubility.

Analysis of Tongkat Ali Roots

Several sample of Tongkat Ali roots from different sources were extracted using the PLE optimum parameters at temperature of 106 °C, pressure of 850 psi and a static time of 30 min. Figure 4 shows the chromatograms of Tongkat Ali root extracts obtained from different sources.

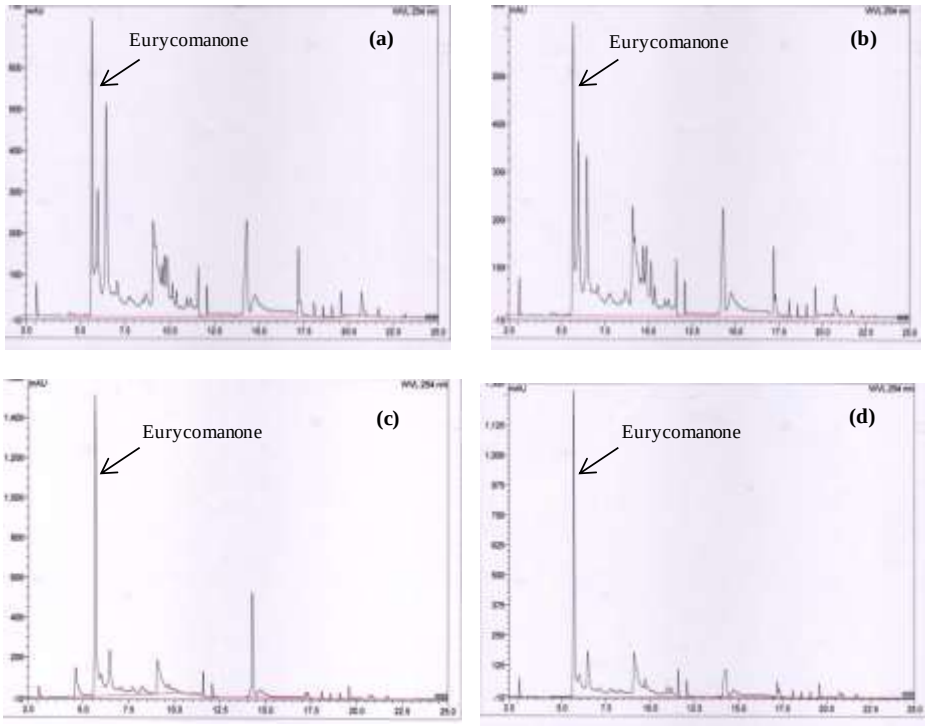

Figure 4. Chromatograms of Tongkat Ali roots of (a) Jengka sample 1(b) Jengka sample 2 (c) Taman Negara sample and (d) Sarawak sample

Figure 5 reveals the amount of eurycomanone extracted from Tongkat Ali root samples obtained from various places in Malaysia. The variation in the amount of eurycomanone in these samples may be due to harvesting age and sources [19].

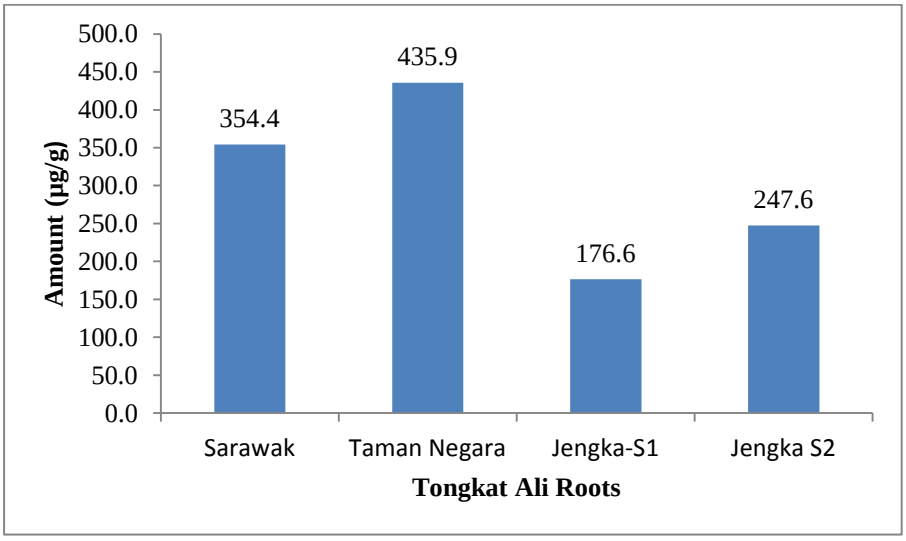

Figure 5. Amount of eurycomanone (µg/g) obtained from Tongkat Ali root samples

Conclusion

Pressurised liquid extraction (PLE) of Tongkat Ali roots was optimised. The PLE method offers important advantages over conventional methods, namely, shorter extraction time (17 min compared to 16 h for Soxhlet extraction), less solvent volumes employed (about 33 mL for PLE compared to 150 mL for Soxhlet extraction) and lower cost (energy cost is higher for Soxhlet extraction) and the possibility of manipulating the composition of the extract by changing the extraction parameters. This extraction method may contribute to the automation in food industry.

Abstract

Mesoporous silica of SBA-15 and SBA-16 were successfully synthesized via the surfactant templating technique using tetraorthosilicate (TEOS) as the silica source and both surfactants, pluronic P123 and F127. Two different modified carbon paste electrodes (MCPE) were fabricated; SBA-15/MCPE and SBA-16/MCPE in compared to unmodified electrode, carbon paste electrode (CPE), for ascorbic acid (AA) and uric acid (UA) determination. Due to the unique properties of mesoporous silica materials, the MCPE fabricated exhibits greater surface enhancement effect, offers better adsorption and increases the response signals of AA and UA towards both MCPEs compared to CPE. The electrochemical behaviours of AA and UA were investigated using cyclic voltammetry. Finally, the electrochemical methods were successfully applied in detection of AA and UA.

Keywords: mesoporous silica, electrochemical sensor, SBA-15, SBA-16, synthesis, electrochemical methods

Abstrak

Mesoporus silika SBA-15 dan SBA-16 telah disintesis dengan jayanya melalui teknik templat surfaktan menggunakan tetraortosilikat (TEOS) sebagai sumber silika dan kedua-dua surfaktan, Pluronic P123 dan F127. Dua elektrod pes karbon yang dimodifikasi (MCPE) yang berbeza, SBA-15/MCPE dan SBA-16/MCPE telah dihasilkan dan dibandingkan dengan elektrod pes karbon yang tidak dimodifikasikan (CPE), untuk penentuan asid askorbik (AA) dan asid urik (UA). Dengan sifat-sifat unik bahan silika, MCPE yang telah difabrikasi mempamerkan peningkatan efek permukaan yang baik, penjerapan yang lebih bagus, dan peningkatan signal respon AA dan UA terhadap kedua-dua MCPE berbanding CPE. Perlakuan elektrokimia AA dan UA telah dikenalpasti dengan menggunakan alat voltametri berkitar. Akhirnya, kaedah elektrokimia telah berjaya diaplikasikan dalam pengesanan AA dan UA.

Kata kunci: silika berliang meso, sensor elektrokimia, SBA-15, SBA-16, sintesis, kaedah elektrokimia

Introduction

Electrochemical sensor is a smart network that acts as an important component in the multifunctional intergrated electrical devices [1]. Electrochemical sensor has been widely discovered in its field of studies. It is commonly used in the detection of favoured molecules [2], hormones [3] or organic compound [4]. AA is an anti-oxidant that influences physiological processes in human body [5]. UA is the primary end product of purine metabolism [6]. AA and UA are considered as important molecules in human metabolism but the improper concentration level of the compounds may lead to various serious diseases. Therefore, the determination of AA and UA in analytical determination and diagnostic research is vital [7]. And to date, various electrochemical methods were developed in

detection of AA and UA utilizing different types of electrodes for example one-dimensional MgO biosensor [8], TiO_2 nanoparticles MCPE [9], Pt nanoparticles supported graphene oxide [10] and reduced grapheme oxide modified electrode [11]. Although there are several research works reported on the determination of AA and UA using mesoporous silica mainly type MCM-41 [12, 13], however, to the best of our knowledge, electrochemical detection of AA and UA using, SBA-15 and SBA-16, has not been reported.

Since the mesoporous silica has been discovered since two decades ago [14], the interest in this field have grown wider and attracted scientist worldwide. Mesoporous silica has large surface area, high pore volume, wide range of pore sizes, and unique mesoporous channels resulting an excellent surface enhancement effect [15, 16], but, its existence in electrochemistry is still very rare [13]. The unique properties of mesoporous silica makes it an excellent component in fabricating electrochemical sensor. With the presence of mesoporous silica, a MCPE provides surface and adsorption enhancement towards the determination of favoured molecules [17-19]. The main objectives of this study was to successfully synthesize the mesoporous silica; SBA-15 and SBA-16 and to build a convenient, cheap, enhanced and sensitive electrochemical method (SBA-15/MCPE and SBA-16/MCPE) for the determination of AA and UA by utilizing the properties of SBA-15 and SBA-16.

Materials and Methods

Chemicals and raw materials

All the chemicals used were of analytical grade and purchased from; Tetraethoxysilane, TEOS (98%, Aldrich), tri-block copolymer Pluronic F127, $EO_{106}PO_{70}EO_{106}$ (Sigma-Aldrich), tri-block copolymer Pluronic P123, $EO_{20}PO_{70}EO_{20}$ (Sigma-Aldrich), Paraffin oil (Biobasic), Graphite powder (<20µm, Aldrich) Hydrochloric acid, HCl (36%, Aldrich), Methanol, CH_4O, Ethanol, C_2H_6O, deionized water, platinum wire, Pt, silver wire, Ag (Sigma-Aldrich), copper wire, Cu, Uric acid, L-Ascorbic acid (vitamin C) (ACS grade, Biobasic), glass tube, epoxy glue.

Instruments

The characterization of the mesoporous materials were investigated using both Rigaku D/max-2500 powder diffractometer with Cu-Kα source (2Θ mode, continuous scanning; 40 kV, 20 mA) and SUPRA 40 FE-SEM from Carl Zeiss AG. Electrochemical measurements were carried out using an Autolab PGSTAT101 potentiostat from Metrohm Autolab B.V. A three-electrode system, consisting of a working electrode (carbon paste electrode (CPE) as well as mesoporous silica modified carbon paste electrode (MCPE), a reference electrode (Ag/AgCl) and a counter electrode (platinum wire).

Synthesis of SBA-15 and SBA-16

The preparation of SBA-15 was adapted from Sayari et al. [20] and minorly modified as follows; 4.0 g of Pluronic P123 was dissolved in 30 ml of deionized water and 120 ml of 2 M HCl in a closed container while stirring at 35 °C for 20 hours. 8.50 g of TEOS was added slowly to the mixture with vigorous stirring for 15 minutes. The mixture was then kept under static condition at constant temperature (35 °C) for 20 hours and transferred to an oven for 24 hours at 90 °C (hydrothermal process). The white precipitation obtained were separated by vacuum filtration. The resulting white solids was then washed with deionized water and dried for 3 days at 45 °. Finally, sample was calcined at 500 °C in air for 6 hours to remove surfactants from mesopores.

The SBA-16 was synthesized according to procedures adapted and minorly modified from Sun & Jun and Boissiere et al. [21, 22]. A amount 2.3 g of Pluronic F127 was dissolved in 0.6 ml concentrated HCl and 103.4 ml methanol with continuous stirring for 2 hours at 35 °C. In a separate beaker, 10.4 ml TEOS, 5.2 ml ethanol and 4.2 ml deionized water were mixed and stirred for 30 minutes at room temperature. The second mixture was slowly added to the first and stirred for an hour at 35 °C. The solution was then kept under static condition for 20 minutes (hydrothermal treatment) at 80 °C. Then, the solution was cooled down at ambient temperature for 4 hours before it was transferred in a closed container and heated for 24 hours at 90 °C to enhance the formation of silica crosslink. Finally, sample was calcined at 500 °C for 10 minutes.

Fabrication of electrochemical sensor

Three types of electrodes were prepared including unmodified carbon paste electrode. The following methods are adapted and slightly modified from Fathirad et al. [23]. The bare carbon paste electrode (CPE) was prepared by

mixing graphite powder with few drops of paraffin oil. While the modified carbon paste electrodes (MCPE) are prepared by mixing 0.85 g of mesoporous silica SBA-15 and 0.15 g graphite powder with the addition of paraffin oil droplets. And the same procedure for SBA-16/MCPE. The pastes were then packed and tightly pressed into the cavity of the glass tubes resulting 3 different electrodes. Electrical contacts are provided by implementing copper wire inside the tube. Finally, the bottom surface of sensors were polished using smooth paper and washed with deionized water.

Analytical procedure

Unless otherwise stated, pH 7.0 phosphate buffer (0.05 M) was used as the supporting electrolyte for both AA and UA. The cyclic voltammetry curves were recorded from 0.0 to 1.0 V per cycle, and oxidation peak currents were individually measured at 0.24 V and 0.79 V.

Results and Discussion

Structural characterization of mesoporous silica

The SEM micrographs shows SBA-15 possessing rod-like shape (Figure 1a) when P123 was used as directing agent with TEOS as the silica source. The production of SBA-16 using Pluronic F127 as surfactant has led the material in forming spherical structure (Figure 1b). SBA-15 and SBA-16 were bind together with graphite powder via the help of paraffin oil (Figure 1c and Figure 1d).

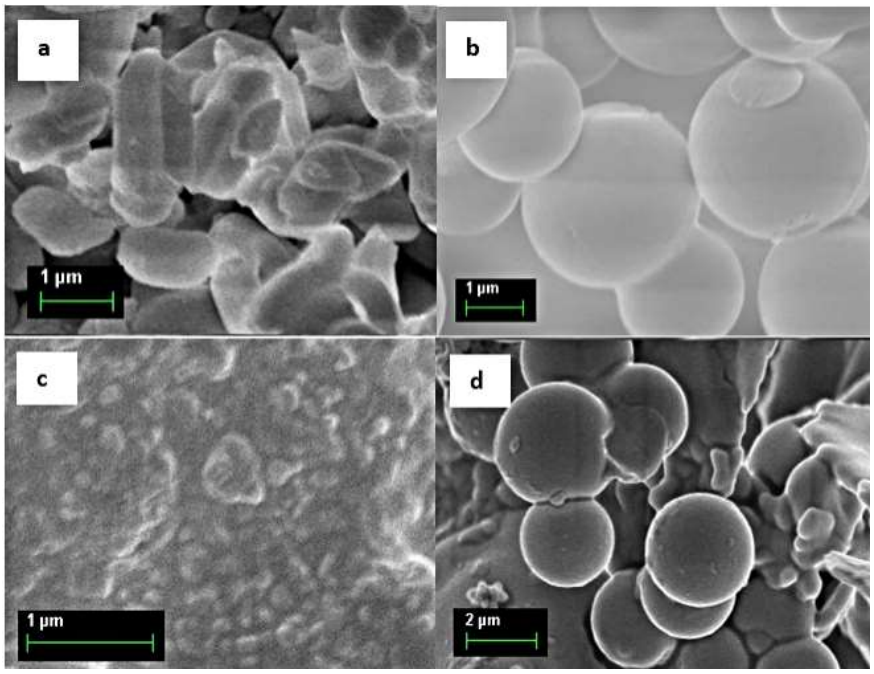

Figure 1. SEM images of SBA-15 and SBA-16. (a) SBA-15 (b) SBA-16 (c) SBA-15/MCPE (d) SBA-16/MCPE

Figure 2 shows X-Ray diffractograms obtained confirm that SBA-15 (diffractogram a) possess hexagonal mesostructure [24, 25] in which it shows three resolved peaks at lower angle 2Θ= 0.5-2.5^{o} which are indexed to (100), (110), and (200) that reflects as the well-ordered mesoporous silica, SBA-15 [26]. As evidence that SBA-16 materials possess a cubic ordering, three peaks of (110), (200), and (211) appears in diffractogram b [27]. The low intensities of peaks shown were discussed previously [28] that this may due to the thickness and roughness of pore walls [29].

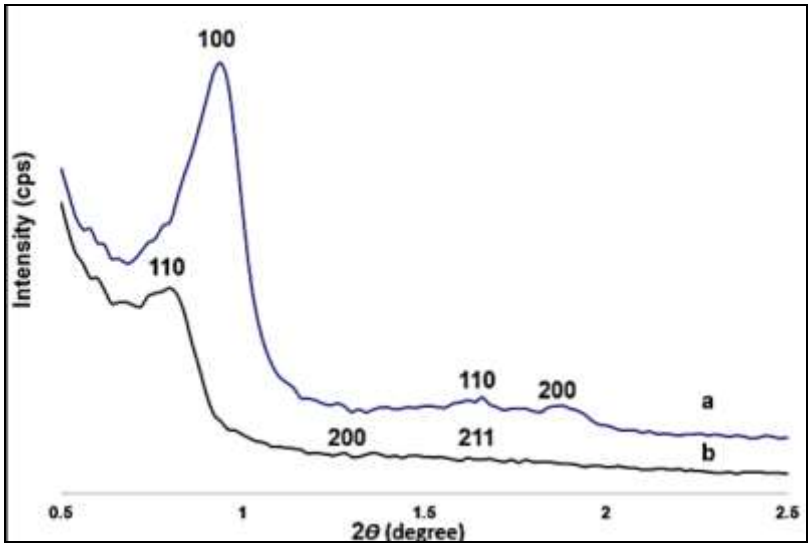

Figure 2. X-Ray diffraction. (A) SBA-15 (B) SBA-16

The electrochemical behaviours

The electrochemical behaviours of AA at three different sensors were studied by using cyclic voltammetry (CV). Figure 3 shows the CV results of $1.0x10^{-3}$ M AA in pH 7 phosphate buffer. During the anodic sweep from 0.00 to 1.00 V, an oxidation peak at unmodified CPE (curve a) is observed at approximately 0.20 V. Reduction peak does not appear which shows that the oxidation of AA is irreversible. When using SBA-15/MCPE (curve b) and SBA-16/MCPE (curve c), the oxidation peaks are greatly enhanced. Curve b shows the oxidation peak of AA at 0.20 V, and the oxidation peak for curve c slightly shifts positively from 0.20 to 0.27 V.

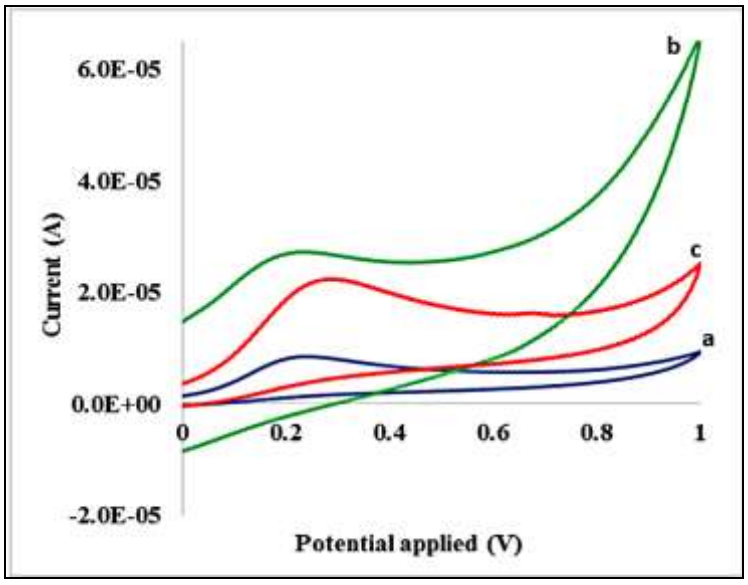

Figure 3. Cyclic voltammograms of $1.0x1^{-3}$M AA in pH 7 phosphate buffer at (a) unmodified CPE (b) SBA-15/MCPE (c) SBA-16/MCPE . Number of cycle: 1. Scan rate: 0.1 V s^{-1}.

Hence, this concludes that both modified sensors possess high efficiency of catalytic activity towards the oxidation of AA, which might be resulted from the short tunnelling distance between AA and porous electrodes. The peak currents of SBA-15/MCPE and SBA-16/MCPE are increased as well which reveals the surface enhancement effect that reflects to the unique properties of mesoporous silica (SBA-15 and SBA-16) consisting large surface are, high pore volume, and good pore network.

Figure 4 shows the CV curves of $1.0x1^{-6}$M UA in pH 7 phosphate buffer at unmodified CPE (curve a), SBA-15/MCPE (curve b) and SBA-16/MCPE (curve c) sensors. During the anodic sweep from 0.20 to 1.00 V, broad oxidation peaks appeared at 0.78 V for both unmodified CPE (curve a) and SBA-16/MCPE (curve c). SBA-16/MCPE sensor slightly enhanced the oxidation peak current. Reduction peak does not appear which concludes that oxidation of UA is reversible. Curve c shows no oxidation and reduction peaks. By comparing both unmodified CPE and SBA-16/MCPE sensor, mesoporous silica (SBA-16) clearly provides the surface enhancement effect towards the detection of UA.

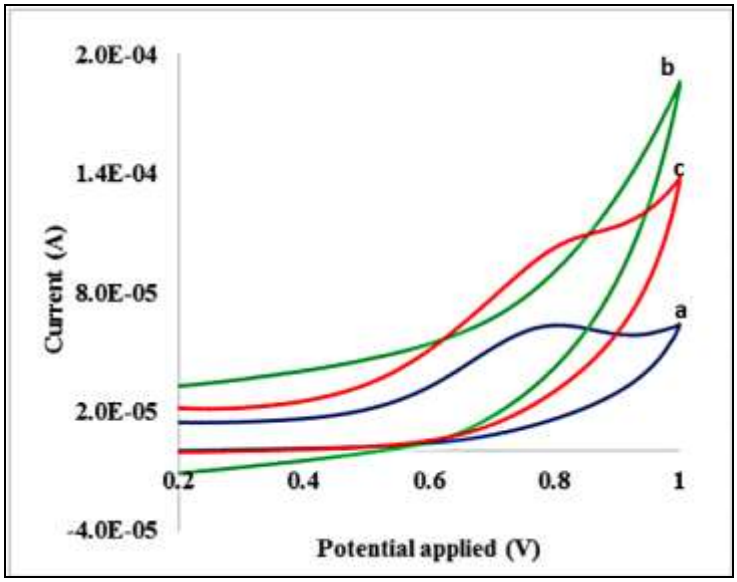

Figure 4. Cyclic voltammograms of $1.0x1^{-6}$M UA in pH 7 phosphate buffer at (a) unmodified CPE (b) SBA-15/MCPE (c) SBA-16/MCPE. Number of cycle: 1. Scan rate: 0.1 V s^{-1}.

Conclusion

Two types of mesoporous silica, SBA-15 and SBA-16 was successfully synthesized using Pluronic P123 and F127 as directing agents with the presence of TEOS as the silica source. SBA-15 and SBA-16 were then used to build two different types of electrochemical sensors (SBA-15/MCPE and SBA-16/MCPE) for the detection of AA and UA. Due to the unique properties that the mesoporous silica possessed, the modified electrodes built exhibit greater surface enhancement towards the determination of AA and UA compared to the unmodified electrode by increasing the oxidation signals. Thus, it can reasonably be concluded that an enhanced, convenient and sensitive electrochemical method was developed to detect AA and UA.

Abstract

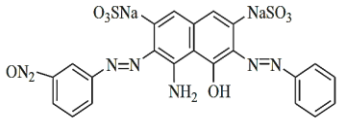
Adsorption isotherm describes the interaction of adsorbates with adsorbent in equilibrium. Equilibrium data was examined using Langmuir and Freundlich isotherm models. Thermodynamic studies were used to evaluate the thermodynamic parameters; heat of enthalpy change (ΔH°), Gibbs free energy change (ΔG°) and heat of entropy change (ΔS°) in order to gain information regarding the nature of adsorption (exothermic or endothermic). Four reactive dyes of anionic type, Acid Blue 29 (AB29), Reactive Black 5 (RB5), Reactive Orange 16 (RO16) and Reactive Red 120 (RR120) were used to obtain equilibrium isotherms at 25 °C, 35 °C, 45 °C and 55 °C. Based on Giles' classification, the isotherm produced were of L2-type, indicating strong dye affinity towards the adsorbent, and with weak competition with the solvent molecules for active adsorption sites. Equilibrium data fitted both Langmuir and Freundlich isotherm models with high correlation coefficient (R^2 > 0.91) indicating the possibility of both homogeneity and heterogeneous nature of adsorption. The negative values of ΔG° indicate the adsorption processes were spontaneous and feasible. The negative values of ΔH° lie between -20 to -75 kJ/mol, suggesting these processes were exothermic and physical in nature. The negative values of ΔS° are indication of decreased disorder and randomness of spontaneous adsorption of reactive dyes on layered double hydroxide as adsorbent.

Keywords: anionic dyes, layered double hydroxides, equilibrium isotherm, thermodynamic parameters

Abstrak

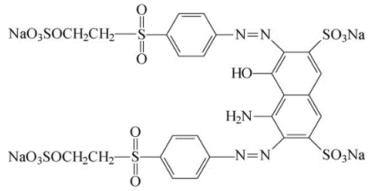
Isoterma penjerapan menerangkan interaksi antara bahan dijerap dan bahan jerap yang berada dalam keseimbangan. Data keseimbangan yang diperolehi dianalisis menggunakan model Langmuir dan Freundlich. Kajian termodinamik digunakan untuk menilai parameter-parameter termodinamik; perubahan haba entalpi (ΔH °), perubahan tenaga Gibbs bebas (ΔG°) dan perubahan haba entropi (ΔS°). Ia bertujuan untuk mendapatkan maklumat mengenai jenis penjerapan (eksoterma atau endoterma). Empat pewarna reaktif jenis anion iaitu, Asid Biru 29 (AB29), Reaktif Hitam 5 (RB5), Reaktif Jingga 16 (RO16) dan Reaktif Merah 120 (RR120) digunakan untuk mendapatkan isoterma keseimbangan pada suhu 25 °C, 35 °C, 45 °C dan 55 °C. Berdasarkan klasifikasi Giles, isoterma yang dihasilkan adalah jenis L2, yakni menandakan bahawa pewarna-pewarna ini mempunyai afiniti tinggi kepada bahan penjerap, dan mempunyai persaingan lemah dengan molekul-molekul pelarut untuk menambat kepada tapak atau permukaan aktif bahan penjerap. Data keseimbangan yang diperolehi didapati sesuai dipadankan dengan model isoterma Langmuir dan Freundlich dengan pekali korelasi yang tinggi (R2 > 0.91), menunjukkan kemungkinan wujud kedua-dua ciri kehomogenan dan heterogen untuk proses penjerapan. Nilai negatif ΔG° menunjukkan proses penjerapan adalah spontan dan boleh dilaksanakan. Nilai negatif ΔH° adalah antara -20 dan -75 kJ/mol, dan ini mencadangkan proses penjerapan adalah eksoterma dan fizikal. Nilai negatif ΔS° adalah petanda penurunan gangguan dan kerawakkan penjerapan spontan pewarna reaktif pada bahan penjerap dwi hidroksida berlapis.

Kata kunci: pewarna anion, dwi hidroksida berlapis, isoterma keseimbangan, parameter termodinamik



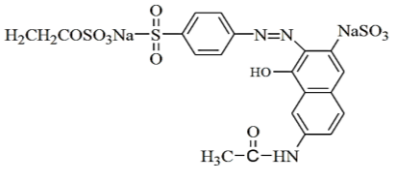
Introduction

Adsorption isotherm used in adsorption studies describes the interaction of adsorbates with adsorbent in equilibrium. It provides insight into adsorption mechanism, surface properties and affinity of adsorbent. Consequently it may be used to compare the properties of different adsorbents quantitatively and explicate the adsorption state of adsorbate on adsorbent surface. Equilibrium data can be analysed using isotherm models such as Langmuir and Freundlich expressions from which equilibrium constants (K_L and K_F) and maximum adsorption capacity (Q_o) can be obtained. The Langmuir adsorption assumes that adsorbate molecules occur on a homogenous surface with a fixed number of adsorption sites. This results in monolayer adsorption without mutual interactions between the adsorbed molecules. The Freundlich model assumes that the dye molecules are adsorbed on the heterogeneous surfaces of the adsorbate which are characterized at different energies. Thermodynamic studies are used to evaluate the thermodynamic parameters; heat of enthalpy change (ΔH°), Gibbs free energy change (ΔG°) and heat of entropy change (ΔS°). These thermodynamic parameters reveal information regarding the nature of adsorption (exothermic or endothermic) and the spontaneity of the adsorption process [1]. If the rate of reaction increases with increase in temperature, the reaction is endothermic. Endothermic adsorption is characterised by increased adsorption capacity and which may involve chemisorption. If an increase in temperature results in decreased adsorption capacity, adsorption is exothermic, which most likely involves physisorption. The objective of this study is to examine and evaluate the adsorption properties of an anionic clay-layered double hydroxide for four anionic dyes (AB29, RB5, RO16 and RR120) in terms of adsorption isotherms and thermodynamic parameters.

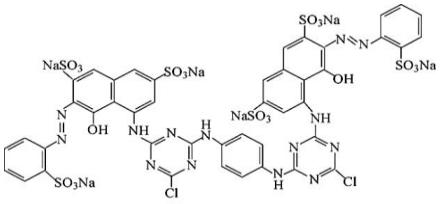


Materials and Methods

Chemicals and raw materials



Magnesium nitrate hydrate (Mg $(NO_3)_2.6H_2O$) and Aluminum nitrate hydrate ($Al(NO_3)_2.9H_2O$) (MERCK) were used to synthesise the adsorbent, layered double hydroxide, Mg-Al-NO_3-LDH by co-precipitation procedure followed by hydrothermal treatment as outlined by previous studies [2-4].The adsorbates, anionic dyes, RB5, AB29, RO16 and RR120 (Sigma Aldrich, Germany) were used to obtain four sets of equilibrium isotherms. The structures of the dyes are shown in Fig.1.



Acid blue 29 (AB29); $C_{22}H_{14}N_6Na_2O_9S$

Reactive Black 5 (RB5); $C_{26}H_{21}N_5Na_4O_{19}S_6$

Reactive Orange 16 (RO16); $C_{20}H_{17}N_3Na_2O_{11}S$

Reactive Red 120 (RR120) ; $C_{44}H_{24}Cl_2N_{14}Na_6O_{20}S$

Figure 1. Chemical structure of anionic dyes

Adsorption Equilibrium

Adsorption equilibrium between adsorbent anionic clay layered double hydroxide ($MgAlNO_3$-LDH) and adsorbates in single dye solution was attained in 24 hours in a water bath shaker operating at 100 rpm and maintained at different temperatures (25 °C, 35 °C, 45 °C and 55°C or 298 K, 308 K, 318 K and 328 K). For comparison purposes the initial pH of all dye solutions were kept constant at pH 5.5 ± 0.5 (using dilute HCl and NaOH) which lies in the range of optimum pH of dyes solutions. A concentration range of 10 – 100 mg/L of single dye solutions was allowed to contact with the adsorbent (0.02 g/50 mL). Based on the equilibrium data of isotherms, the thermodynamic parameters were calculated.

Results and Discussion

Effect of solution temperature on percentage dye removal

The effect of temperature on percentage dye removal for AB29, RB5, RO16 and RR120 are given in Fig. 2 (a)-(d). It was found that the uptake of the dyes by the adsorbent decreased with increasing temperature from 25 °C to 55 °C, indicating energy was released as a result of adsorption. General surface adsorption by anionic dye onto layered double hydroxides can be represented by the expression in equation 1:

$$\text{LDH-surface} + \text{Dye}^- \longrightarrow \text{LDH-Surface}^-/\text{Dye}^- \quad (1)$$

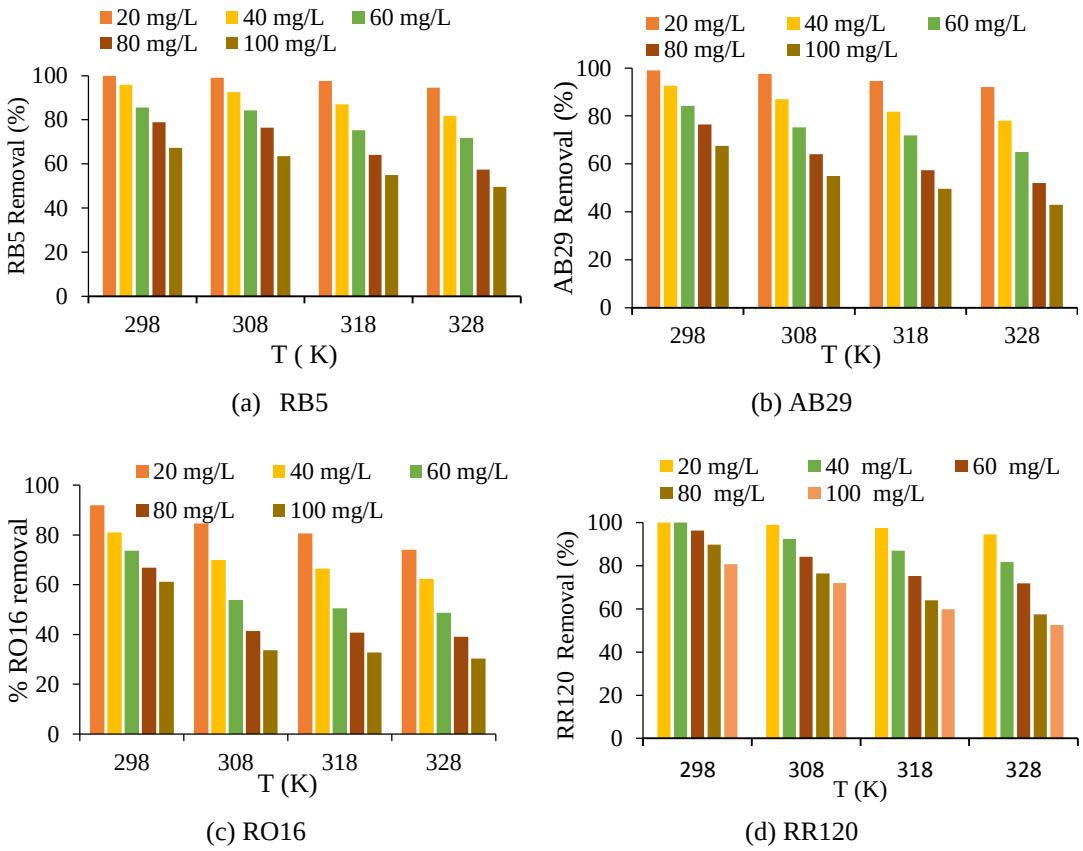


Figure 2. Effect of temperature on percentage removal of anionic dyes by LDH (a) RB5 (b) AB29, (c) RO16 (d) RR120 at different temperatures

This type of adsorption is deemed exothermic in nature [5-7]. This scenario is equivalent to increase in energy content of the system, with a reduction of surface activity [8] and the probability of colliding molecules capturing one another, thus requiring the adsorbent to have more energy [7]. Therefore the resulting reduction in the rate of adsorption may also be explained by the tendency of dye molecules to escape from the solid phase to bulk phase as temperature was increased [9].

The exothermic nature of anionic dye adsorption conforms to most adsorption of dyes including reactive dyes using various adsorbents. Examples from previous studies of exothermic adsorption are the uptake of Remazol Black B by *Rhizopus arrhizus* [8] and RO16 onto AC (A*nanas comosus* (L.)) [10].

Adsorption Isotherm

The relationship between the amount of adsorbate adsorbed on the adsorbent's surface and in liquid state when equilibrium state is achieved at constant temperature is often represented by curves (q_e vs C_e) called adsorption isotherm. Adsorption isotherm is characterized by constants which are functions of surface properties, affinity and adsorption capacity of adsorbents [8]. Fig. 3(a)-(d) shows the adsorption isotherms for RB5, AB29, RO16 and RR120. The shapes of the isotherm give the first diagnostic tool to obtain information about the nature of adsorption. This information is vital for an engineer in order to optimize the design parameters for adsorption system, besides aiding him to establish the most appropriate correlation for equilibrium curves. Auta & Hameed [11] and Giles & Smith [12] classified these isotherms into four main categories: L, S, H and C. Based on the Giles' classification, the isotherms produced correspond to the L-type (sub-group 2 or H). L-type isotherms display concavity toward the abscissa axis and are characteristics of high affinity of adsorbed molecules towards adsorbents. In L-type isotherms, a monolayer formation (plateau) is established. Fig. 3 (a)-(d) indicates that the reactive dyes were effectively removed at lower concentration while higher initial concentrations tend to reach maximum capacity as indicated by the plateau. As such the anionic dyes used in this study can be considered as favourably removed from solutions with low competition from water molecules onto substrates (LDH) until at high solute (dye) concentration when the surface coverage reached maximum [13].

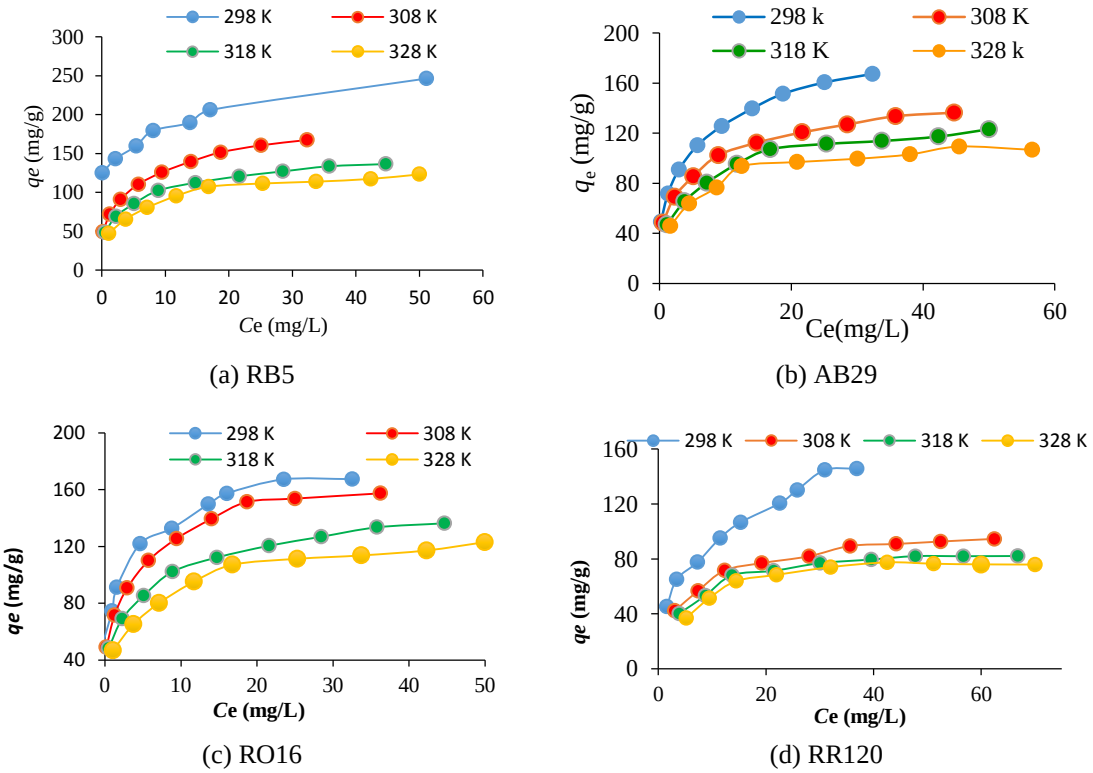

Figure 3. Adsorption isotherms for dyes- LDH (a)-(d): RB5, AB29, RO16, RR120 at different temperatures

Adsorption isotherms modeling

Quantification of dye removal and the use of equilibrium models offer insight into the characterization of these solid surfaces especially on heterogeneity of the adsorbent surface. Two well-known and widely used models, the Freundlich and Langmuir isotherms, have been adopted to explicate dye-clay interaction. To account for the relevance of these two isotherm models, the values of Langmuir and Freundlich parameters correlation coefficients, R^2 at various temperatures together with their respective constants were obtained from the linear plots. The linearised Langmuir equation (1) can be presented graphically in the form of (C_e/q_e) vs C_e in Fig.4 (a)-(d).

$$\frac{C_e}{q_e} = \frac{1}{Q_O K_L} + \frac{C_e}{Q_O} \quad (1)$$

C_e = dye concentration at equilibrium, mg/L; q_e= adsorption capacity at equilibrium, mg/g and Q_o=maximum monolayer capacity (mg/g); K_L = Langmuir constant related to the free energy of adsorption;

The linearized Freundlich equation is given in equation 2

$$\log q_e = \log K_F + \frac{1}{n} \log C_e \quad (2)$$

The Freundlich constant, *n*, reflects both the average binding energy and the energetic heterogeneity of the sorbent binding sites [14]. The constant, K_F indicates adsorption capacity. As shown in Fig. 5, the plot of ln q_e versus ln C_e is employed to determine the value of K_F and n from intercept and slope respectively.

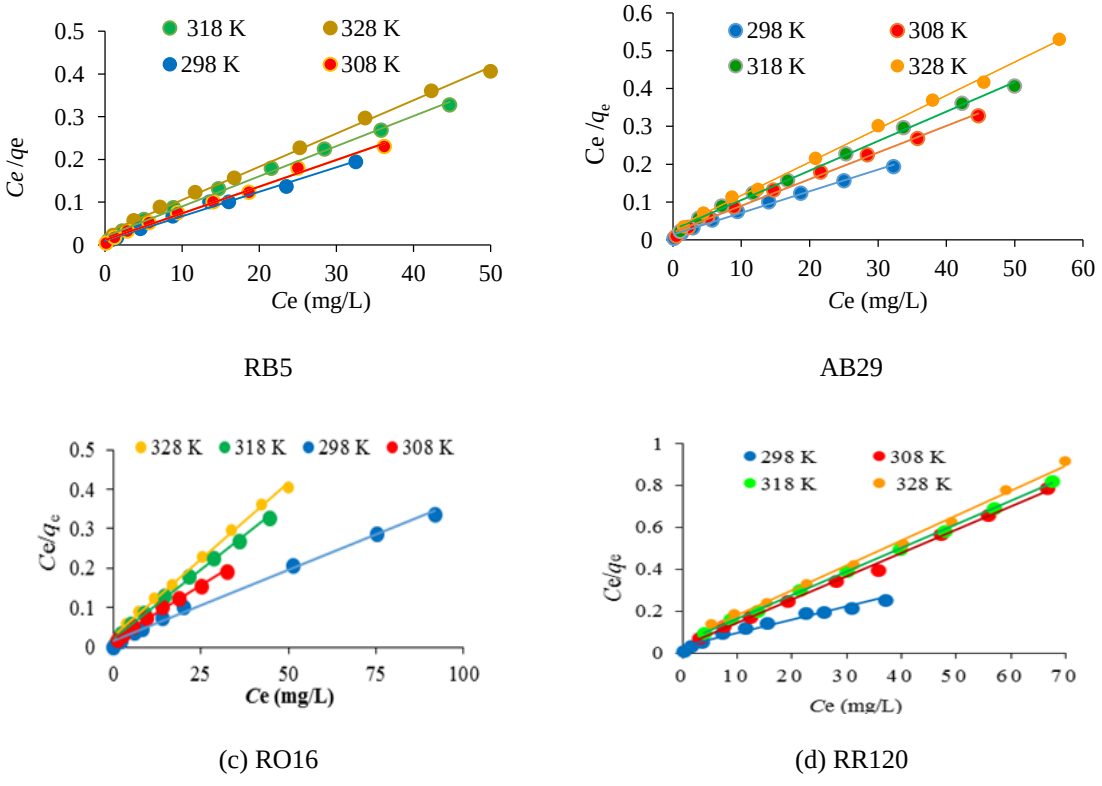

Figure 4. Langmuir isotherm at different temperatures for (a) AB29 (b) RB5 (c) RO16 (d) RR120

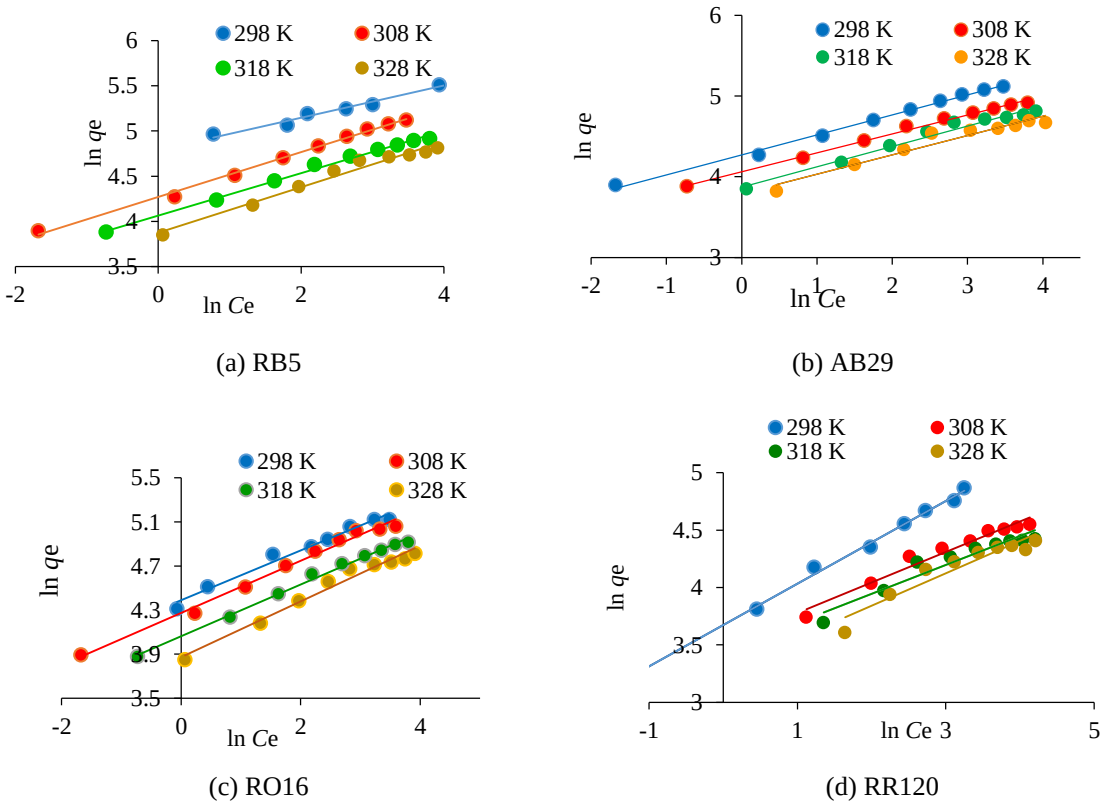

Figure 5. Freundlich isotherm at different temperatures for (a) AB29 (b) RB5 (c) RO16 (d) RR120

The high correlation coefficient values (R^2 = 0.906 - 1.000) for Langmuir and Freundlich (0.91-1.00) models strongly imply the fact that the dye-LDH adsorption closely follows both Langmuir and Freundlich models of adsorption under the present experimental conditions. This finding is not unusual as previous study by Ip *et al* [15] also found that adsorption of RB5 by bamboo activated carbon followed a hybrid of Langmuir and Freundlich equations. The dye binding capacities reflected by maximum monolayer adsorption capacities, Q_o (mg/g) were found to be in the order: RB5 (277.8) > AB29 (186.4) > RO16 (172.4) > RR120 (166.7).

Thermodynamics of adsorption

Analysis of thermodynamic parameters reveals negative values of ΔG°, indicating that the process of adsorption was spontaneous and feasible. The values of negative ΔG° also decreased slightly as temperature was increased from 298K to 328K, showing that the adsorption process was thermodynamically feasible at room temperature but less with higher temperatures. The negative values of enthalpy change, ΔH° confirm the exothermic nature of dye-LDH adsorption system. In this study, the negative values of ΔH° lie between -20 to -75 kJ/mol suggesting the process was physical in nature. The negative values of ΔS° are indication of decreased disorder and randomness of spontaneous adsorption of reactive dyes on the adsorbent.

Conclusion

The high correlation coefficient values (R^2= 0.906 - 1.000) of anionic dyes indicate the adsorption equilibrium data was well described by Freundlich and Langmuir isotherm models suggesting the existence of more than a single mechanism in adsorption of anionic dyes by LDH. In this case the conformity to Langmuir implied homogeneity and second order reaction, meanwhile the compliance to Freundlich indicate the heterogeneity. The adsorption

capacity of RB5, AB29, RO16 and RR120 onto LDH decreased with increasing temperature indicating exothermic adsorption. The affinity of anionic dyes towards LDH followed the order: RB5 > AB29 > RO16 > RR120. Thermodynamically, dye uptake was spontaneous and exothermic and mainly physical in nature.

Abstract

Various hazardous events can cause chemical, microbial or physical hazards to a water supply system. The World Health Organization (WHO) and some countries have introduced the hazardous event analysis for identifying potential events which may be harmful to the safety of drinking water. This study extends the application of the hazardous event analysis into drinking water production using managed aquifer recharge (MAR). MAR is a way of using an aquifer to secure water resources by storing freshwater for future use and pumping it whenever necessary. The entire drinking water production process is subjected to the analysis from the catchment area to the consumer. Hazardous event analysis incorporates site-specific data as well as common issues occurring in the process of drinking water production. The hazardous events are classified based on chemical, microbial or physical characteristics. Likelihood and severity values are assigned, resulting in quantitative risk by multiplying them. The study site is located at a coastal area in the delta of the Nakdong River, South Korea. The site has suffered from salt water intrusion and surface water pollution from the water upstream. Nine major hazardous events were identified out of total 114 events from 10 drinking water production processes. These major hazardous events will provide useful information on what to be done to secure the water quality produced by a new water supply method.

Keywords: managed aquifer recharge, hazardous event analysis, drinking water, coastal area

Abstrak

Pelbagai kejadian berbahaya boleh menyebabkan pencemaran kimia, mikrob atau fizikal kepada sistem bekalan air. Pertubuhan Kesihatan Sedunia (WHO) dan beberapa buah negara telah memperkenalkan analisa berbahaya untuk mengenalpasti kejadian yang berpotensi membahayakan keselamatan air minuman. Kajian ini meliputi penggunaan analisa berbahaya dalam pengeluaran air minuman menggunakan akuifer terkawal cas semula (MAR). MAR adalah satu cara menggunakan akuifer untuk mendapatkan sumber air dengan menyimpan air tawar untuk kegunaan masa depan dan mengepam bila-bila masa yang diperlukan. Keseluruhan proses pengeluaran air minuman adalah tertakluk kepada analisa dari kawasan tadahan kepada pengguna. Analisa berbahaya membekalkan maklumat khusus tempat serta isu – isu yang biasa berlaku dalam proses pengeluaran air minuman. Perkara – perkara berbahaya dikelaskan berdasarkan kimia, mikrob atau ciri – ciri fizikal. Kemungkinan dan nilai – nilai ekstrim yang diberikan, menyebabkan risiko kuantitatif dengan mendarabkan mereka. Tapak kajian terletak di kawasan pantai iaitu di delta Sungai Nakdong, Korea Selatan. Tapak tersebut terdedah kepada air masin dan pencemaran air permukaan dari hulu sungai. Sembilan kejadian berbahaya dikenalpasti daripada jumlah 114 yang berlaku dalam 10 proses pengeluaran air minuman. Kejadian berbahaya utama ini akan memberikan maklumat yang berguna mengenai apa yang perlu dilakukan untuk menjamin kualiti air yang dihasilkan dengan kaedah baru bekalan air.

Kata kunci: akuifer caj semula, analisas kejadian berbahaya, air minuman, kawasan pantai

Introduction

Drinking water supplies in coastal areas are exposed to salt water intrusion and pollutants derived upstream, which affects the water quality. In addition, changes in rainfall patterns in relation to climate change also negatively affect the supply of drinking water and cause water resource management issues. In this respect, managed aquifer recharge (MAR) has been introduced to overcome such problems. MAR is a method used to bank or treat water resources using aquifers [1], whereby the water is naturally infiltrated or injected into the aquifer using a pump. This study introduces a method for aquifer storage transfer and recovery (ASTR) of MAR, which entails injecting water into a storage well using a pump and then recovering it from a different well. ASTR has some advantages. First, the use of ASTR delivers a constant supply of fresh water because it uses two different wells: the injection well and the abstraction well (Figure 1). Second, it can be used in saline aquifers because the injected water forms a lens or bubble of fresh water within the saline groundwater [2 - 4]. Third, after the intake and treatment of surface water, a drinking water supply system with ASTR uses aquifers to add natural filtration before supplying water to customers (Figure 2). In comparison with general purification plants, it is able to treat polluted surface water more safely and to decrease the load experienced by purification facilities [1].

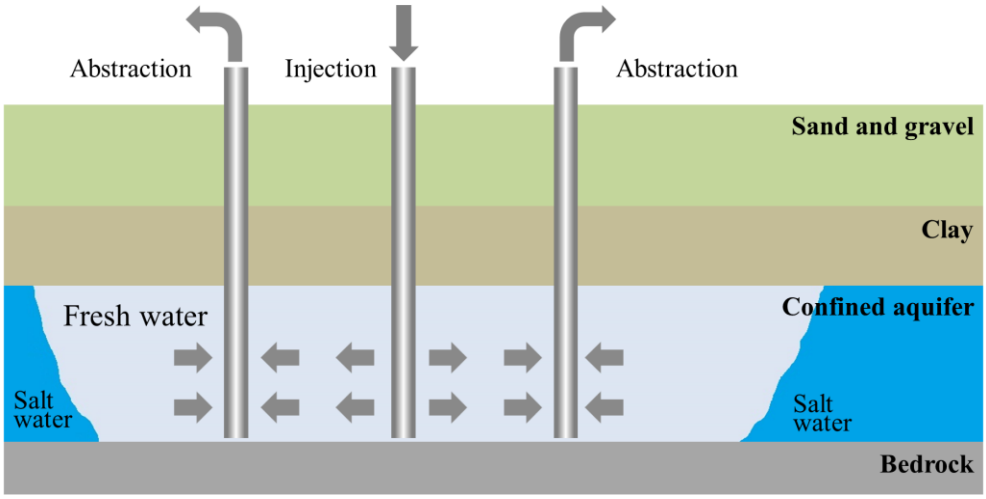

Figure 1. Schematic of ASTR in confined aquifer

Although ASTR is a more enhanced method than that used in general drinking water supply systems, it remains susceptible to multifarious threats such as microbial and chemical agents that can harm public health [5]. Examples of threats may include suspended solid (SS), cyanobacteria, and trihalomethanes (THMs). When the drinking water supply system does not appropriately mitigate these multifarious threats, the health of the consumer can be affected because of the deterioration of the drinking water quality. These multifarious threats are hazards, which are physical, microbial and chemical agents that can bring harm to public health [5]. Hazards below the drinking water standards are harmless to humans and have no inconveniences felt when the water is ingested. However, if such hazards are exponentially increased by any triggers, they can become harmful if consumed. Such triggers are known as hazardous events, and they fail the safety of the drinking water supply system by aggravating hazards [5].

Hazards and hazardous events can be determined using hazard analysis or the identification of critical control points in HACCP, which assesses hazards and establishes control systems to ensure the safety of food [6]. Using hazard analysis, or hazardous event analysis of HACCP, it is possible to prevent water quality accidents, and therefore the application to drinking water supply systems is being expanded globally.

Havelaar [7] adopted the HACCP from the food industry and applied it to drinking water supplies, and attempted to reinforce the safety of drinking water production using a hazard analysis of HACCP. The water qualities of the treatment plant in Iran were improved by applying HACCP [8, 9]. Australian drinking water guidelines [10] and the Water Safety Plan (WSP) [5] of the World Health Organization (WHO) have also accepted HACCP in relation to drinking water production. The WSP has been accepted in economically advanced countries and has also been applied in some regions of Africa that suffer from a shortage of fresh water [11]. In relation to the above examples, it appears that ensuring the safety of drinking water is gradually being considered globally.

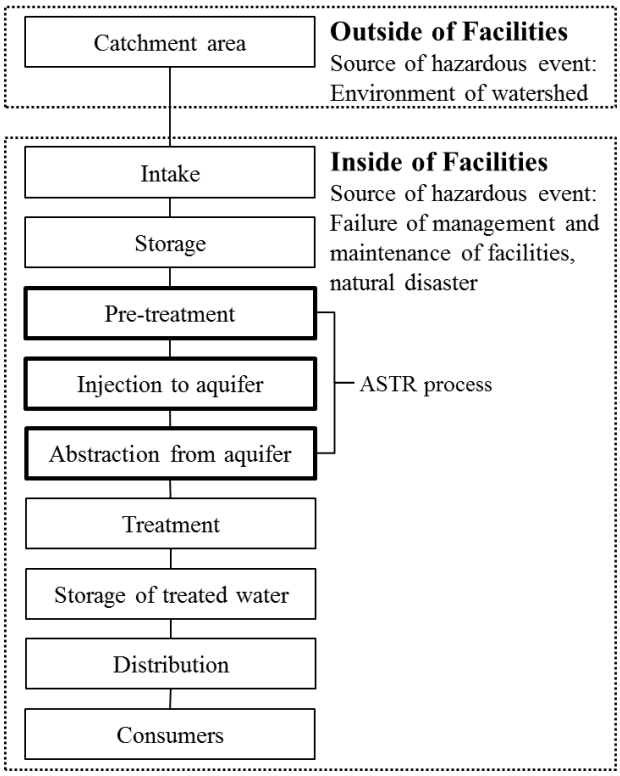

Figure 2. Drinking water supply system using ASTR

This study applied a hazardous event analysis to a drinking water supply system using ASTR, which is widely recognized as being an environment-friendly drinking water supply system [1]. Hazardous event analysis would contribute to restoring the public's lost faith in the safety of drinking water, because it can be used to prevent hazardous events through documenting potential events that could obstruct the achievement of water quality goals.

Materials and Methods

Ten processes of drinking water supply system using ASTR are analyzed (Figure 2). The analysis enables one to evaluate all hazardous events caused by natural and anthropogenic activities such as flood, drought, and the inappropriate maintenance and management of facilities. In this study, although various methods of analysis have previously been introduced by other studies, the analysis table of the WHO is adopted [12].

Hazardous events can be classified as physical, microbial, or chemical [5]. A value between 1 and 5 is then assigned to the likelihood and severity of a hazardous event. The values were given by authors' judgement based on literature review, field survey, and opinion from experts. Table 1 shows the criteria used to determine likelihood and severity.

Risk is then determined by multiplying likelihood and severity and has a risk range of 1 – 25 (Eq. 1). Then the risk rating was categorized, which is classify as low (L, 1—5), medium (M, 6—9), high (H, 10–14), and very high (VH, > 15). Risk ratings of H and VH are considered to be major hazardous events that require effective management.

$$Risk = Likelihood \times Severity \quad (1)$$

Table 1. The criteria for score of likelihood and severity

	Score	Criteria[a]
Likelihood	1	Has not happened in the past and it is highly improbable that it will happen in the future
	2	Is possible and cannot be ruled out completely
	3	Is possible and under certain circumstances could happen
	4	Has occurred in the past and has the potential to happen again
	5	Has occurred in the past and could happen again
Severity	1	Insignificant or no impact
	2	Short term or localized, not health-related non-compliance or aesthetic issues
	3	Widespread aesthetic issues or long-term non-compliance not health-related
	4	Potential long-term health effects
	5	Catastrophic public health impact

[a] modified after Bartram et al. [5]

Study area

The pilot study was conducted on Samrak Park in the Nakdong River estuary, South Korea (Figure 3). This area is experiencing difficulties in the drinking water supply due to following reasons. First, the water quality of the Nakdong River has deteriorated due to the constant inflow of pollutants from upstream metropolitan cities and industrial areas [13]. Second, the ground water is saline water. Third, chemical leakage accidents have occurred in nearby industrial areas. These caused the low level of trust to the drinking water. Although upstream pollutants are contained by the Changnyeong-Haman weir (Figure 3), the public finds it difficult to trust the quality of the drinking water produced by the water purification plant.

Physical, microbial, and chemical clogging of an injection well can occur during the ASTR operation in relation to the various substances contained within surface water. Clogging not only hinders the injection of water, but also leads to the generation of an unpleasant odor, microorganisms, and toxic materials. When clogging occurred, the wells were closed in many cases. To determine whether pre-treatment is necessary to prevent clogging, the pollutant concentration of the injected water (surface water) is checked. There can be various water quality parameters and their concentration levels to be used for checking the clogging possibility. Here we adopted Australian guidelines for ASTR.

Australian guidelines for water recycling instructs that surface water should undergo pre-treatment prior to injection if the water quality is SS > 10 mg/L or TOC > 10 mg/L [14]. Figure 4 shows the results of a water quality analysis at Goopo (Figure 3) nearby Samrak Park. Water quality was changed after building Changnyeong-Haman weir in 2011. TOC of the Nakdong River is lower than 10 mg/L every year. But, SS is higher than 10 mg/L although the weir had an effect of containing SS. Therefore, the river water needs pre-treatment before being injected.

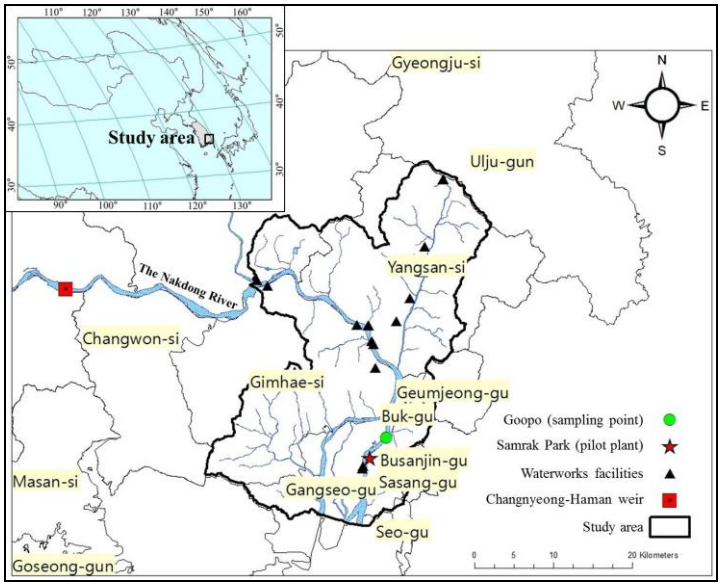

Figure 3. The downstream of the Nakdong River. Study area is at the downstream of Changnyeong-Haman weir. Pilot plant is located at Samrak Park.

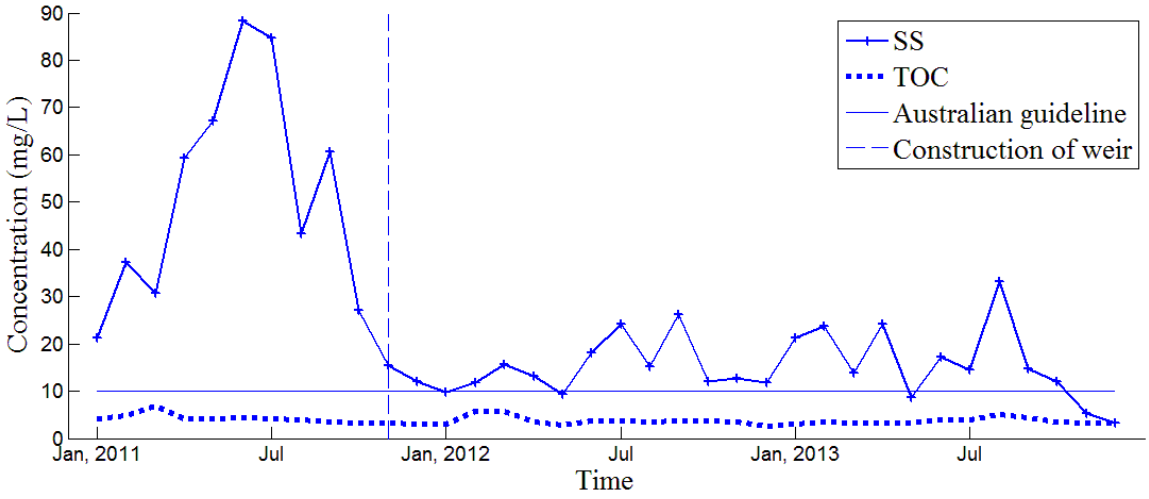

Figure 4. Water quality of the Nakdong River at Goopo (Source: www. water.nier.go.kr)

Results and Discussion

Hazardous events were considered that were unique to the study area and to the special features of ASTR such as pre-treatment, injection to aquifer, and abstraction from aquifer. In this respect, a total of 114 hazardous events were derived from ten processes of the ASTR, and a summary of hazardous events is given in Table 2.

Table 2. The number of hazardous events identified in drinking water supply system using ASTR

Process	No.	Process	No.
Catchment area	25	Abstraction from aquifer	8
Intake	3	Treatment	8
Storage	10	Storage of treated water	15
Pre-treatment	19	Distribution	17
Injection to aquifer	5	Consumers	4

Pollutants that directly flow into a catchment area are exposed to nature. The discharge of wastewater from industrial areas, inflow of chemical fertilizers or animal feces from agricultural and livestock industries, and the inflow of domestic sewage from metropolitan areas are all considered to be hazardous events. Pollutants accumulated on the road and railways flow into the river via surface water flow are also determined to be hazardous events. Hydraulic structures such as weirs, dams, and estuary banks are also considered to be hazardous events because they affect the water quality by interrupting the water flow. Furthermore, because the catchment area is affected by governmental policies, it is possible that an environment could be either polluted by development, or improved by environmental conservation measures or remediation policies.

A catchment area is affected by the weather conditions in addition to anthropogenic activity, and the concentration of pollutants in a river fluctuates in times of flood and drought. Other factors causing hazards are increases in temperature (promoting algal growth), and the development of stratification according to seasonal changes causing anaerobic conditions on the bottom of lakes and rivers.

When surface water is taken from a catchment area to be treated in a confined facility, the water is directly affected by the management and maintenance of aquifers and purification facilities. The malfunction of monitoring devices, the generation of disinfection by-products, power failure, and the corrosion of the equipment are considered to be potential hazardous events.

Although during the process of ASTR the water is exposed to nature within the aquifers, the number of possibly occurring hazardous events is small because the area for the ASTR process is strictly selected and limited in consideration of natural filtration. However, the inflow of outside pollutants and microorganisms through injection wells or abstraction wells, and the possibility of well-clogging are all considered hazardous events, as is the release of heavy metals from the aquifers.

It is possible that when the treated water is distributed to customers, a re-growth of microorganisms in the treated water could occur because there is still some concentration of microorganisms in treated water. The malfunction of pumps and pipe damage are also considered to be hazardous events.

Overall, 114 hazardous events were derived and Table 3 shows the nine major hazardous events that were determined to have risk ratings of ‘High’ and ‘Very High’. Possible hazards were then determined from the hazardous events. Although major hazardous events should be preferentially taken care to reduce risk, it is acknowledged that certain hazardous events cannot be handled by the maintenance facilities and need to be controlled by local or national government.

Table 3. Major hazardous events recorded during this study

Process	Hazardous event	Type†	Likelihood	Severity	Risk	Risk rating‡	Hazards
Catchment area	Illegal release of waste water from restaurants and private waste water treatment plants [15]	M, C	3	5	15	H	Pathogens, nutrients, surfactants, metal, heavy metal, non-biodegradable organics, colour, odor, taste
	Discharge of waste water from factories in the upstream of the Nakdong River (e.g. Eogok Local Industrial Complex) [10, 15]	C	4	5	20	VH	Metal, heavy metal, non-biodegradable organics
	Release by accidents of major chemicals from industrial complex [10, 16]	C	2	5	10	H	Non-biodegradable organics
	Frequent oil leakage accidents [16]	C	2	5	10	H	NAPLs
	Land use (Effects of Busan, Kimhae and Yangsan cities) [10]	M, C, P	5	2	10	H	Pathogens, sulfur oxides, nutrients, turbidity, colour, surfactants, organic matter, oil-contaminant
	Rapid change of river water quality by flood and drought [10]	M, C	3	5	15	H	Pathogens, nutrients, turbidity, colour, algae, toxic material, odor, taste
	Year-round occurrence of eutrophication [7, 10, 17]	M, C	4	5	20	VH	Algae, toxic material, colour, odor, taste
Storage	Rapid growth of cyanobacteria by abnormal high temperature in storage tank [7, 10]	M	2	5	10	H	Algae
Storage of treated water	Regrowth of pathogens or carcinogen (THMs) by inappropriate maintenance of residual chlorine [10]	C	2	5	10	H	Pathogens, disinfection by-products

Conclusion

In this study, the entire drinking water system was analyzed from source to tap. The study area was located in the Nakdong River downstream, South Korea. Various pollutants are known to enter the Nakdong River from metropolitan cities and from the industrial areas upstream. In this study, nine major hazardous events with risk ratings equal to or higher than 'High' were classified out of the 114 hazardous events derived. It is considered that the preliminary management of major hazardous events would be effective prevention in relation to water quality accidents in a drinking water supply using ASTR.

Abstract

The electrolyte chemistry (nature and its composition) plays a critical role in determining the nanotube architecture and its growth process. In the present study, the formation of well-ordered titania nanotubes (TNT) is achieved by electrochemical anodization of titanium substrate in aqueous ethylene glycol-glycerol electrolyte (EG/Gly). The resulted samples were characterized using X-ray Diffraction (XRD) and the morphology changes were monitored by Field Emission Scanning Electron Microscopy (FESEM). Compositional changes of the titania nanotubes (TNT) were determined using Energy Dispersive X-ray Spectroscopy (EDX). The influence of anodization voltage, volume ratio of electrolyte and NH_4F content on the morphology and geometry of titania nanotubes have been investigated. The nature of electrolytes influenced the ordering and uniformity of nanotubes. In addition, nanotubes with various diameters ranging from 62 – 112 nm and lengths of 1.1 – 1.3 μm were obtained by controlling the anodization voltage and volume ratio of EG/Gly. Ultimately, anodization of Ti at 20 V in 1:1 volume ratio of EG/Gly containing 0.25 – 1.0 wt.% NH_4F appears to be an optimum condition for controlling the ordering of nanotubes.

Keywords: titania, nanotube, anodization, glycerol, ethylene glycol

Abstrak

Kimia elektrolit (sifat dan komposisinya) memainkan peranan kritikal dalam menentukan senibina nanotiub dan proses pertumbuhannya. Dalam kajian ini, pembentukan nanotiub titania (TNT) tertertib rapi boleh dicapai melalui penganodan subtrat titanium secara elektrokimia dalam larutan akueus etilena glikol-gliserol (EG/Gly). Pencirian sampel dilakukan menggunakan pembelauan sinar-X (XRD) dan perubahan morfologi pula diawasi menggunakan mikroskopi pengimbasan elektron pancaran medan (FESEM). Perubahan komposisi nanotiub titania ditentukan dengan penyerakan tenaga sinar-X (EDX). Kesan voltan penganodan, nisbah isipadu elektrolit dan kandungan NH_4F ke atas morfologi dan geometri nanotiub titania telah dikaji. Sifat elektrolit mempengaruhi penertiban dan keseragaman nanotiub. Tambahan pula, pelbagai diameter nanotiub berukuran dari 62 – 112 nm dan 1.1 – 1.3 μm panjang dapat dicapai melalui pengawalan voltan penganodan dan nisbah isipadu EG/Gly. Penganodan Ti pada 20V dalam nisbah isipadu 1:1 EG/Gly yang mengandungi 0.25 – 1.0 wt.% NH_4F merupakan keadaan optimum dalam pengawalan penertiban nanotiub.

Kata kunci: titania, nanotiub, penganodan gliserol, etilena glikol

Introduction

Water pollution problem had become a critical issue worldwide. Various methods had been used in order to remove the pollutants for instance; biodegradation, coagulation, adsorption, advanced oxidation process (AOP) and membrane process [1]. Many studies had found that semiconductor materials can photodegrade recalcitrant organic matter under the sunlight illumination using AOP [2,3]. One of them is titania (TiO_2), an inexpensive and photostable semiconductor, which had been studied extensively for the purification of water and air [4,5] due to its high oxidative power. There are three different crystalline structures of titania: anatase, rutile and brookite being anatase and rutile with tetragonal structure and brookite with orthorhombic structure. However, among these crystalline structures, anatase is metastable and is the most photoactive [6]. In this context, titania nanotubes (TNT) have received wide attention from the research community over the last decade because of its wide application in energy conversion and storage, photocatalysis, membrane and sensing. In order to fabricate and functionalize TNT, several methods such as sol-gel method, hydrothermal, and anodization have been used to modify the morphology and functions of TiO_2 [7]. Electrochemical anodization of Ti is one of the promising methods to produce self-organized nanotubes, which is more favorable for electron transport pathways in photoelectrode performance [8]. This method is a simple process that involves connecting the Ti substrate to an anode in electrolyte solution and then applying current/voltage. Other advantages include strong adhesion between oxide layers and the substrate and facile control of the surface morphology [9]. Generally, dilute fluoride anion containing electrolytes is used, with optimization anodization conditions and evaluates the parameters such as pH, water content, fluoride content, anodization voltage, and anodization time on the formation of tubes and resulting geometry [10]. Therefore, in the present work, an attempt is made to fabricate TNT by electrochemical anodization in ethylene glycol and glycerol electrolytes with different anodization parameters such as anodization voltage, volume ratio of ethylene glycol and glycerol and concentration of fluoride ions. The effects of these parameters are studied to observe the impact on the formation and morphology of the TNT.

Materials and Methods

Materials and instruments

Ti foils (0.127 mm, 99.7 % purity) was purchased from Sigma Aldrich and was used as substrate for producing ordered TiO_2 nanotubes film (TNT). Acetone and isopropanol (R&M Chemicals) were used in cleaning of Ti substrate. Ethylene glycol (Fisher, 99.8% p.a), glycerol (Fisher, 98.0% p.a) and ammonium fluoride (Fluka, 98.0%) were used as components for preparation of electrolytes used in anodization process. All reagents were used without further purification. Deionized water (Millipore Alpha Q System, 18.2 MΩ) was used throughout the experiments. Crystalline structure of the TNT films was determined by X-ray diffraction (XRD, Shimadzu D6000) using Cu K_α radiation (λ = 1.5406 Å). The surface morphological and cross sectional features of the films were studied using a field emission scanning electron microscope, FESEM (Zeiss, SUPRA 40 VP, Germany). Quantitative measurements of the geometrical features of TNT were done using image analysis software; Image J. FESEM micrographs were taken from at least three different locations on each sample to ensure the measurements of tube diameter were representatives and to calculate the samples variability (as indicated by the standard deviations). About 100 measurements of tube diameter were taken per sample. The tube length was measured directly from cross section images of mechanically bent samples. An energy dispersive X-ray (EDX) analyzer fitted to the Carl Zeiss FESEM chamber was used to analyze the composition of the as-anodized and calcined TNT films**.**

Preparation of titania nanotubes

The Ti foil was first cut into small rectangle of 1cm × 2cm. Then, it was cleaned by sonicating in acetone, 2-propanol and deionized water for 15 minutes each using an ultrasonicator (Analab Scientific Instruments). After that, the Ti foil was washed with deionized water and then dried at room temperature. The anodization process was conducted in a standard 2-electrode cell in which the Ti foil was served as the anode and the graphite electrode as the cathode. The distance between the two electrodes was fixed at 2 cm. Both electrodes were immersed in electrolyte containing ethylene glycol, glycerol, 50% deionized water and 0.5 wt% NH_4F. The voltage was provided by a DC power supply and the anodization process was carried out at room temperature under continuous stirring. Anodization was carried out at 20 V unless otherwise stated in 1:1 vol.% ethylene glycol and glycerol (herein denoted as EG/Gly) for 60 minutes except for the effect of electrolyte ratio. After anodization, the resulting films were immediately rinsed with deionized water and subsequently dried in air. The as-anodized films were amorphous

initially. To induce crystallinity, the films were annealed at 500 ^{o}C in a Thermolyne 21100 furnace for 2 hours with a heating rate of 2 ^{o}C/min.

Results and Discussion

Effect of voltage

Electrochemical growth of TNT from Ti substrate is considered as a complex reaction, primarily involved three kinds of chemical effect, namely the electric field dissolution (shown as Eq. 1), electric field oxidation (shown as Eq. 2) and chemical dissolution (shown as Eq. 3).

$$Ti \rightarrow Ti^{4+} + 4e^{-} \quad (1)$$

$$H_2O \rightarrow 2H^{+} + O^{2-},\ Ti^{4+} + O^{2-} \rightarrow TiO_2 \quad (2)$$

$$NH_4F \rightarrow NH_4^{+} + F^{-},\ TiO_2 + 6F^{-} + 4H^{+} \rightarrow [TiF_6]^{2-} + 2H_2O \quad (3)$$

At the beginning of anodization, TiO_2 layer is grown due to the electric field dissolution and oxidation. Due to accumulation of electric charge at the interface between TiO_2 and Ti, Ti^{4+} will disrupt the TiO_2 layer and formed nanapores. Consequently, the thickness of TiO_2 layer increases due to electric field dissolution and oxidation, but at the same time, TiO_2 nanopores layer becomes thinner due to chemical dissolution. Growth of nanotubes is believed to be the result of the TiO_2 layer moving forward to the Ti substrate by the effect of oxidation and dissolution continuously. The nanotubes are produced and elongated when the rate of electric field induced dissolution and oxidation of Ti is faster than the rate of chemical dissolution of TiO_2. If the electric field induced oxidation and chemical dissolution are equal, the TiO_2 nanotubes length would remain constant [11].

Figure 1 shows the current density profile of nanotubes formed at different voltage. Generally, current density drops intially followed by a sudden increase and continues to stabilize and reach an equilibrium. The current drop indicates the formation of TiO_2 layer on the Ti as shown in Eq. 2. After the formation of the oxide layer, the current density increases when the fluoride ions attack the TiO_2 layer which lead to the formation of nanotubes as shown in the Equation 3. When the voltage is increased, the electric current also increased until the titania layer is thick enough for electric resistance causing current to decrease. When the dissolution of titania and the formation of the nanotubes start, the current increases again. The electric current remains constant when equilibrium is achieved between the oxide formation and dissolution. From Figure 1, all samples show similar characteristics of the current density where current density increases with increasing voltage.

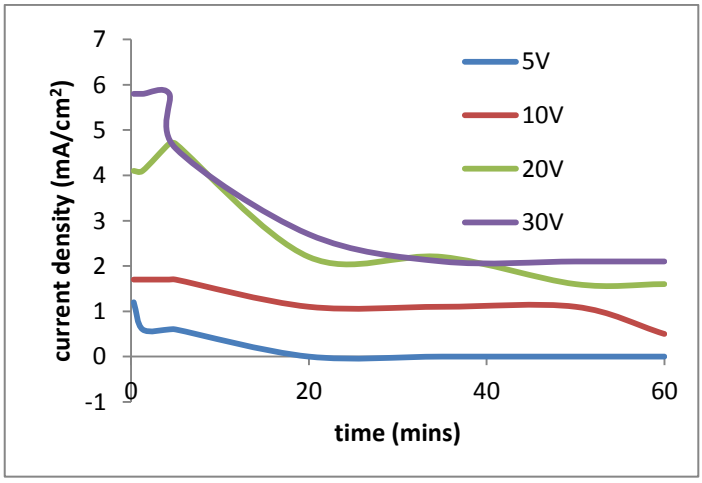

Figure 1. Current density profiles of titania nanotubes formed in 1:1 vol.% of EG/Gly at different voltage

Figure 2 shows the FESEM images of titania nanotubes anodized at different voltages range from 5V to 30V. It can be observed that Ti plate anodized at 5V demostrated porous structure as the voltage supplied was inadequate to form titania nanotubes. Similar observation was applied to the 10V Ti plate where the pore sizes are slightly bigger than that anodized at 5V. At 20 V, well-aligned and unifrom nanotubes can be seen clearly. The tops of the tubes are open and clean. The diameters of these nanotubes are about 86±11 nm with a wall thikcness of 17 ± 5 nm. However, when the applied voltage is too high (30 V), the nanotubes was destroyed or disintegrated, in which few nanotubes can be found among sponge-like structure. This is probably ascribed to electric field induced dissolution and oxidation occur too rapidly. The outer diameter of nanotubes fabricated at 30V is also bigger than that prepared at 20V, which is 122 ± 19 nm as higher voltage can strike out bigger pores leading to increase pore size with increasing voltage.

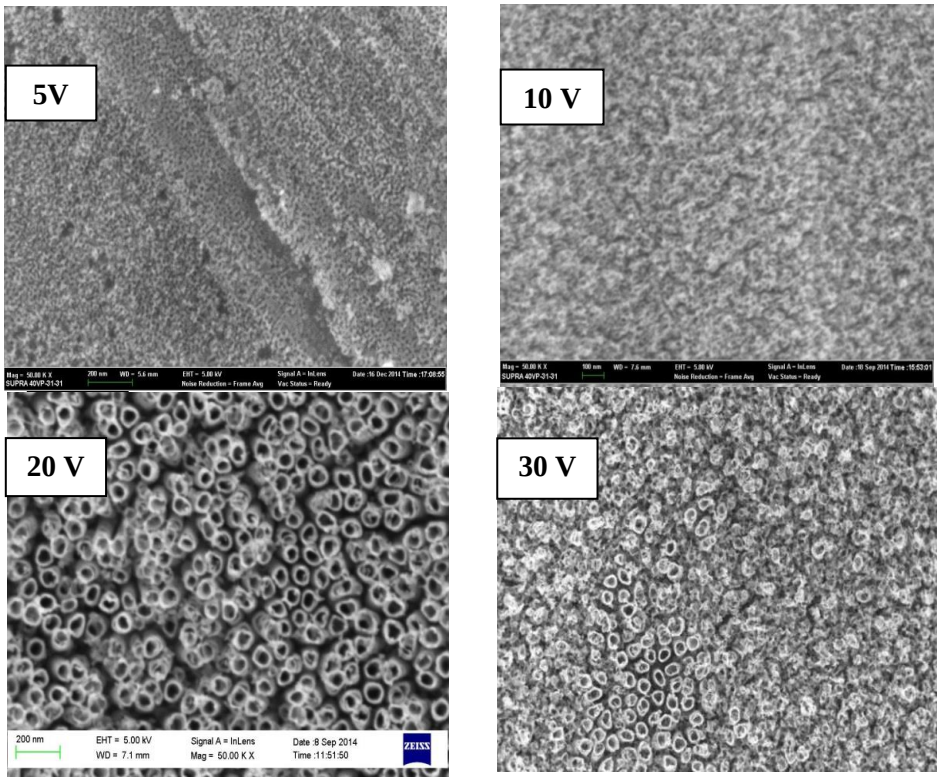

Figure 2. FESEM images showing the formation of titania nanotubes in 1:1 vol.% of ethylene glycol- glycerol for 60 minutes.

Effect of volume ratio of ethylene glycol-glycerol electrolyte

Ethylene glycol and glycerol are organic electrolytes with different viscosity, being the glycerol (945 cP) is more viscous than ethylene glycol (13.5 cP). The viscosity of the electrolyte affects the movement of ions during anodization process and thus resulting in formation of samples with different morphologies. To further compare the effects of electrolyte composition on the nanotubes growth process, mixture of different volume ratio of ethylene glycol and glycerol was explored. Figure 3 shows the FESEM images of titania nanotubes anodized at 20 V in different volume ratio of ethylene glycol and glycerol electrolyte. From Figure 3, it is obvious that equal ratio of both electrolytes gives uniform and clear nanotubes. However, nanotubes tend to clump together with increasing ethylene glycol ratio. In contrast to the observation obtained using different anodization voltage, there is no discernible change in nanotubes diameter as a function of volume ratio of ethylene glycol to glycerol. These nanotubes have a diameter of 85±10 nm with a wall thickness of 17 nm. When the ratio of glycerol is increased,

nanotubes with larger diameter (102 ± 16 nm) were obtained. In addition, higher ratio of glycerol to ethylene yields more compact, uniform and well-aligned nanotubes, indicating the viscosity of the electrolyte has an effect on the uniformity and ordering of nanotubes.

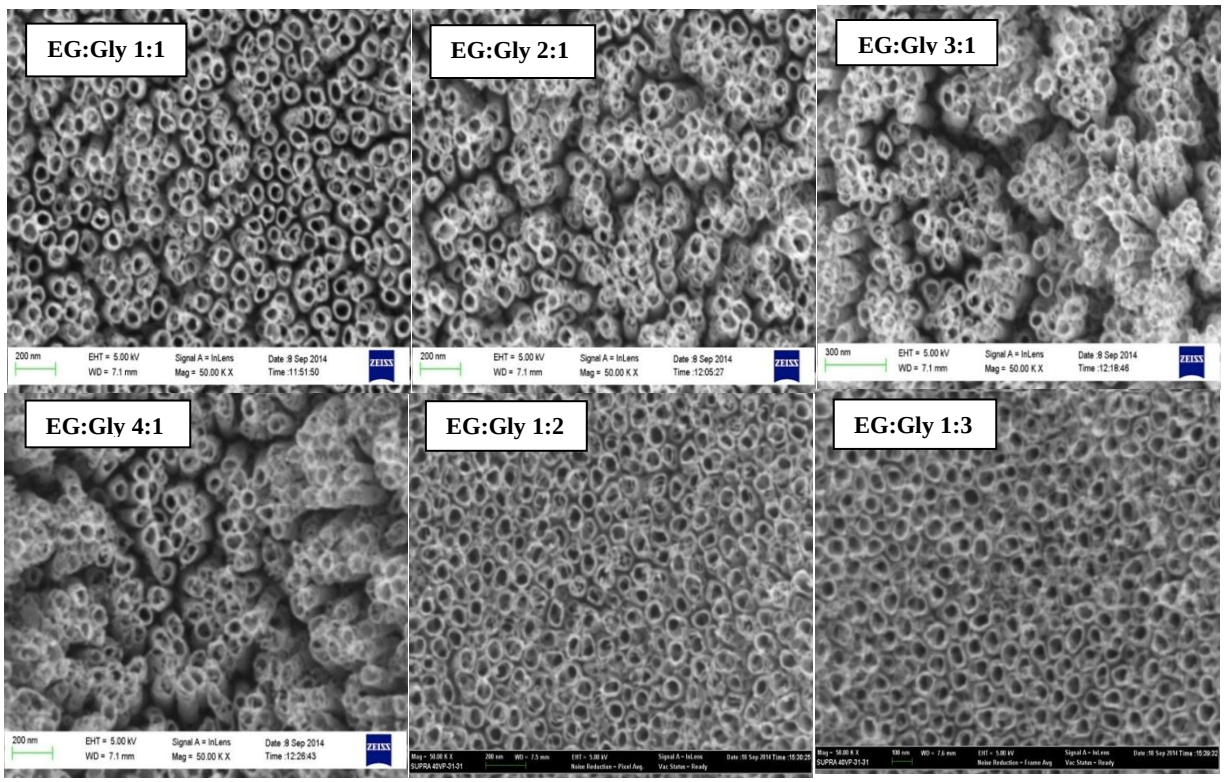

Figure 3. FESEM images of titania nanotubes anodized at 20 V in different ratio concentration of ethylene glycol/ glycerol electrolyte for 60 minutes

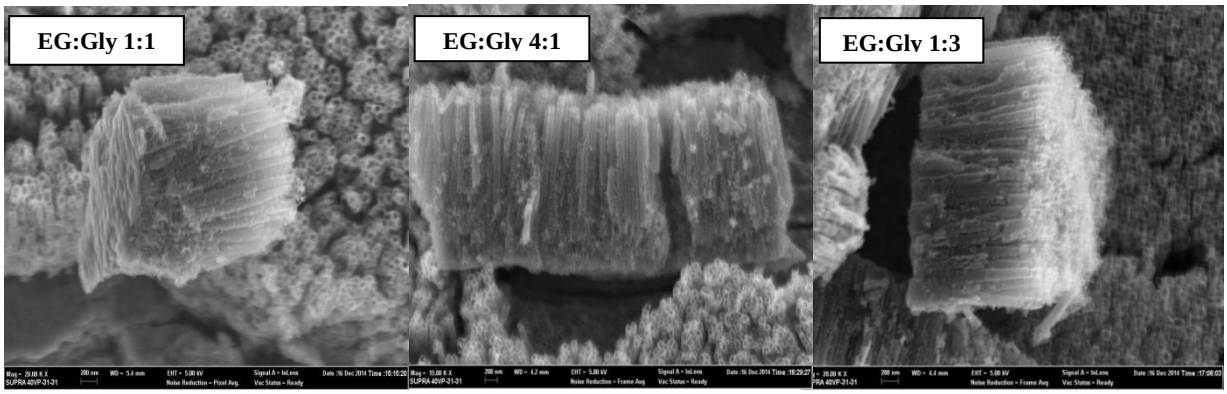

Figure 4. Cross sectional FESEM images of titania nanotubes prepared in different volume ratio of ethylene glycol to glycerol electrolyte.

The lateral view of titania nanotubes with different ratio of EG/Gly in Figure 4 shows that the TiO_2 nanotubes are cylinder-shaped structure and the tubes are packed vertically side by side, and their average length is about 1.1-1.3 μm as shown in Table 1. It seems that the length of nanotubes was not much affected by the ratio composition in the present study where the highest nanotube length was obtained in 1:1 volume ratio of ethylene glycol to glycerol. With addition of water to the electrolyte (50 vol.% in this study), the viscosity of the electrolyte was reduced and thus relatively higher rate of chemical dissolution of TiO2 is expected. This caused the formation of ripples of the side wall of nanotubes as shown in Figure 4.

Table 1. Length measurements of titania nanotubes prepared in different volume ratio of ethylene glycol to glycerol

Ratio concentration (EG:G)	**Length (nm)**
1:1	1320 ± 126
1:3	1112 ± 10
4:1	1275 ± 36

It is interesting to observe the difference of composition of TiO_2 anodized in different volume ratio of ethylene glycol to glycerol. Table 2 shows the EDX result of the as-anodized sample in EG:Gly 1:1 and calcined samples prepared in EG:Gly 4:1 and EG:Gly 1:3, respectively. Apart from the Ti and O, fluorine that originated from NH_4F and carbon from ethylene glycol or/and glycerol was found on the surface of the samples. The as-anodized sample contains higher amount of fluoride ions that act as the pore initiating agent than its calcined counterpart. This is because the fluoride ions were eventually lost during the calcination process. As for the calcined sample prepared in 1:3 EG:Gly, the sample still contain 1.5 wt.% fluorine and but in negligible amount. Same observation was obtained for calcined sample prepared in 1:1 and 4:1 EG:Gly where very little amount of carbon was found in the sample.

Table 2. Elemental composition of titania nanotubes prepared at 20 V in different volume ratio of ethylene glycol to glycerol

Element	**Weight %**			
	As-anodized EG:G 1:1	**Calcined EG:G 1:1**	**Calcined EG:G 4:1**	**Calcined EG:G 1:3**
C	0.91	0.79	1.17	-
O	41.29	35.43	41.65	41.80
F	7.07	1.46	-	1.45
Ti	56.46	56.59	57.18	56.75

The XRD patterns of the titania nanotubes formed in different volume ratio of ethylene glycol to glycerol upon calcination at 500 ^oC are shown in Figure 5. Apparently, a mixture of anatase and rutile was observed for all samples, indicating the electrolyte nature has no effect on the crystal structure of TNT. The diffractions of Ti peaks can be observed at $2\theta = 35.1^o$, 38.6^o, 40.2^o and 53.1^o respectively. The anatase phase can be seen at $2\theta = 25.4^o$, 38.0^o, 48.2^o, 54.0 and 55.2^o corresponding to (101), (004), (200), (105) and (211) plane. Rutile phase was obtained at $2\theta = 44.2^o$ corresponding to (210) plane.

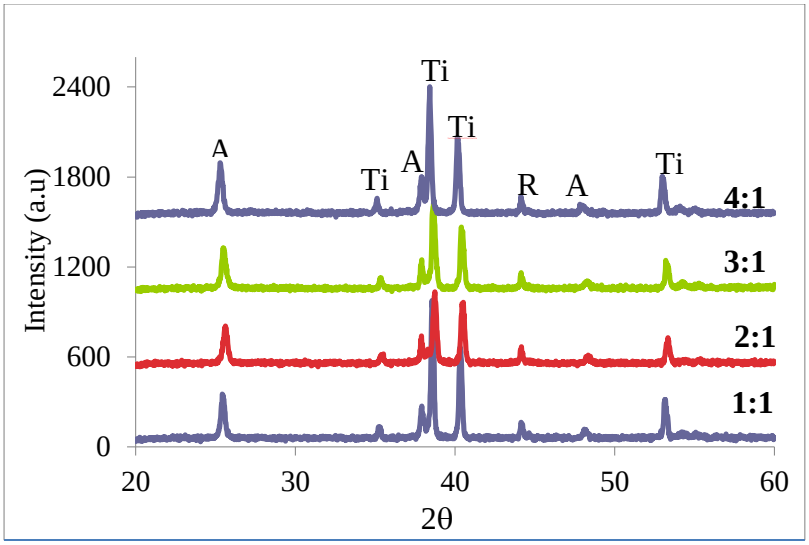

Figure 5. XRD patterns of TNT prepared at 20 V in different concentration ratio of EG:G. A, R and Ti represents anatase, rutile and titanium respectively

Effect of NH_4F concentration

Fluorides ions participate in the chemical dissolution reaction with negligible amount of them were deposited on the surface of TNT. However, most of them form $[TiF_6]^-$ species in electrolyte as shown in Eq. 3 [12]. The presence of fluoride ions is a key factor to activate the pore drilling, which give rise to the formation of highly ordered nanotubes [13,14]. The influence of fluoride ions on the morphology of TNT is schematically presented in Figure 6.

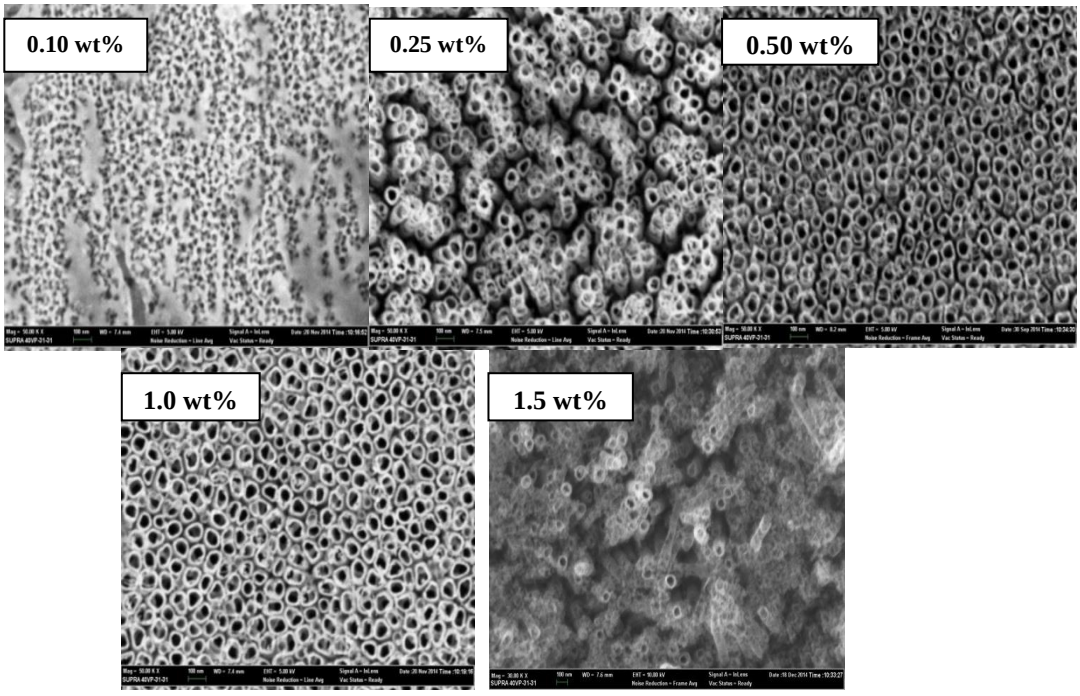

Figure 6. FESEM images of TNT prepared at 20 V in different NH_4F content in 1:1 EG: G for 30 minutes

Apparently, at a NH_4F content of 0.1 wt.%, only an ordered porous TiO_2 film is obtained. This result is attributed to the fact that chemical dissolution rate occurs too slowly to form nanotubes under low F^- content and thus only nanopores is obtained under such condition. Nevertheless, uniform, clean, and well-aligned nanotubes can be formed at NH_4F content of 0.25 wt. % to 1.0 wt.% NH_4F, indicating the amount of NH_4F is adequate for the formation of nanotubes. With increasing concentration of NH_4F to 1.5 wt.%, nanotubes tend to clump together and collapse eventually, ascribed to too rapid chemical etching rate. Table 3 shows the measurements of the nanotube diameter and wall thickness. Nanotubes formed in 1.0 wt. % resulted in bigger diameter and thicker wall, compared to those formed in 0.25 wt.% NH_4F.

Table 3. Measurements of TNT prepared at 20 V in different NH_4F content in 1:1 EG:G for 30 minutes

Concentrations (wt.%)	Outer diameter (nm)	Inner diameter (nm)	Wall thickness (nm)
0.10		porous structure	
0.25	96±14	62±11	17±4
0.50	92±11	57±9	18±5
1.00	112±10	75±4	17±3
1.50		nanotubes collapse	

Conclusion

In summary, TNT was successfully synthesized via electrochemical anodization of Ti in mixture of ethylene glycol and glycerol. Our results revealed that the electrolyte composition affects the morphological features and diameter of TNT. It was found that 20 V is the optimum voltage to form uniform and well aligned nanotubes with a diameter of 86 nm and 1.3 μm in length. A minimum of 0.25 wt.% NH_4F is required to yield an aligned nanotubes. Besides, volume ratio of EG/Gly has no effect on the crystal structure of the TNT formed but does affects the uniformity and ordering of nanotubes.

Abstract

Reduction of molybdenum trioxide, MoO_3 to molybdenum dioxide, MoO_2 by using carbon monoxide, CO has been studied by temperature programmed reduction (TPR) and X-ray diffraction spectroscopy (XRD). The influence of carbon monoxide concentration on the reduction of MoO_3 have been investigated by comparing the reduction behaviour of MoO_3 to MoO_2 with 20 vol.% and 40 vol.% of CO concentration. The XRD results show that by using 20% of CO, reduction to MoO_2 takes place at 700°C in 60 minutes. However, by using 40% of CO, complete reduction to MoO_2 takes place at 700°C in only 30 minutes. Moreover, excess of CO results in the formation of molybdenum carbide, Mo_2C. It is suggested that by using CO, complete reduction from MoO_3 to MoO_2 gives two-steps reduction ($MoO_3 \rightarrow Mo_4O_{11} \rightarrow MoO_2$) with Mo_4O_{11} as an intermediate product. It can be concluded that the reducing behavior of MoO_3 is strongly dependent on the concentration of CO and reaction time.

Abstrak

Penurunan molibdenum trioksida, MoO_3 kepada molibdenum dioksida, MoO_2 dengan menggunakan karbon monoksida, CO telah dikaji menggunakan suhu penurunan berprogram (TPR) dan spektroskopi pembelauan sinar-X (XRD). Kesan kepekatan karbon monoksida terhadap penurunan MoO_3 telah dikaji dengan membandingkan kesan penurunan MoO_3 kepada MoO_2 menggunakan kepekatan karbon monoksida di antara 20 % dan 40 %. Keputusan XRD menunjukkan bahawa dengan menggunakan 20 % kepekatan CO, penurunan kepada MoO_2 berlaku pada suhu 700 °C dalam masa 60 minit. Walau bagaimanapun, dengan menggunakan 40 % kepekatan CO, penurunan lengkap kepada MoO_2 berlaku pada suhu 700 °C dalam masa hanya 30 minit. Selain itu, pendedahan kepada CO berlebihan akan menyebabkan pembentukan molibdenum karbida, Mo_2C. Adalah dicadangkan bahawa dengan menggunakan CO, penurunan lengkap daripada MoO_3 kepada MoO_2 terdiri daripada dua peringkat penurunan ($MoO_3 \rightarrow Mo_4O_{11} \rightarrow MoO_2$) dengan menghasilkan Mo_4O_{11} sebagai produk perantara. Ini boleh disimpulkan bahawa kelakuan penurunan MoO_3 adalah amat bergantung kepada kepekatan CO dan tempoh masa tindak balas.

Introduction

Metallic molybdenum offers excellent mechanical, thermal and electric properties and good corrosion resistance and is widely used as an alloying agent for manufacturing steels, cast irons and super-alloys to increase their mechanical strength, hardness, swiftness and resistance to corrosion and wearing [1]. Molybdenum powder is manufactured in two-step process starting from MoO_3. The first step reduction is exothermic in nature that is carried out at lower temperatures and involves transformation of MoO_3 to MoO_2. The second step reduction is endothermic in nature where MoO_2 is further reduced to Mo [2]. The reduction of MoO_3 to MoO_2 is a crucial stage in the production of metallic molybdenum. The reduction of MoO_3 to MoO_2 by using hydrogen consists of two reduction stages, namely $Mo^{6+} \rightarrow Mo^{5+}$ and $Mo^{5+} \rightarrow Mo^{4+}$ [3]. It seems that during the reduction of MoO_3, MoO_3 is first reduced to Mo_4O_{11}, then to MoO_2. Generally, pure molybdenum powders are produced using the well known two-step hydrogen reduction process [4]. The first step occurs in the temperature range of 450 - 650 °C and reduces the input material to MoO_2. The second step reduction is performed in the 1000 - 1100 °C range and this process results the formation of molybdenum metal. Nevertheless, usage of hydrogen as a reducing agent of MoO_3 reduction is expensive. Carbon is also used to reduce MoO_3 at elevated temperature (600 - 1200 °C) [5]. When metal oxides react with carbon, one of the reaction products would be gaseous and could be readily separated from the solid reaction products [6]. Therefore, it would be highly desirable to develop an alternative process to manufacture molybdenum. Reduction of MoO_3 by using CO as reductant was suggested as an alternative process for producing molybdenum. However, currently there are limited number of studies using CO for reduction of MoO_3 to MoO_2. In this study, we report the influence of CO content on the reduction behaviour of MoO_3. The isothermal and non-isothermal temperature programmed reduction (TPR) was performed to investigate the reduction behaviour of MoO_3 to MoO_2 by using CO as a reducing agent and later characterizing by XRD. Reduction of MoO_3 to MoO_2 by CO was suggested to follow two reduction stages which are shown as Equation 1 and Equation 2.

$$4MoO_3 + CO \rightarrow Mo_4O_{11} + CO_2 \quad (1)$$

$$Mo_4O_{11} + 3CO \rightarrow 4MoO_2 + 3CO_2 \quad (2)$$

Materials and Methods

Chemicals and raw materials

Commercial molybdenum trioxide, MoO_3 (AnalaR) powder was obtained from BDH Chemicals Ltd.. The gas mixture of carbon monoxide (CO) in nitrogen (20 and 40 vol % of CO) from Linde Malaysia was used.

Reduction of molybdenum trioxide

The commercially bought MoO_3 powder was calcined to remove impurities at 400 °C for 4 hours in air and then cooled to room temperature before undergo the reduction process by using a Micromeritic Autochem 2920 Chemisorption Analyzer apparatus. The completeness of the reduction of the powder was analysed using a temperature programmed reduction (TPR) method. In this experiment, a mixed gas of 20 % CO in 80 % nitrogen and 40 % CO in 60 % nitrogen was introduced into the apparatus at an effective flow rate of 20 mL/min. Then, temperature was increased from 40 to 700 °C with a heating rate of 10 °C/min and continued with isothermal reduction for 30 and 60 minutes at 700 °C.

Characterization method

The crystal structures of the MoO_3 powder before and after reactions were determined by XRD's Bruker AXS D8 Advance type. The radiation source used was Cu Kα (40 kV, 40 mA) to record the 2θ diffraction angles from 10° to 80° at wavelength ($\lambda = 0.154$ nm). For identification purposes of crystalline phase composition, diffraction patterns obtained were matched with standard diffraction data (JCPDS) file.

Results and Discussion

Thermodynamic Consideration Data

According to the thermodynamic analysis for the reduction of MoO_3 by using CO as a reducing agent to the reaction in Equation 3 and Equation 4, the Gibbs free energy changes due to reaction and the equilibrium composition of the oxides was calculated.

$$MoO_3 + CO \rightarrow MoO_2 + CO_2 \quad (3)$$

$$2MoO_2 + 6CO \rightarrow Mo_2C + 5CO_2 \quad (4)$$

From the calculation, the Gibbs free energy for formation of MoO_2 for reaction Equation 3 is $\Delta G_{(298\ K)}$ = -29.8 kcal/mol which clearly indicates that the reaction is favorable. However, if excess CO is introduced to the reduction system, the formation of Mo_2C will take place according to reaction Equation 4 with the $\Delta G_{(298\ K)}$ = -34.9 kcal/mol which means the reaction is very spontaneous.

Characterization by TPR

The reduction behaviour of MoO_3 to MoO_2 was studied using TPR. Figure 1 shows the TPR profile of non-isothermal reduction of MoO_3 until 700 °C continued with isothermal reduction at 700 °C for 60 minutes by using 20% and 40% of CO in nitrogen. Complete reduction to MoO_2 needs to complete at temperature lower than its melting point (795 °C) since MoO_3 will end up as an alloy fused mass when it is taken to its melting point [5].

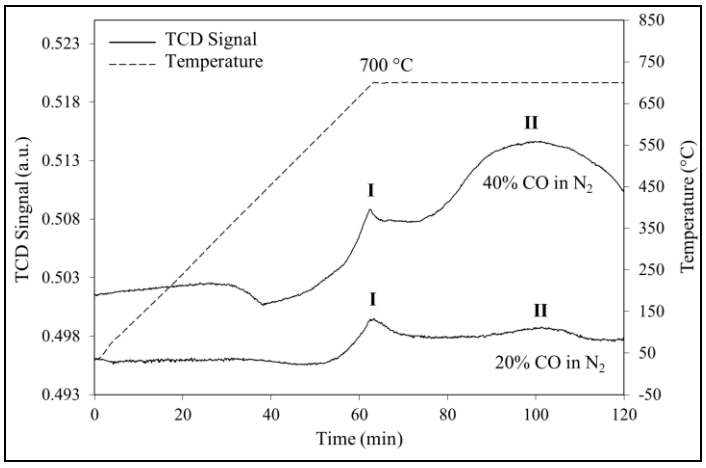

Figure 1. TPR profile of non-isothermal reduction of MoO_3 with 20% and 40% of CO in nitrogen at 40-700 °C and continued with isothermal reduction at 700 °C for 60 minutes.

The TPR profile of MoO_3 represents two reduction events (denoted I and II) which event I owing to peak displayed at early reaction time may regard to the reduction of MoO_3 to Mo_4O_{11}, while event II is subsequent to reduction steps of Mo_4O_{11} to MoO_2. However, with excess of CO supply to the reduction system, it brings to the formation of Mo_2C. The profile monitor CO consumption peaks by using 20 % of CO in nitrogen which started at about 530 °C was pointed to the first stage of reduction (event I) in agreement with Dang et al. [7], as mentioned that the MoO_3 is firstly reduced to Mo_4O_{11}, then to MoO_2. After continuing the reaction with isothermal reduction at 700 °C for 40 minutes, new broad peak is observed due to sample changes that occurred, reflecting to second stage reduction of Mo_4O_{11} to MoO_2.

Then, for the reduction of MoO_3 in 40 % of CO atmosphere, the TPR profile shows two peaks that reflect the two stages of reduction. By increasing concentration of CO to 40 % CO, the reduction peaks are leading to a low temperature to 420 °C, while the second peak can be monitored after 10 minutes, starting off with isothermal reduction at 700 °C. It seems that, the reduction of MoO_3 is observed to occur with a slight shift to lower temperature by increasing the concentration of CO. In addition, it shows that the reducing behaviour of MoO_3 is

strongly dependent on the concentration of CO. The phases formed after the reduction by TPR were analysed by recording XRD pattern of the residual obtained after selected reduction condition.

Characterization by XRD

To investigate the reduction behaviour of MoO_3 by using different concentration of CO, the samples were collected and XRD patterns were measured. The XRD profile obtained in Figure 2 revealed the MoO_3 (JCPDS 74-7383) was not yet reduced to MoO_2 even after flowing with 20 % of CO until 700 °C. It is due to insufficient of CO and heat supply to the reaction. However, by flowing with 40% of CO the XRD patterns showed peaks that identified with MoO_2 phases (JCPDS 76-1807). From the results, the reduction of MoO_3 by using 20% and 40% of CO concentration shows two stages process ($MoO_3 \rightarrow Mo_4O_{11} \rightarrow MoO_2$) in respect to a trace of intermediate Mo_4O_{11} (JCPDS 89-0687) which presence is identified at 700 °C. It is comparable with literature reported by Lalik [8] that suggested formation of Mo_4O_{11} as the earliest product in the reduction of MoO_3.

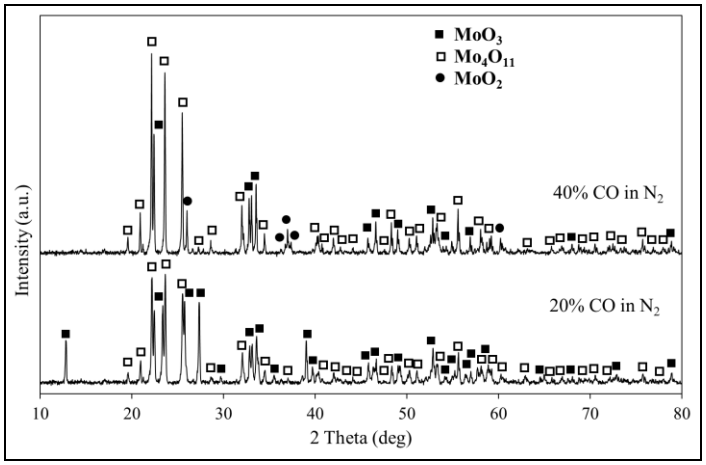

Figure 2. XRD patterns of non-isothermal reduction of MoO_3 with 20 % and 40 % of CO in nitrogen until 700 °C

Since MoO_3 is not completely reduced to MoO_2, isothermal reduction with 20 % and 40 % of CO in nitrogen was conducted at 700 °C for 30 minutes to complete reduction to MoO_2. From the XRD profile obtained in Figure 3, it is seen that by using 20% of CO, the MoO_2 peaks start to appear and MoO_3 peaks nearly disappear. Most of the peaks are intermediate phases of Mo_4O_{11}. However, by using 40 % of CO, the intensity of MoO_2 peaks sharply increase and intermediate phases of Mo_4O_{11} completely disappear. It shows that, reduction to MoO_2 in 20 % of CO concentration required higher heat supply to be accomplished compared by using 40 % of CO. It is seen that the higher concentration of CO will give the higher reduction to MoO_3.

Isothermal reduction at 700 °C was increased to 60 minutes to study the reduction behaviour by excessing the CO supplied. Figure 4 shows the XRD patterns of isothermal reduction for 60 minutes by using 20 % and 40 % of CO. As it is shown, MoO_3 was completely reduced to MoO_2 after isothermal reduction using 20 % of CO at 700 °C for 60 minutes. Figure 4 show the formation of carbide will take place in excess of CO. This was confirmed by the XRD profile of 40 % of CO displayed a decrease in the intensity of the MoO_2 peaks and new formation peaks of Mo_2C (JCPDS 65-8766) when the isothermal reduction prolongs until 60 minutes. This XRD patterns match well to previously reported pattern for processing of Mo_2C [9].

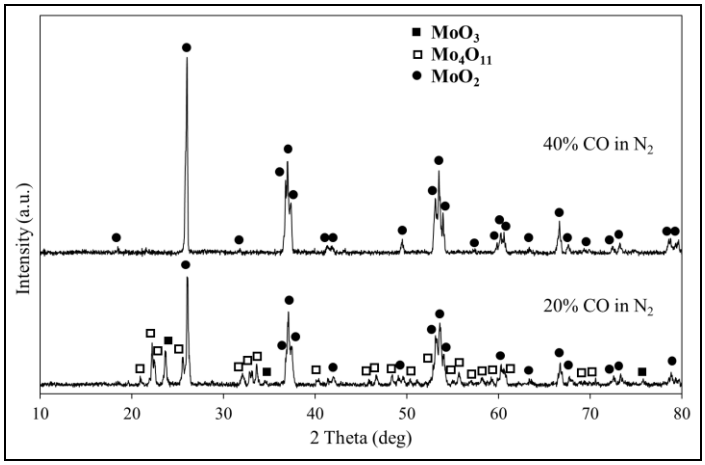

Figure 3. XRD patterns of non-isothermal reduction of MoO_3 with 20 % and 40 % of CO in nitrogen until 700 °C and continued with isothermal reduction at 700 °C for 30 minutes

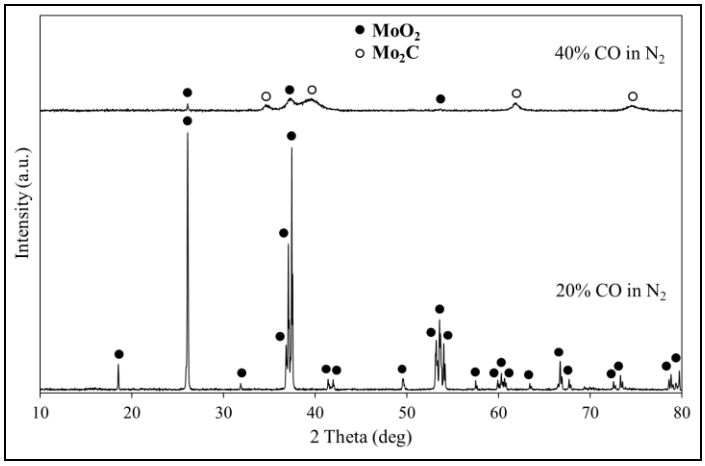

Figure 4. XRD patterns of non-isothermal reduction of MoO_3 with 20% and 40% of CO in nitrogen until 700 °C and continued with isothermal reduction at 700 °C for 60 minutes

Conclusion

In conclusion, the reduction behaviour of MoO_3 by TPR technique and XRD characterization shows that the reduction reaction of MoO_3 is strongly dependent on the concentration of CO and reaction time. The reduction reaction follows the consecutive two-steps mechanism, namely, MoO_3 is firstly reduced to Mo_4O_{11} and then Mo_4O_{11} is reduced to MoO_2. However, if excess of CO is introduced to the system, the formation of Mo_2C will take place.

Abstract

Gnetum is a genus of gymnosperms, the sole genus in the family Gnetaceae with approximately 40 species. Various species has been used for the treatment of rheumatitis, arthritis, bronchitis and asthma in folk medicines. *Gnetum cuspidatum* Blume is known throughout tropical Southeast Asia from Thailand, Vietnam, Cambodia, Malaysia, Sumatra, Java, and Borneo to the Maluku, Sulawesi and New Guinea. In this research work, a methanol extract of the lianas of *Gnetum cuspidatum* was subjected to vacuum liquid chromatography for fractionation. Later, several selective fractions had undergone the repetitive radial chromatography technique for further purification. Four known constituents categorized as stilbene type of compound have been successfully isolated and identified which include resveratrol (1), gnetucleistol C (2), gnetucleistol D (3) and gnemonol M (4). The structures and configuration of the reported compounds were elucidated on the basis of 2D-NMR correlations and comparison with the literature.

Abstrak

Gnetum merupakan genus gymnosperms, genus tunggal dalam keluarga Gnetaceae dengan kira-kira 40 spesies. Pelbagai spesies telah digunakan untuk rawatan rheumatitis, arthritis, bronkitis dan asma dalam perubatan penduduk tempatan. *Gnetum cuspidatum* Blume dikenali di seluruh tropika Asia Tenggara dari Thailand, Vietnam, Kemboja, Malaysia, Sumatera, Jawa, Borneo dan ke Maluku, Sulawesi dan New Guinea. Satu ekstrak metanol daripada lianas *Gnetum cuspidatum* telah menggunakan vakum kromatografi cecair untuk pemisahan. Kemudian, beberapa pemisahan yang terpilih telah menjalani teknik kromatografi jejarian secara berulang kali untuk penulenan lanjut. Empat sebatian yang dikategorikan sebagai jenis stilbene telah berjaya diasingkan dan dikenalpasti iaitu resveratrol (1), gnetucleistol C (2), gnetucleistol D (3) dan gnemonol M (4). Struktur dan konfigurasi sebatian yang telah dilapor ini berdasarkan korelasi 2D-NMR dan perbandingan dengan kajian literatur.

Kata kunci: Gnetaceae, *Gnetum*, *Gnetum cuspidatum*, stilben

Introduction

The genus *Gnetum* from the family of Gnetaceae comprises approximately 40 species which were found in the tropical lowlands of the world from Northeastern South America, tropical West Africa, and South China to Southeast Asia. The plants are known to contain stilbenoids or oligostilbene and have been ethnobotanically used as folk medicine as well as food [1]. Previously, many studies have been done on several species of *Gnetum* and

revealed various stilbenes and oligostilbenes type of compounds as its major chemical constituents. Interestingly, some of the isolated compounds display multiple bioactivities such as antioxidant, anti-inflammatory and antitumor [2].

In our search for structurally and biological interesting compounds from tropical plants found in Malaysia, the lianas of *Gnetum cuspidatum* has been investigated. *Gnetum cuspidatum* Blume is known throughout tropical Southeast Asia from Thailand, Vietnam, Cambodia, Malaysia, Sumatra, Java, and Borneo to the Maluku, Sulawesi and New Guinea. Previous study revealed the isolation of isorhapontigenin from the stem [3] and two new compounds recently report by Shimokawa et al. [4] known as cuspidan A and cuspidan B from the bark of this plant.

In this study, the methanol extract of the lianas of this plant has led to the isolation of four known stilbenoid compounds, resveratrol (1) [5], gnetucleistol C (2) [6], gnetuclesitol D (3) [7] and gnemonol M (4) [8]. The structures were determined using spectroscopic techniques of 1D and 2D NMR, MS and comparison with previous reports

Materials and Methods

Chemicals and raw materials

All the chemicals used were of analytical grade and purchased from Sigma Chemical Co. (St Louis, Missouri). The lianas of *Gnetum cuspidatum* was collected at Taman Negara, Pahang in August 2011 and identified by Dr Shamsul, a botanist from Universiti Putra Malaysia (UPM), Serdang.

Extraction and isolation of constituents from plant materials

The lianas were air-dried, ground (2 kg) and macerated in methanol which then filtered and concentrated under reduced pressure to obtain crude extract (214.8 g). The crude extract with less tannin (62.60 g) then was subjected to fractionation by using vacuum liquid chromatography (VLC) with various composition of solvent system [n-hexane: EtoAC (7:3, 6:4, 5:5, 3:7, 2:8, 1:9) and EtoAC: MeOH (10:0, 9:1, 8:2)] to yield five major fractions. All pure compounds reported were obtained from one single fraction. Fraction 4 (10.54 g) was subjected to isolation and purification using separation technique of multiple radial chromatography and preparative thin layer chromatography (pTLC) with solvent system of chloroform: methanol (8.5:1.5), and chloroform: acetone (8:2) to yield **1** (1mg), **2** (3.1mg), **3** (6.1mg) and **4** (12.1mg).

Purification and structure elucidation of pure compounds

The structure determination of the constituents isolated from the plants was done using several spectroscopic methods. The ^{1}H-NMR and ^{13}C-NMR were recorded in acetone-D on Bruker 300 Ultrashield NMR spectrometer measured at 300MHz for ^{1}H NMR and 75MHz for ^{13}C NMR. Chemical shifts were reported in ppm (δ) and the coupling constants are given in Hz. The mass spectra were measured on Agilent Technologies LC-MS. Melting point was measured by Fisher Johns 'micro melting point apparatus'.

For purification process to obtain a single constituent, various chromatographic techniques have been applied. Vacuum liquid chromatography (VLC) used silica gel 60, 70 – 230 mesh ASTM (Merck 1.07747), column chromatography using Si-gel Merck 60 (200 – 400mesh) and TLC analysis on pre-coated Si-gel plates Si-gel Merck Kiesel gel 60 F254 0.25mm, 20 x 20 cm while glass supported silica gel 60 F_{254} was used for preparative thin layer chromatography.

Results and Discussion

Four known compounds, resveratrol (1), gnetucleistol C (2), gnetucleistol D (3) and gnemonol M (4) (Figure 1) were successfully isolated from the methanol extract of the lianas of *G.cuspidatum*. The known compounds were elucidated on the basis of NMR (^{1}H and ^{13}C) technique and by comparison of physical and spectroscopic data with values found in the literature. Table 1 displayed all ^{13}C NMR data of the compounds isolated. Resveratrol (1), a naturally occurring stilbene in *Gnetum* plants was obtained as white amorphous powder. ^{1}H NMR (300 MHz, in Acetone-d6) revealed two sets of *ortho*-coupled aromatic protons on a *p*-substituted phenyl moieties (ring B) at δ_H7.40 (2H, d, J = 8.7 Hz, H-2, 6) and δ_H6.82 (2H, d, J = 8.4 Hz, H-3, 5). The spectrum also displayed one set of

meta-coupled aromatic proton δ_H6.53 (2H, d, *J* = 2.4 Hz, H-10, 14) and one *meta*-triplet at δ_H6.26 (1H, t, *J* = 2.1, 2.4 Hz, H-12) on a 1,3,5-trisubstituted benzene ring (ring A). A pair of *trans*-coupled olefinic proton at δ_H6.99 (1H, d, *J* = 16.8 Hz, H-7) /6.90 (1H, d, *J* = 16.2 Hz, H-8) were also observed.

Gnetucleistol C (2) was obtained as an amorphous white powder. The ^{1}H NMR spectrum in acetone-d6 exhibited signals attributable to a methoxy proton at δ_H3.95 (3H,s), an AB_2 system at δ_H6.39 (1H, t, *J* = 2.1 Hz, H-4), δ_H 6.91 (2H, d, *J* = 2.1 Hz, H-2, 6), an ABX system at δ_H6.75 (1H, d, *J* = 8.1 Hz, H-11), δ_H7.12 (1H, dd, *J* = 8.4, 0.9 Hz, H-13), δ_H7.23 (1H, t, *J* = 8.4, 8.1 Hz, H-12), and a doublet at δ_H7.14 (1H, d, *J* = 0.9 Hz, H-8), which display a long-range correlations with the signal of C-1 and C-9. Based on comparison with the ^{1}H and ^{13}C NMR data of gnetifolin A [5], compound **2** was deduced to have a benzofuran skeleton and was categorized under arylbenzofuran monomer type of stilbene.

Gnetuclesitol D (3), also known as 2-methoxyresveratrol was obtained as white amorphous powder. ^{1}H NMR (300 MHz, in Acetone-d6) displayed a single peak at δ_H3.89 (3H, s), showing the existence of an additional substituent which was a methoxy group on carbon 2 of ring B. Signals of one set of *meta*-coupled aromatic protons at δ_H6.53 (2H, d, *J* = 2.4 Hz, H-10, 14) and one *meta*-triplet at δ_H6.27 (1H, d, *J* = 2.1 Hz, H-12) were revealed on ring A. The spectrum also showed an ABX system on a 1,2,4-trisubtituted benzene ring (ring B) at δ_H6.79 (1H, d, *J* = 8.1 Hz, H-6), δ_H (6.99, dd, *J* = 2.1, 8.4 Hz, H-5) and δ_H7.21 (1H, d, *J* = 2.1, H-3). A pair of *trans*-coupled olefinic proton at δ_H7.05 (1H, d, *J* = 16.5 Hz, H-7) /6.89 (1H, d, *J* = 16.2 Hz, H-8) was also shown.

Gnemonol M (4) was obtained as a colorless amorphous powder. The ^{1}H NMR spectrum showed the presence of six sets of H-atoms in ABX systems on two units of 1,3,4-trisubstituted benzene rings at δ_H6.96 (1H, d, J = 1.8 Hz, H-2a)/6.72 (1H, d, J = 8.1 Hz, H-5a)/6.65 (1H, dd, J = 1.8, 8.1 Hz, H-6a); δ_H6.61 (1H, d, J = 2.1 Hz, H-2b)/6.57 (1H, d, J = 8.1 Hz, H-5b)/6.39 (1H, dd, J = 2.1 Hz, 8.1, H-6b). The spectrum also showed four sets of *meta*-coupled H-atoms in AB systems on two units of tetra-substituted benzene rings at δ_H6.54 (1H, d, J = 2.7 Hz, H-14a)/6.06 (1H, d, J = 1.8 Hz, H-12a); δ_H6.44 (1H, d, J = 2.4 Hz, H-14b)/6.16 (1H, d, J = 2.4 Hz, H-12b). Four benzylic methine singlets at δ_H4.20 (H-7a); 3.69 (H-8a); 4.13 (H-8b); 3.77 (H-7b), two signals for methoxyl groups at δ_H3.79 (OMe-3a); 3.64 (OMe- 3b), and phenolic proton at δ_H8.02 was also observed in the spectrum.

Conclusion

Four known stilbenoids were successfully isolated and characterized from the methanol extract of the lianas of *Gnetum cuspidatum* Blume. These stilbenoids compounds include resveratrol (1), gnetucleistol C (2), gnetucleistol D (3) and gnemonol M (4). As previous study found that oligostilbenoids from G*netum* displayed diverse pharmacological properties, further detailed on its phytochemical investigation is worth to be explored.

Abstract

A series of heterogenous catalysts based on supported ruthenium were prepared from $RuCl_3$ precusor by impregnation method. The effect of support materials (bentonite, TiO_2, Al_2O_3 and SiO_2) on catalytic activity of Ru catalyst for hydrogenolysis of glycerol were investigated under mild reaction condition of 150°C and 20 bar initial hydrogen pressure for 7 hours reaction time and glycerol concentration was 20%(wt). It was found that the type of support material have significant effects on the activity and selectivity of glycerol hydrogenolysis. The order of Ru catalyst activity was Ru/bentonite > Ru/Al_2O_3 ≈ Ru/TiO_2 > Ru/SiO_2. This study showed that bentonite supported Ru catalyst was the most active with glycerol conversion reaching 62.5% compared to other supports. All the tested catalyst exhibited high selectivity to 1,2-propanediol with more than 80%. Characterization of the catalysts was carried out using BET, XPS, FESEM-EDX and TEM to obtain the physicochemical properties of the catalysts.

Keywords: hydrogenolysis, ruthenium, bentonite, 1,2-propanediol, glycerol

Abstrak

Satu siri pemangkin heterogen berasaskan logam ruthenium berpenyokong disediakan daripada prekusor garam $RuCl_3$ menggunakan teknik impregnasi. Kesan bahan penyokong (bentonit, TiO_2, Al_2O_3 dan SiO_2) terhadap aktiviti pemangkin Ru dalam hidrogenolisis gliserol dilakukan pada keadaan tindak balas yang sederhana dengan suhu 150°C, tekanan awal hydrogen 20 bar, masa tindak balas 7 jam dan kepekatan gliserol 20%(wt). Keputusan yang diperolehi menunjukkan jenis bahan penyokong mempunyai kesan signifikan terhadap aktiviti dan pemilihan dalam hidrogenolisi gliserol. Turutan aktiviti pemangkin Ru adalah Ru/bentonit > Ru/Al_2O_3 ≈ Ru/TiO_2 > Ru/SiO_2. Kajian ini menunjukkan pemangkin Ru yang disokong atas bentonit adalah pemangkin yang paling aktif dengan peratus penukaran mencapai 62.5% berbanding dengan penyokong lain. Semua pemangkin yang diuji menunjukkan peratus pemilihan terhadap produk 1,2-propandiol yang tinggi iaitu melebihi 80%. Pencirian pemangkin dilakukan menggunakan alat BET, XPS, FESEM-EDX dan TEM bagi mendapatkan sifat-sifat fizikokimia pemangkin.

Kata kunci: hidrogenolisis, ruthenium, bentonit, 1,2-propanediol, gliserol

Introduction

Glycerol, one of the renewable resources, is obtained as a by-product in hydrolysis of fat, soap-manufacturing process and production of biodiesel [1]. Production of every 9 kg biodiesel, about 1 kg of crude glycerol by-product

is formed [2]. Nowadays, biodiesel derived from vegetable oils and animal fats has received considerable attention. The recent rapid development of biodiesel processes has caused some concern over the oversupply of glycerol in the glycerol market. The glycerol market will likely to be saturated because of limited utilization of glycerol at the present time. It is known that glycerol can be catalytically converted into functionalized and value-added chemical via a variety of reaction routes such as oxidation, hydrogenolysis, dehydration, pyrolysis, steam reforming, etherification, esterification, oligomerization and polymerization [3]. The hydrogenolysis of glycerol produces 1,2-propanediol (1,2-PDO) and ethylene glycol (EG) as a major products with a 4 % annual market growth [4]. Typical uses of 1,2-propanediol are in unsaturated polyester resins, functional fluids, pharmaceuticals, cosmetics, paints and others [5]. Process that can efficiently convert glycerol to a useful compound would be important as an economical and sustainable process. Conversion of glycerol using supported catalyst has been extensively studied by several groups [6-9]. In published papers the effect of various supports (TiO_2, SiO_2, NaY, γ-Al_2O_3 and active –carbon) on Ru catalysts were investigated and found that the support material can influence the metal particles size.

Most of the previous studies have employed solid acid like carbon [2], alumina [10] and silica [8, 11] to be used for supporting the metal catalyst. Bentonite which has surface area about 100 m^2/g is natural clay raw material that has high content of montmorillonite and less amounts of other clay minerals. Previous report have shows that bentonite can be used as support material in catalytic reaction.[12, 13] They found that Ru-Cu bimetallic catalysts supported on clay exhibited 100 % of glycerol conversion and 85 % yield of 1,2-propanediol at 230°C and 8 MPa. Previous study by Yuan et al. claimed that solid base (hydrotalcite and MgO) supported Pt catalysts exhibited the predominant activity and higher 1,2-PDO selectivity than that of solid acids (Al_2O_3, H-ZSM5 and H-Beta)[14].

Since there are only a few studies focus on the application of solid base supported metal catalyst in hydrogenolysis of glycerol, therefore we want to report an efficient solid-base supported Ru catalyst for glycerol hydrogenolysis to 1,2-PDO. In this work, the effect of other support materials (Al_2O_3, SiO_2 and TiO_2) with bentonite material on catalytic performance of ruthenium (Ru) based catalysts in the hydrogenolysis glycerol were investigated. The scope of this study was to investigate the effect of support materials on the structure and physicochemical characteristics of the catalyst as well as the catalytic performance in the glycerol hydrogenolysis reaction.

Materials and Methods

Chemicals

Ruthenium chloride hydrate, $RuCl_3.H_2O$ used as a metal precursor was purchased from Sigma. Aldrich. TiO_2, SiO_2 and Al_2O_3 used as support were purchased from Sigma, Aldrich. The clay mineral used in this work is a calcium-rich bentonite (CaB) was obtained as powder from PT Superintending Company of Indonesia also used as support.

Catalyst preparation

All the supports were calcined in air at 500 °C for 3 hours before used to remove moisture and impurities. About 0.09 gram of $RuCl_3$ was dissolved in acetone and stirred for 15 minutes. Then, approximately 1.8 g of support was added into the resulting solution and sonicated for 1 hour. After that, the mixture was dried in oven at 60 °C overnight. The supported catalyst was calcined in N_2 flow (10 ml/min) at 300 °C for 2 hours and then reduced in H_2 flow (10 ml/min) at 200 °C for 2 hours.

Catalyst characterization

The X-ray photoelectron spectrum (XPS) data of the as-prepared samples were obtained by XPS Ultra from Kratos, UK using 300 W MgK α radiation. The base pressure was about 3 x 10^{-9} mbar. The binding energies were referenced for the C 1s line at 284.5 eV from adventitious carbon. Transmission electron microscope (TEM) images were taken for determination of the particle size with a CM12 instrument (Philips) operated at 200 kV. General morphology information of the samples was examined by FESEM with LEO 1450VP model equipped with energy dispersive X-ray detector (EDX). All the samples were scanning in a high-vacuum mode at 20 kV.

Catalytic reaction

The catalytic hydrogenolysis reactions were carried out in a 50 ml stainless-steel autoclave, PARR reactor equipped with an electronic temperature controller and a mechanical stirrer. Reaction was normally conducted under the following standard conditions: 150°C temperature, 20 bar initial hydrogen pressure, 1.0 g catalyst weight, 23 ml of

20%(wt) aqueous solution of glycerol, 7 h reaction time and at constant stirring speed. Before reaction started, the reactor was flushed three times with N_2 in order to remove oxygen gas and pressurized with H_2 to 20 bar.

Results and Discussion

The physical properties of prepared catalysts by BET nitrogen adsorption isotherm are presented in Table 1. The trend shows that BET surface area of supported catalyst increased following this order: Ru/TiO_2 < Ru/bentonite < Ru/SiO_2 < Ru/Al_2O_3. BET analysis revealed that BET surface area of Ru/bentonite was decreased drastically. It seems that about 65.8% of Ru particle was loaded into the mesoporous of bentonite. This result indicates that pore volume of bentonite was large and much Ru particle could load into pore of bentonite.

The isotherm plot revealed that the catalysts studied exhibited a very much similar types of isotherms, having a mixture of Type III and Type IV (Table 2). The isotherm plot displayed a hysteresis loop which is of the Type H2 according to the IUPAC classification. Type H2 indicating the presence of non-uniformed cylindrical pores.

Table 1. Surface area of supports and supported catalyst

Support	**BET Surface Area (m^2/g)**	**Supported Catalysts**	**BET Surface Area (m^2/g)**
Bentonite	101.3	Ru/bentonite	35.4
TiO_2	8.8	Ru/TiO_2	7.9
SiO_2	130.5	Ru/SiO_2	125.3
AlO_3	155.6	Ru/Al_2O_3	141.4

Table 2. Types of isotherms, porosity, hysteresis and shape of pore for catalysts studied

Catalysts	**Type of isotherms**	**Types of pores**	**Types of hysteresis**	**Shape of Pore**
Ru/bentonite	IV	Mesopore	H2	Non uniform cylindrical pore
Ru/TiO_2	IV	Mesopore	H4	Uniform slit shape
Ru/SiO_2	IV	Mesopore	H4	Uniform slit shape
Ru/Al_2O_3	III and IV	Mesopore and macropore	H3	Non-uniform slit shape

Since XRD analysis did not show any peak related to Ru species except Ru/bentonite, therefore in order to investigate the presence of Ru species on the support, EDX analysis was done. Figure 1 clearly shows the existence of Ru species on the support.

The presence of Ru species was also indicated in the XPS wide scan and the binding energy (B.E) as shown in Table 3. The B.E of 280 and 283 eV is related to the chemical states of Ru^0 and Ru^{n+} respectively [15].

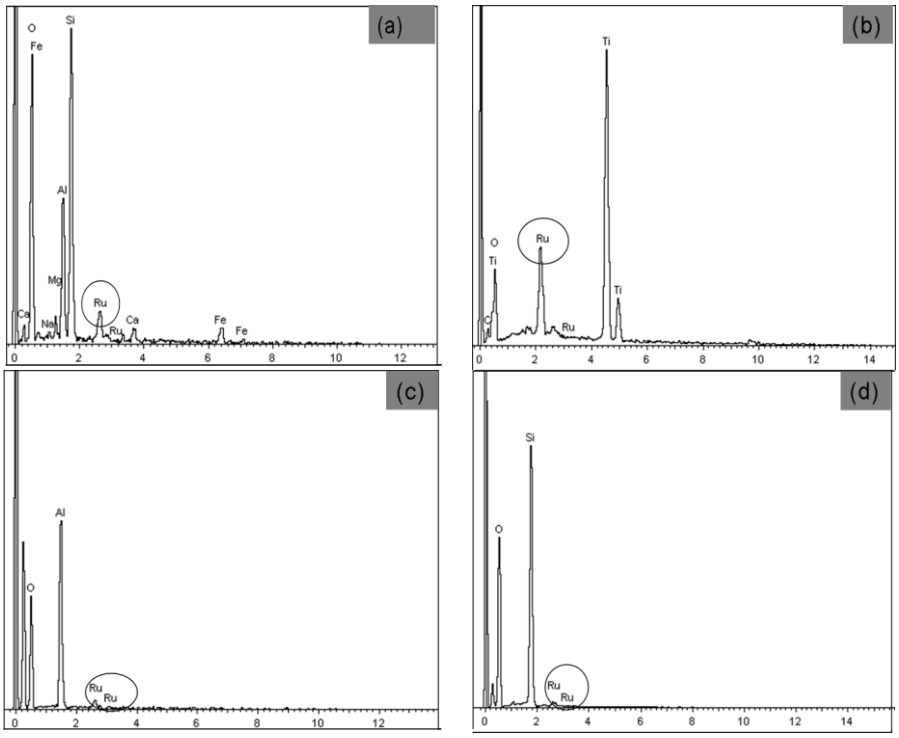

Figure 1. Analysis EDX spectrum of (a) Ru/bentonite, (b) Ru/TiO_2, (c) Ru/Al_2O_3 and (d) Ru/SiO_2

Table 3. XPS data for the supported catalyst

Supported catalyst	**Binding energy (eV)**		
	C 1s	**Ru $3d_{5/2}$**	**Ru $3d_{3/2}$**
Ru/bentonite	284.8	282.0	-
Ru/TiO_2	284.8	281.0	283.3
Ru/SiO_2	284.8	281.5	283.4
Ru/Al_2O_3	284.8	281.7	283.5

Chemical state of the Ru element was investigated via narrow scan and the spectra are shown in Figure 2. Since the binding energy (B.E) of Ru $3d_{5/2}$ (≈ 280 eV) overlapped with that C 1s (≈ 284.5 eV), it was difficult to resolve the small Ru peak out from the large peak of C 1s. The Ru 3d spectra revealed the presence of two different chemical states on the surface (Ru^0 at 281.0 eV and Ru^{4+} at 283.3 eV) except Ru species on bentonite shows chemical state of Ru^0 species only. Previous study have found that B.E of ≈ 283.0 eV was assigned to RuO_2 which is corresponding to Ru^{4+} species.[9] Meanwhile according to [3] the B.E value of Ru^0 species was in the range 280- 281 eV.[9] The presence of Ru^{4+} species indicated the Ru exists as oxide form and this species might be form during calcinations process.

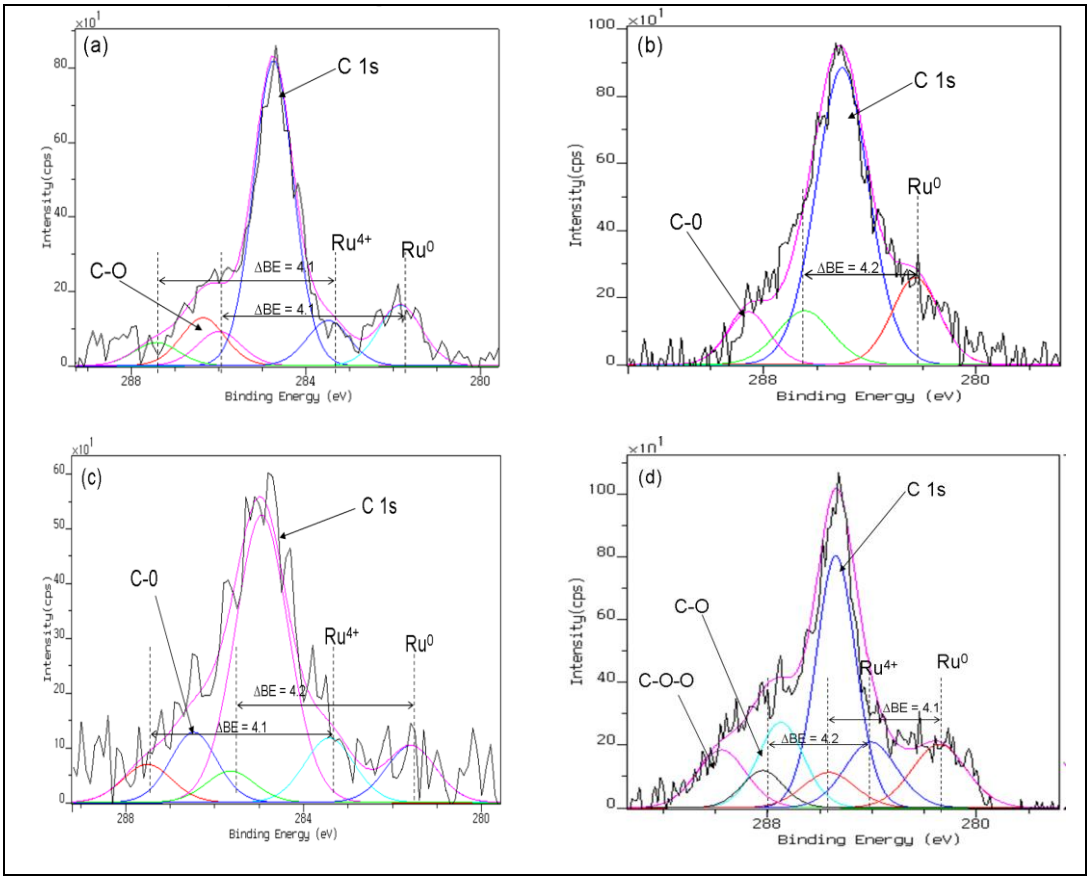

Figure 2. XPS narrow scan of Ru $3d_{5/2}$ for (a) Ru/Al_2O_3, (b) Ru/bentonite, (c) Ru/TiO_2 and (d) Ru/SiO_2

Figure 3 present the morphology of the catalyst analyze by TEM and the average size particle measured by TEM of Ru particle on bentonite, Al_2O_3, SiO_2 and TiO_2 obtained were ≈ 1.5 nm, < 2nm, ≈2 nm and 4-6 nm. This result indicate that particles size of Ru were much smaller on bentonite support than others support and activity of Ru/bentonite was expected was much higher than others catalyst in hydrogenolysis glycerol.

Glycerol hydrogenolysis reaction

The effect of support materials on catalytic of behavior of Ru catalyst for hydrogenolysis glycerol was investigated under mild reaction condition of 150 °C, 20 bar initial hydrogen pressure for 7 hours reaction time. The concentration of aqueous glycerol and catalyst loading used in this study are 20 %(wt) and 5 % respectively. The order of Ru catalyst activity was Ru/bentonite > Ru/Al_2O_3 ≈ Ru/TiO_2 > Ru/SiO_2. Figure 4 shows that Ru/bentonite catalyst was the most active catalyst which gave glycerol conversion reached 62.8 %. Good catalytic of Ru/bentonite is supported by TEM analysis since the average particle Ru/bentonite obtained was the smallest among the catalyst studied. Previous study reported that activity of Ru based catalyst was most active on smaller particle size of Ru.[2] Mapping analysis by FESEM showed that dispersion of Ru particle was also related to the catalytic activity of Ru catalyst. Ru/bentonite which is most active was relatively more dispersed on bentonite support compared to other support. This result indicates that bentonite which has basic property support gave high conversion compared to acidic support (SiO_2, Al_2O_3 and TiO_2). Interestingly, Ru/bentonite also gave high selectivity to 1,2-propanediol (80.1 %) compared to other catalysts which are support on TiO_2, SiO_2 and Al_2O_3.

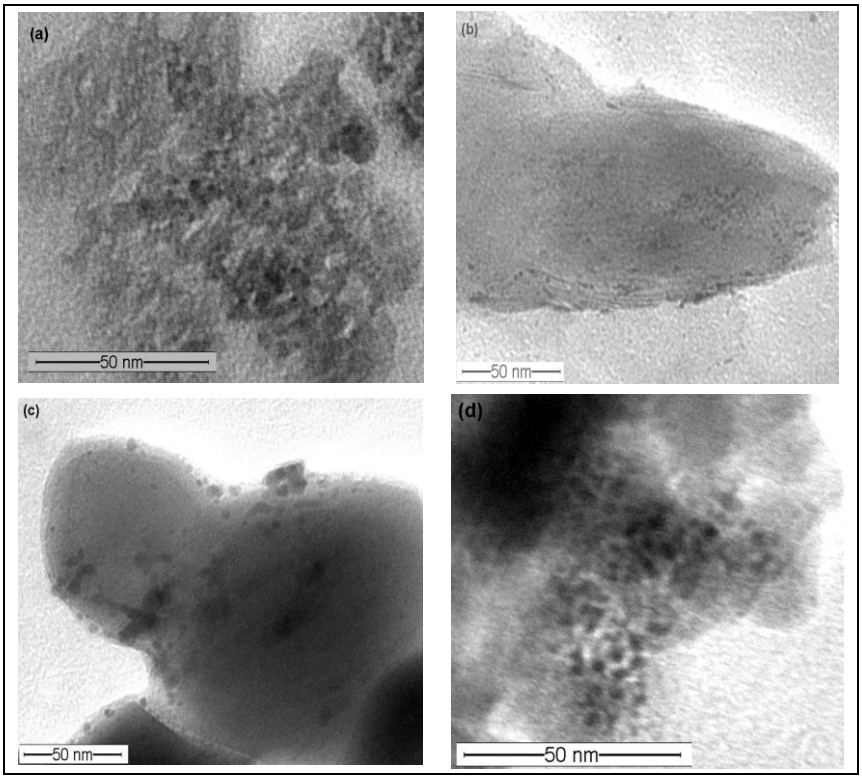

Figure 3. TEM image of (a) Ru/Al_2O_3, (b) Ru/Bentonite, (c) Ru/TiO, and (d) Ru/SiO_2

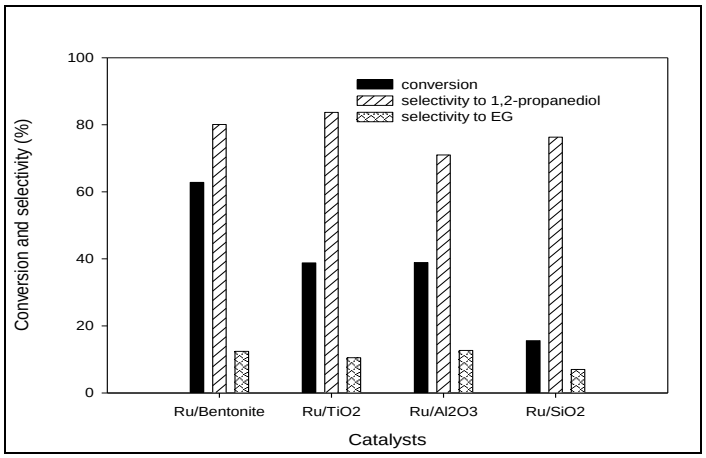

Figure 4. Hydrogenolysis glycerol over Ru-based catalyst at different support

Furthermore, XPS analysis showed that RuO_2 species was reduced to Ru^0 species completely on bentonite compared to other supports. This result indicates that Ru^0 species was the active species that contributes the best

performance of Ru/bentonite catalyst. Surface area of Ru/bentonite analyzed by BET shows moderate BET surface area (35.4 m^2/g) compared to Ru/SiO_2 (131.0 m^2/g) and Ru/Al_2O_3 (141.0). However this does not indicate that the catalyst is not good for hydrogenolysis reaction because BET surface area is not the only factor that contributes to good catalytic activity of the catalyst. Other factors such as types and shapes of pore need to be considered [9].

From the catalytic result, there is a correlation between the types of pores with the activity of the catalyst. The catalyst with Type H2 (non-uniformed cylindrical pore) gave pores which have good catalytic activity with 62.8% conversion. The other catalysts with Type H4 (non-uniformed slit shaped) gave only around 10-35% conversion. As such we can assume that cylindrical pore is an ideal pore shape for hydrogenolysis glycerol reaction. This is because the adsorption and desorption process can easy to takes place in cyclindrical pore during hydrogenolysis glycerol.

Conclusion

It was found that the nature of support material greatly influence the performance of the supported Ru catalyst. A bentonite suppored Ru catalyst (Ru/bentonite) exhibited the predominant activity and selectivity among the test catalyst and in a base-free aqueous solution under lower pressure. To best of our knowledge, Ru/bentonite system catalyst has not been reported yet for hydrogenolysis glycerol. Further study on the acidity and basicity of support has to be carried out.

Abstract

Microalgae is an economical and potential raw material of biomass energy, which offer a wide range of commercial potential to produce valuable substances for applications in aquaculture feed, pharmaceutical purposes and biofuels production. However, lack of an economical, efficient and convenient method to harvest microalgae is a bottleneck to boost their full-scale application. Hence, this study was performed to investigate the potentialities of *Moringa oleifera* seed derivatives as an environmentally bio-coagulant to harvest microalgae *Chlorella* sp. biomass from the water column, which acts as a binder to coagulate particulate impurities to form larger aggregates. Results shown *M. oleifera* to have better biomass recovery of 122.51% as compared to 37.08% of alum at similar dosages of 10 $mg \cdot L^{-1}$. In addition, it was found that the zeta potential values of mixed microalgae-coagulant suspension shows positive correlation on the flocculation parameters. For biomass recovery, the correlation for *M. oleifera* protein powder showed the R^2-value of 0.9565 whereas the control chemical flocculant, alum with the R^2-value of 0.7920. It was evidence that *M. oleifera* has a great potential in efficient and economical for environmentally microalgae harvesting and the adaptation of biological harvesting technology especially for the purpose of aquaculture feed in Malaysia.

Abstrak

Mikroalga merupakan bahan mentah yang murah dan berpotensi untuk tenaga biojisim, yang menawarkan pelbagai peluang pengkomersialan untuk menghasilkan bahan bernilai untuk aplikasi dalam makanan akuakultur, farmaseutikal dan penghasilan bahan bakar bio. Walaubagaimanapun, kekurangan kaedah yang murah, cekap dan mudah untuk penuaian mikroalga merupakan halangan untuk meningkatkan aplikasi teknologi ini dalam skala yang lebih besar. Oleh itu, kajian ini telah dijalankan untuk menyiasat potensi derivatif biji *Moringa oleifera* sebagai bio-penggumpal biojisim mikroalga *Chlorella* sp., yang bertindak sebagai pengikat untuk menggumpalkan zarah enapcemar membentuk agregat yang lebih besar dari kolum air. Keputusan menunjukkan *M. oleifera* mempunyai pemulihan biojisim yang lebih baik iaitu 122.51% berbanding alum iaitu 37.08% pada dos yang sama sebanyak 10 $mg \cdot L^{-1}$. Di samping itu, nilai keupayaan zeta campuran mikroalga dan penggumpal menunjukkan kolerasi positif terhadap parameter penggumpalan. Dalam pemulihan biojisim, kolerasi bagi serbuk protein *M. oleifera* menunjukkan nilai R^2 iaitu 0.9565 manakala penggumpal kimia kawalan, alum mempunyai nilai R^2 iaitu 0.7920. Ini membuktikan bahawa *M. oleifera* mempunyai potensi tinggi untuk penuaian mikroalga yang berkecekapan tinggi dan murah serta penyesuaian teknologi penuaian biologi terutamanya untuk tujuan makanan akuakultur di Malaysia.

Introduction

The exploration of potential natural coagulant is crucial for sustainability in mass microalgae harvesting. Microalgae harvesting in mass cultivation industry consisting of two stage process involving bulk harvesting and thickening. Bulk harvesting was aimed at the separation of biomass from the bulk suspension using flocculation techniques whereas thickening concentrated the slurry through energy intensive techniques such as centrifugation and filtration [1]. Chemical coagulants normally applied in the bulk harvesting stage. Thus, microalgae harvesting in massive scale would require high amount of chemical flocculants, which is not sustainable for long-term green technology application. Natural coagulant could be investigated for the desired flocculation characteristics similar to chemical flocculants. Plant-based natural coagulant is more environmental friendly and not pose health risks as chemical flocculants such as aluminum and ferric salts. The use of inorganic coagulants such as ferric chloride, $FeCl_3$ and aluminum sulfate, $Al_2(SO_4)_3$ shortly known as alum is proven to be effective for some microalgae flocculation, however it is certainly unacceptable if the harvested biomass is to be used for aquaculture purposes, animal feed or organic fertilizer. It was reported that the major component of alum and acrylamide could lead to human health implications, such as involvement in Alzheimer's disease and the cause of cancers [2]. According to Zheng et al. [3], these flocculants are required in high doses, both are more than 0.75 $g \cdot L^{-1}$ for microalgae harvesting.

In Malaysia, *M. oleifera*, commonly known as *kacang merunggai* is available locally and inexpensive hence making them a viable alternative to chemical coagulant in water and wastewater treatment, which is also possible as bio-flocculants in the microalgae biomass separation process and harvesting [4]. Bio-coagulant from *M. oleifera* was reported to have a high flocculation potential in water treatment, attaining 92 – 97 % flocculation efficiency [5, 6]. Previous study also concluded that *M. oleifera* seeds as a strong candidate as a bio-flocculant for microalgae harvesting at optimal pH range [7]. *M. oleifera* seed active compounds are known as the peptides of molecular weight ranging from 6 to 20 kDa, with an isoelectric pH value between 9 to 10 [6, 8].

Dispersion of microalgae cells in the water column leads to the difference of surface charges between microalgae biomass suspension and chemical ions of the cultivation media. According to Chen et al. [9], the proper reaction mechanisms existing at the colloid surfaces are differential loss ions from the crystal lattice because of the rupture of ionic or covalent bond, adsorption of charged species from the surrounding solution and ionization of chemical groups on the surface. The suspending microalgae cells in the water carried charge, which result in the generation of the electrical-double-layer. In solution, the presence of a net charge on a particle affects the distribution of ions surrounding it, resulting in an increase in the concentration of counter-ions. This region over which this influence extends was referred as electrical-double-layer. Conventionally, this layer is thought of as existing as two separate regions, which are inner region and outer layer. An inner region consists of strongly bound ions to the particle known as stern layer while the outer layer called diffuse layer associated with counter-ions. In the electrophoresis, an electric field is applied to a dispersion of particle, sometimes liquid droplets or even gas bubbles which gives rise to a motion of the charged particles with respect to the bulk liquid [10]. As the particle moves through solution, due to gravity or an applied voltage, the ions move with it. At some distance from the particle there exists a boundary, beyond which ions do not move with the particle. This is known as the surface of hydrodynamic shear, or the slipping plane which exists somewhere within the diffuse layer. During this phenomenon, the potential which is zeta potential do exists at the slipping plane.

The measurements of zeta potential is crucial in determining the stability of a colloidal suspension. Normally in a colloidal system, the dispersion are stable in which particles do not aggregate. The aggregation of particles in suspension depends on the magnitude of the zeta potential. In many instances stable dispersion are required. In other cases, such as water and wastewater treatment, paper manufacturing and oil recovery, unstable dispersion are desired. Stable or unstable dispersion could be produced in a variety of ways, which are by changing the pH of dispersion, addition of electrolyte and addition of coagulant. Generally, zeta potential study was correlated with coagulation-flocculation process. By measuring zeta potential, the isoelectric point (i.e.p.) in a colloidal system could be determined. Isoelectric point is very important from a practical consideration which normally indicated the least stable point in a colloidal system. At this point, the potential energy barrier opposing coagulation disappears,

and it is called the critical coagulation concentration [11]. Effective coagulation process could be performed in order to remove or recover the colloids from its suspended system.

The nature of suspended microalgae and surface charge could make the solid-liquid separation more difficult. However, the determination of zeta potential could lead to the understanding of isoelectric point of a colloidal system and eased explanation of the mechanism and interfacial phenomena occurring during coagulation-flocculation process of microalgae under various coagulants. The aim of this study was to explore the potential use of *M. oleifera* as a novel low cost bio-coagulant for microalgae *Chlorella* sp. harvesting. The interaction of the zeta potential of commercial coagulant which are alum, natural *M. oleifera* seed powder and *M. oleifera* protein powder in harvesting locally isolated freshwater microalgae, *Chlorella* sp. were investigated. The correlation of zeta potential and flocculation ability was explored to explain the interaction between coagulants and microalgae cells in suspended. Selected conditions for coagulation-flocculation were presented, as well as removal and microalgae biomass recovery percentage for different dosage at optimum pH. In this study, the experimental strategy was focused on coagulation-flocculation process corresponding to the profiles of zeta potential with respect to pH for different coagulants used such as alum, *M. oleifera* seed powder and *M. oleifera* protein powder.

Materials and Methods

Study area

Microalgae maintenance and flocculation assays were carried out at the Institute of Tropical Aquaculture, Universiti Malaysia Terengganu, Terengganu. The determination of zeta potential of microalgae suspension and *M. oleifera* seed derivatives were performed at the Civil Engineering Lab, Department of Civil Engineering, Universiti Putra Malaysia, Selangor.

Preparation of alum stock solution

Stock solution of aluminum sulfate (10 $mg \cdot L^{-1}$ Al^{3+}) supplied by Sigma Aldrich was prepared by dissolving 1 g of dry solid in 99 mL of deionized water. The alum powder was totally soluble in the water. A fresh solution was prepared every day for reliable results. In this study, the zeta potential of alum was compared with natural coagulants of *M. oleifera* seed powder and protein powder in harvesting freshwater microalgae, *Chlorella* sp..

Cultivation of freshwater microalgae, *Chlorella* sp.

The inoculum of pure culture of freshwater microalgae, *Chlorella* sp. was obtained from the microalgae culture collections of the Live Feed Culture Lab, Institute of Tropical Aquaculture, Universiti Malaysia Terengganu, Malaysia. *Chlorella* sp. was cultivated in Bold's Basal Medium (BBM) with controlled temperature of 25 ± 2 °C and 24 h illumination at 3350 lumen until late exponential phase in which cell density reached averagely 2.0×10^7 $cells \cdot mL^{-1}$.

Spectrophotometric analysis of *Chlorella* sp. biomass

The *Chlorella* sp. biomass were measured using spectrophotometric colorimetric method to facilitate rapid measurement. Spectrum analysis was performed to determine the peak absorption wavelength for the spectrophotometric colorimetric technique which was at 686 nm. For the establishment of standard calibration curve, *Chlorella* sp. biomass was measured using haemocytometer (Marienfield Neubauer-improved 0.1 mm depth, Germany) and syringe liquid sampler particle system (PMS SLS-2000, USA).

Preparation of *M. oleifera* seed powder

M. oleifera seeds were obtained within the region of Kuala Terengganu, Malaysia. The plant were authenticated by the Faculty of Bioresources and Food Industry, Universiti Sultan Zainal Abidin (UniSZA) Tembila, Terengganu, Malaysia. The plant was deposited at the university herbarium. The collected dry pods were unshelled to obtain the seeds. Pods shells were removed manually and only qualified contaminant-free seeds were selected to be used as coagulant. Then, the seeds consisted of cupule, seed coat and seed kernel were grounded using laboratory mill and sieved through 600 µm stainless steel sieve to obtain homogenous fine powders from each seed structure.

Purification of *M. oleifera* seed protein

The procedures for the purification of *M. oleifera* coagulation polymer were carried out based on Kwaambwa, and Maikokera method [12]. Dried de-oiled *M. oleifera* powder was used for the extraction of coagulant protein polymer. The extraction was performed by adding 3% (w/v) NaCl solution and this suspension was continuously agitated for 12 h in orbital shaker at controlled temperature of 25 ± 2 °C. The extract was filtered with Whatman filter No.44 and further heated in such a way that no white precipitation is formed at the bottom of solution. The heated crude protein extract solution was then poured into the dialysis tube and submerged completely for 12 h with constant temperature of 2 ± 2 °C. After completion of the dialysis procedure, the salt present in the crude brown protein was osmotically extracted into the surrounding water solution leaving white protein extract inside the dialysis tube. Then, the protein was dried at room temperature to form fine protein powder.

Coagulation-flocculation and sedimentation experiments

Coagulants tested in this study included alum, *M. oleifera* seed powder and *M. oleifera* protein powder. Coagulation-flocculation and sedimentation experiments were performed in glass beakers 0.12 m height by 0.09 m diameter (h/D = 1.33) using a 250 mL microalgae volume. Flocculants, previously dissolved in water at concentration 10 $mg \cdot L^{-1}$ were added to the microalgae sample under intense stirring at 150 rpm for 3 minutes to ensure complete solubility of the flocculants. Following that, the stirring was reduced to gentle agitation at 20 rpm for 20 minutes, so as to initiate flocs formation. After that, the suspension was leaved for sedimentation in 20 minutes. When interphases appear, it was clear and 3 mL sample was taken at the top (clear supernatant) for removal efficiency and 3 mL from bottom (saturated *Chlorella* sp. biomass) for biomass recovery. The absorbance of the sample were measured using UV-vis spectrophotometer (Shimadzu UV-1800, Japan). All experiments were carried out in triplicates. Percentage of biomass removal was calculated from the absorbance ratio at clarified zone against the culture absorbance at the beginning of the experiment according to Equation 1:

$$Biomass\ removal\ (\%) = \frac{Abs_{668}\ initial\ culture - Abs_{668}\ clarified\ zone}{Abs_{668}\ initial\ culture} \times 100 \quad (1)$$

Measurements of zeta potential

Methods of measuring zeta potential on a particles dependent both which are the particle and the suspension formulation. In general, the size and concentration of particles are the key parameters that determine which technique is applicable. In this study, zeta potential was measured based on the dispersion concentration of each coagulants which are alum, *M. oleifera* seed powder and *M. oleifera* protein powder in water at room temperature. Zeta potential was not measured directly. Perhaps the most widely used technique for measuring zeta potentials in electrophoresis. By applying an electric field across the sample, charged particles were induced to move. The velocity of particles known as electrophoretic mobility (EM). The electrophoresis measurements were carried out by injecting 25 mL of the aqueous dispersions of each coagulants into the cell of zeta potential instrument (Zeta-Meter System 3.0+, USA) at room temperature. The electrophoresis cell holds the sample for viewing under the microscope. It consists of two electrode chambers connected by an optically polished electrophoresis tube which is 10 cm long and 4 mm in diameter. Zeta potential measurements also was performed on suspending freshwater microalgae, *Chlorella* sp. culture before and after the addition of coagulants in order to investigate the effects of coagulants on its isoelectric point. By directly measuring the electrophoretic mobility of particle in dispersion, the zeta potential was determined using Henry's Equation 2 [13]:

$$\mu = \frac{2\varepsilon_0 \varepsilon_r \zeta f(\kappa r)}{3\eta} \quad (2)$$

where,

μ = electrophoretic mobility
ε_0 = permittivity of a vacuum
ε_r = medium dielectric constant (or permittivity)
ζ = zeta potential
κ = *Debye-Hückle* parameter
r = hydrodynamic radius of particle
η = viscosity of medium
$f(\kappa r)$ = Henry's function

The Henry's function generally has value either 1.5 or 1.0. For the measurements of zeta potential in aqueous solutions of moderate electrolyte concentration, a value of 1.5 is used. In this study, zeta potential was calculated according to the Henry's equation, applying Smoluchowski approximation [14].

Statistical analysis

Zeta potential of *Chlorella* sp., alum, *M. oleifera* seed powder and *M. oleifera* protein powder with respect to pH were recorded in Microsoft Office Excel™ throughout the experimental period. Graphical analyses were performed using Originlab OriginPro 8.6™ whereas the statistical determination involving One-Way ANOVA and post-hoc analysis utilizing Tukey's HSD Test were implemented via Minitab 16™. A confidence level of 95% ($\alpha = 0.05$) was selected in order to strictly determine the significance of between the dosages and types of coagulant used with the dependent parameters on microalgae biomass recovery.

Results and Discussion

Zeta potential analysis

Figure 1 shows the zeta potential values of freshwater microalgae, *Chlorella* sp. biomass and *M. oleifera* seed derivatives suspension in the range of pH 2 to pH 12. Both *M. oleifera* seed powder and *M. oleifera* protein powder zeta potential values decreases from 45.68 and 28.51 mV at pH 2 to the zeta potential values of -38.59 and -15.93 mV at pH 11, respectively. Control coagulant, alum also had decreased zeta potential value as pH increased from pH 2 to pH 12 with the value of 59.64 to -38.40 mV. In addition, *Chlorella* sp. biomass exhibited moderate decrease of the zeta potential value from -24.15 to -49.99 mV at pH 2 to pH 11. As shown in Table 1, *Chlorella* sp., alum and *M. oleifera* protein powder had significant regression with the Boltzmann Sigmoidal Model with the R^2-values of 0.9512, 0.9965 and 0.9549, respectively. Zeta potential values of *Chlorella* sp. and coagulants at various pH fitted with the model were shown in Figure 2.

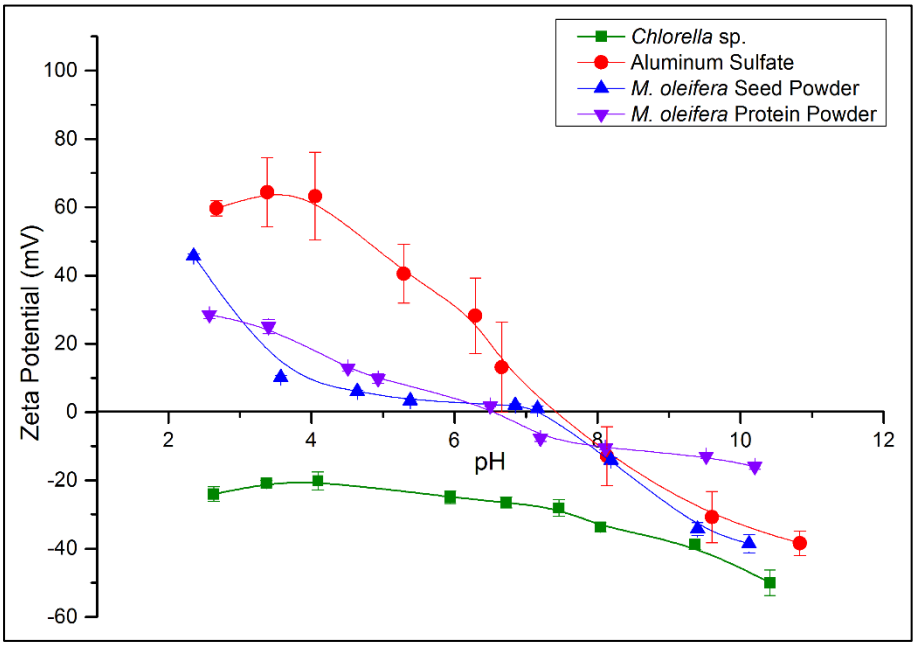

Figure 1. Spline curves of zeta potential values of *Chlorella* sp., aluminum sulfate, *M. oleifera* seed powder and *M. oleifera* protein powder at various pH.

Table 1. Boltzmann sigmoidal parameters of zeta potential at various pH for microalgae, *Chlorella* sp. and several coagulant suspensions

Suspension	Reduced Chi-Square	Adjusted R-Square	Boltzmann Sigmoidal Fit			
			Initial Value, A_1	Final Value, A_2	Centre, X_0	pH Constant, dx
Chlorella sp.	1.1477	0.9512	-19.7754 ± 2.6250	-83.0073 ± 110.0826	10.8864 ± 6.1201	2.0215 ± 1.4815
Aluminum Sulfate	0.1779	0.9965	62.6897 ± 2.2368	-41.5764 ± 3.4869	6.9651 ± 0.1999	1.1466 ± 0.2026
M. oleifera Seed Powder	112.9585	0.6962	411055.3 ± 1.2849 x 10^{10}	-1.7475 ± 7.0051	-8.5312 ± 37406.3888	1.1958 ± 2.5013
M. oleifera Protein Powder	8.8414	0.9549	32.8811 ± 11.2681	-18.9550 ± 5.3989	5.7435 ± 0.6186	1.6050 ± 0.6980

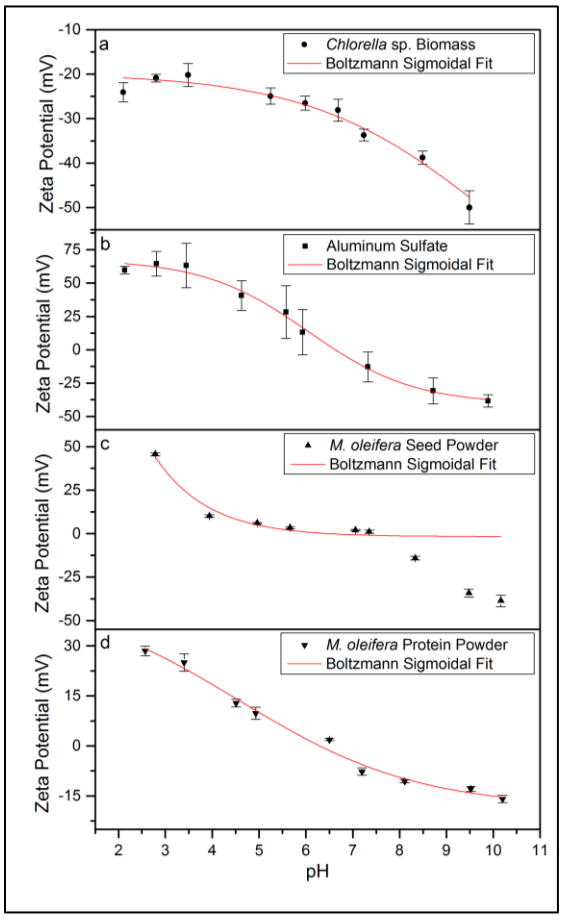

Figure 2. Zeta potential values of *Chlorella* sp. (a), aluminum sulfate (b), *M. oleifera* seed powder (c) and *M. oleifera* protein powder (d) at various pH fitted with Boltzmann Sigmoidal Model.

Through the model fittings, it was found that the initial zeta potential values were respectively -19.78, 62.69 and 32.88 mV for *Chlorella* sp., alum and *M. oleifera* protein powder. Whereas, the predicted final zeta potential values were respectively -83.01, -41.58 and -18.96 mV. The zeta potential of *M. oleifera* seed powder however could not be fitted with the sigmoidal model which yield R^2-value of 0.6962. In order to harvest the *Chlorella* sp. biomass, the coagulants were mixed at various coagulant dosages with the microalgae biomass undergoing flocculation assay and also yielded the mixed suspension zeta potential values and flocculation performance which were removal efficiency and biomass recovery, which were shown in Figure 3 and Figure 4, respectively.

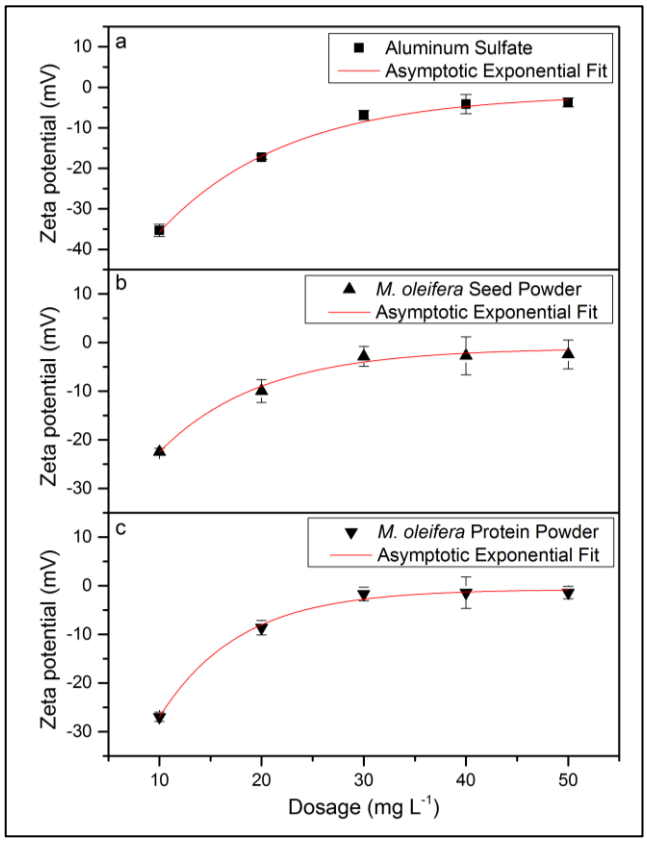

Figure 3. Zeta potential values of *Chlorella* sp. suspension mixed with aluminum sulfate (a), *M. oleifera* seed powder (b), *M. oleifera* protein powder (c) at various coagulant dosages fitted with Asymptotic Exponential Model.

The observed zeta potential values were further analyzed through fitting with the Asymptotic Exponential Model to optimize the coagulant dosage. It was found that the mixed suspension of *Chlorella* sp. with *M. oleifera* protein powder yield the highest i.e.p. of -0.74 mV as compared to -1.13 and -1.62 mV respectively for *M. oleifera* seed powder and alum at the dosage of 50 mg·L^{-1}. Higher i.e.p. values of *M. oleifera* seed protein suggested that it would have better flocculation rate as compared to *M. oleifera* seed powder and alum. In addition, *M. oleifera* protein powder also had the highest response range of 94.50 mV whereas *M. oleifera* seed powder had the lowest zeta potential response range of 58.23 mV as dosage increased from 0 mg·L^{-1} to 50 mg·L^{-1}. Aluminum sulfate showed the highest rate of 0.92 mV per mg·L^{-1} increase of coagulant followed by *M. oleifera* seed powder and seed protein, respectively 0.90 and 0.88 mV per mg·L^{-1}. This value shows that the ζ-potential value of *Chlorella* sp. was highly correlated to the dosage of coagulant used. The addition of dosage cause the value of ζ-potential increase. The

increasing of ζ-potential value indicate the disturbance on the stability of microalgal cells suspension. This is due to the charge neutralization of negatively charged cells with the addition of positively charged coagulants. Same trend was also observed by Muyibi et al. [15] which stated that the gradual decreased in biomass recovery was due to over dosage that led to restabilization of the destabilized suspended solids which previously had agglomerated into flocs.

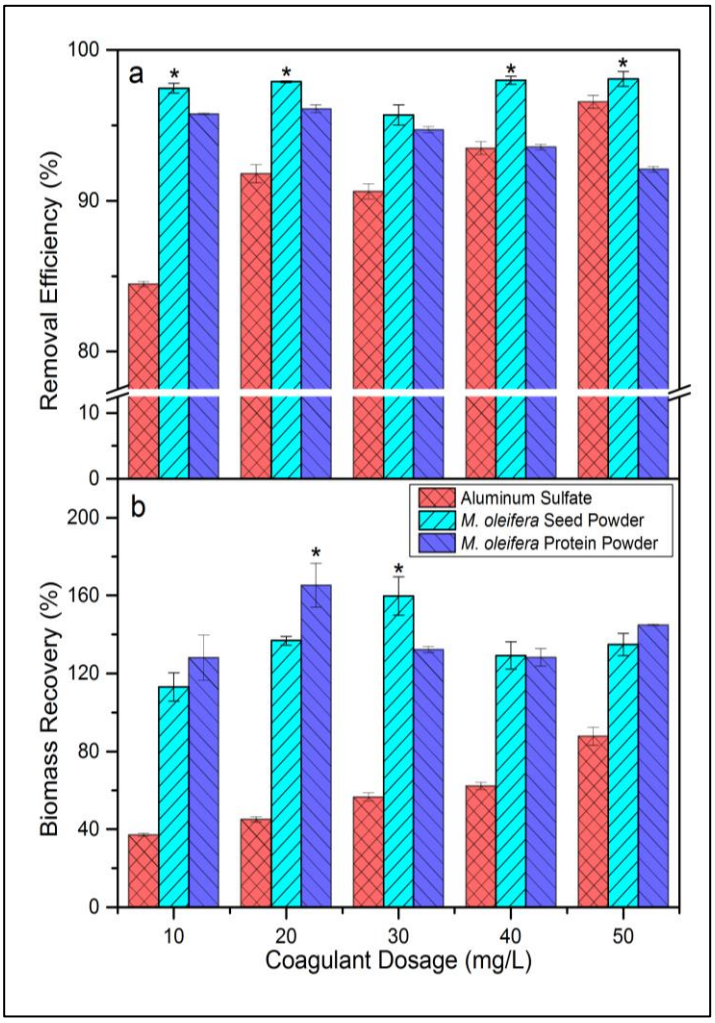

Figure 4. Removal efficiency (a) and biomass recovery (b) of aluminum sulfate, *M. oleifera* seed powder and *M. oleifera* protein powder at various coagulant dosages. Treatment with the significantly highest values was marked with asterisk (*).

Flocculation assays

Flocculation performance of coagulant consisted of removal efficiency and biomass recovery. Removal efficiency is the effectiveness of coagulant in removing the suspended particles from the water column producing a clear supernatant. Meanwhile, biomass recovery is its proficiency in aggregating, settling and compacting the suspended particles at the bottom of the jar test vessel. Figure 4 showed the removal efficiency and biomass recovery of alum, *M. oleifera* seed powder and *M. oleifera* seed derivatives with regards to various coagulant dosage of 10 to 50 $mg \cdot L^{-1}$. *M. oleifera* seed powder achieved significantly highest ($P<0.05$) removal efficiency of above 97% at coagulant dosage of 10, 20, 30, 40 and 50 $mg \cdot L^{-1}$ as compared to other coagulants. The removal efficiency of alum

increased as dosage were increased but *M. oleifera* protein powder showed opposite trend. It could be observed that the maximum removal efficiency for *M. oleifera* protein powder was 96.09% at dosage of 20 $mg \cdot L^{-1}$ and decreased to 92.08% as the dosage increased to 50 $mg \cdot L^{-1}$. *M. oleifera* seed powder however showed consistent removal efficiency among various dosages. All coagulants showed increased biomass recovery as the dosage was increased up to 50 $mg \cdot L^{-1}$. *M. oleifera* protein powder had the significantly highest biomass recovery of 207.46% as compared to other coagulants. *M. oleifera* seed powder, however only showed increased biomass recovery at the dosage of 10 to 30 $mg \cdot L^{-1}$ with the maximum percentage of 159.78%. At the dosage of 40 $mg \cdot L^{-1}$, the biomass recovery decreased at 30.48%. This negative relationship could be explained by the continuous addition of coagulant exceeding the optimum dosage which leads to the formation of excess coagulant residue since all of the available suspended microalgae already formed larger colloids [6].

Table 2 shows the coefficients for Asymptotic Exponential Model with the R^2-value of 1.4443, 0.3026 and 0.4537 for *Chlorella* sp. suspension with aluminum sulfate, *M. oleifera* seed powder and *M. oleifera* protein powder, respectively. In addition, the output of the flocculation assays showed the ability of *M. oleifera* seed extracts not only in harvesting but also concentrate the recovered *Chlorella* sp. biomass for up to 159.78% and 207.46%, respectively for *M. oleifera* seed powder and *M. oleifera* protein powder. The performance of *M. oleifera* seed powder was confirmed by Teixeira et al. [4] which reported its performance in harvesting marine microalgae from cultivation medium with the removal efficiency of more than 90%. Nevertheless, other research involving the investigation on *M. oleifera* protein powder was still lacking.

Table 2. Asymptotic exponential parameters of zeta potential at various pH for mixed suspension of microalgae, *Chlorella* sp. with coagulants.

Microalgae + Coagulants	**Reduced Chi-Square**	**Adjusted R-Square**	**Asymptotic Exponential Fit**		
			Asymptote, a	**Response Range, b**	**Rate, c**
Chlorella sp. + Aluminum Sulfate	1.4443	0.9844	-1.6233 ± 1.7103	75.8976 ± 8.6003	0.9232 ± 0.0096
Chlorella sp. + *M. oleifera* Seed Powder	0.3026	0.9919	-1.1332 ± 1.6076	58.2269 ± 10.3332	0.9046 ± 0.0212
Chlorella sp. + *M. oleifera* Protein Powder	0.4537	0.9952	-0.7401 ± 0.8427	94.5035 ± 14.6837	0.8799 ± 0.0151

Correlation of zeta potential values and flocculation performance

Prior to the correlation analysis, the zeta potential values of mixed suspension of *Chlorella* sp. and coagulants were fitted with the Asymptotic Exponential Model yielding the i.e.p. value (asymptote), zeta potential response range and rate of zeta potential change regarding dosage. Figure 5 shown the correlation of zeta potential and biomass recovery. *M. oleifera* protein powder showed the highest correlation between the zeta potential values and mean biomass recovery with the R^2 value of 0.9565. This was followed by alum and *M. oleifera* seed powder with R^2-value of 0.7920 and 0.7059, respectively. For alum, biomass recovery decreased beyond the dosage of 30 $mg \cdot L^{-1}$ which was inconsistent with the measured zeta potential. Same trend was also observed by Muyibi et al. [5], which stated that the gradual decreased in biomass recovery was due to over dosage that led to restabilization of the destabilized suspended solids which previously had agglomerated into flocs.

Correlation of zeta potential values and flocculation performance involved the use of zeta meter and only jar tests in which only coagulation/flocculation and settling processes were employed. It is therefore recommended that investigations be carried out through pilot plant studies which involves continuous biomass harvesting and various unit operations and processes employed for mass microalgae cultivation. Some studies reported that flocculation of microalgae can occur spontaneously without the need for chemicals, referred to as autoflocculation which can be

induced by increasing the medium pH [16]. According to Harith et al. [17], harvesting efficiency of *Chaetoceros calcitrans* of higher than 90% was achieved by adjusting the culture pH to 10.2 using either NaOH or KOH. The alteration of pH of the culture medium lead to the changes in the zeta potential and hence reduce the colloidal stability. In this study, the addition of coagulant dosage reduce the zeta potential of the microalgae colloidal and increased the biomass recovery percentage. On the other hand, the usage of non-toxic organic polymer, such as polyacrylamide copolymers, chitosan, and cationic starch have been intensively investigated for large-scale applications [18,19]. Unfortunately, they are not economical for microalgae due to its higher price. The coagulant residuals in both algal biomass and harvested water are not only negative for downstream processing but also reduce the possibilities for culture medium recycling.

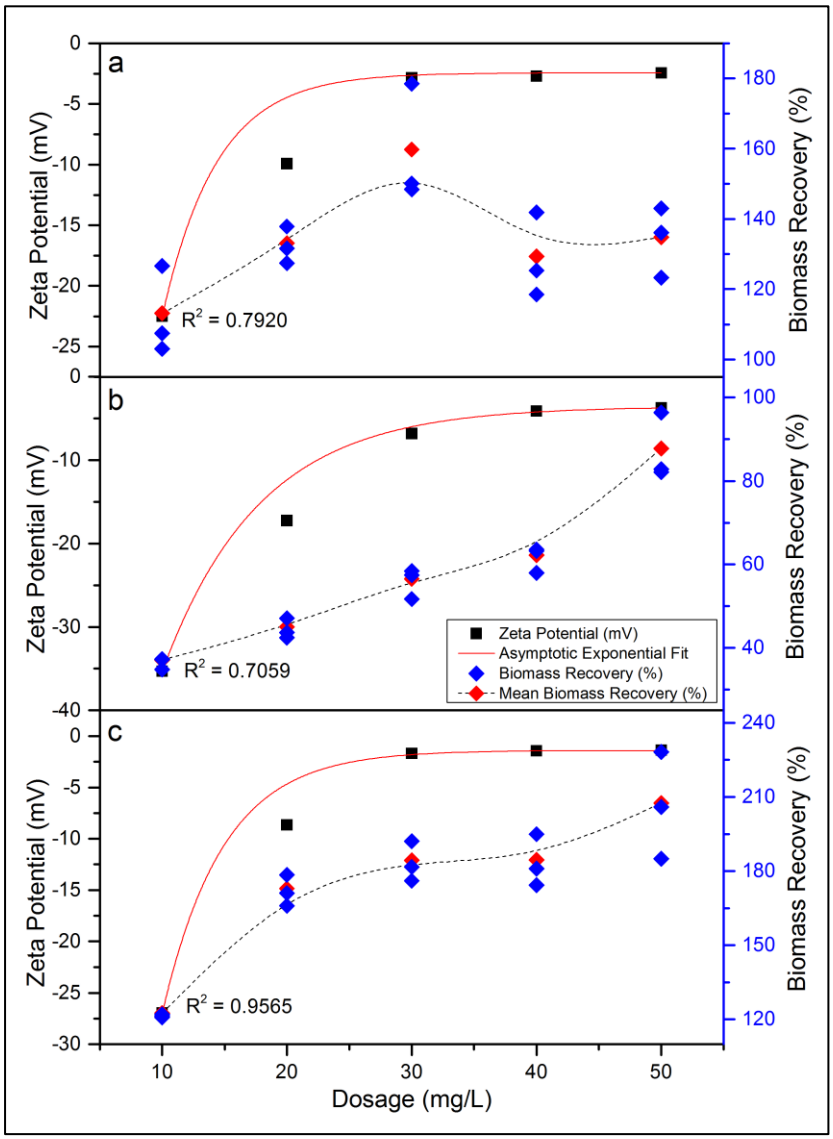

Figure 5. Correlation curves between zeta potential values and biomass recovery of aluminum sulfate (a), *M. oleifera* seed powder (b) and *M. oleifera* protein powder (c).

Conclusion

In addition to the traditional practice of conventional water treatment, *M. oleifera* seed and protein powder as bio-flocculant was proven to be a highly potential alternative to the chemical flocculant in harvesting microalgae *Chlorella* sp. biomass from the culture medium. Indeed, both *M. oleifera* seed derivatives had a higher removal efficiency and biomass recovery as compared to alum even at low dosage. *M. oleifera* seed derivatives were also found to concentrate the density of harvested microalgae to about twofold the initial density. It was also found that the application of the zeta potential determination to predict the flocculation performance of coagulant was probable since both value was highly correlated. Further investigation on the interaction of the zeta potential of *M. oleifera* seed derivatives on the flocculation of different microalgae species is highly recommended. The use of *M. oleifera* seed derivatives as bio-flocculant could assist in lowering the economic cost and providing environmentally-friendly approach for mass microalgae cultivation and the sustainable development of bio-based renewable energy in the future.

Abstract

The aim of this study is to evaluate chemical and biological profile of methanol extracts from Malaysian propolis produced by two commonly found stingless bee species, *Heterotrigona itama* (MHI) and *Geniotrigona thoracica* (MGT). Test samples were analyzed for physicochemical parameters such as moisture, fat, crude fibre, crude protein, carbohydrate and ash content. Tests for phytochemical screening by thin layer chromatography of both extracts revealed that presence of terpenoids, flavonoids, phenols and essential oils but steroids, saponin and coumarins only occur in MHI. Both extracts displayed a characteristic profile and vary from each other. Accordingly, MHI possess higher antioxidant activity with an IC_{50} of 15.0 ± 0.21 ug/mL compared to MGT with IC_{50} of 270.0 ± 0.19 ug/mL. MHI showed moderate nitric oxide scavenging activity, while MGT only showed mild inhibition. Antidiabetic activity was determined by α-glucosidase inhibition and found significantly better than that of acarbose (positive control). In conclusion, data gathered in this study revealed that bee species play role in determining the chemical and biological profile of particular propolis and should put into account in decision of further development for propolis.

Keywords: physico-chemical, phytochemical, TLC profiling, antioxidant, antidiabetic

Abstrak

Tujuan kajian ini adalah untuk menilai profil kimia dan biologi ekstrak metanol propolis dari Malaysia yang dihasilkan oleh dua species lebah kelulut yang biasa dijumpai, *Heterotrigona itama* (MHI) dan *Geniotrigona thoracica* (MGT). Sampel telah dianalisis untuk parameter fizikokimia seperti kelembapan, lemak, serat kasar, protein mentah, karbohidrat dan kandungan abu. Pemeriksaan keatas analisis fitokimia menggunakan kromatografi lapisan nipis untuk kedua-dua ekstrak menunjukkan kehadiran terpenoid, flavonoid dan minyak pati tetapi steroid, saponin dan coumarin hanya wujud dalam MHI. Kedua – dua ekstrak menunjukkan profil yang berbeza antara satu sama lain. Sehubungan itu juga, MHI mempunyai aktiviti antioksidan yang lebih tinggi dengan IC_{50} 15.0 ± 0.21 ug/mL berbanding MGT (270.0 ± 0.19 ug/mL). MHI menunjukkan aktiviti perencatan nitrik oksida yang sederhana, sementara MGT menunjukkan perencatan yang sedikit sahaja. Aktiviti antidiabetik telah ditentukan menggunakan perencatan α-glukosida dan didapati lebih baik secara signifikan daripada acarbose (kawalan positif). Kesimpulannya, data yang dikutip dalam kajian ini menunjukkan bahawa spesies lebah memainkan peranan dalam menentukan profil kimia dan biologi propolis tertentu dan perlu dipertimbangkan dalam membuat keputusan untuk pembangunan propolis.

Kata Kunci: fisikokimia, fitokimia, profil KLN, antioksidan, antidiabetik

Introduction

Propolis is a complex resinous substance manufactured by stingless bees and these resins are used to line the inside of nest cavities and reduce the size of hive entrances. The composition of propolis depends on the type of plants accessible to the bees. Propolis has a wide range of biological activities, as antibacterial [1], anti-inflammatory [2], antiulcer [3], antioxidant [4], hepatoprotective [5], and tumoricidal [6] activities and high repellent index against ants [7]. It is generally accepted that bees collect resinous plant materials, produced by a variety of botanical processes, in different parts of plants.

The specificity of local flora is responsible for the chemical composition of propolis [8]. The chemical compositions and biological activities of propolis are attributed to plant sources, geographical area and collecting season [9, 10]. Since bees use the natural available vegetation to create propolis, there is a high variability in the composition of propolis [11]. Propolis has over 150 constituents and its rich in biochemical constituents, including mostly a mixture of polyphenols, flavonoid aglycones, phenolic and ketones [12]. The most studied component was flavonoids and phenolic compounds and they have been reported as the types of antioxidant that possess a strong inhibitory effect against lipid oxidation through radical-scavenging. Besides that, contents of flavonoid and other phenolic substances have been suggested to play a preventative role in the development of cancer and heart disease [13, 14].

In Malaysia, research in propolis has been carried out sparsely. Until now, there are only some preliminary investigations on the composition and biological activity of Malaysian propolis from stingless bee. The present study is an attempt to investigate the physicochemical, preliminary phytochemical, TLC profiling and biological activity of two methanol extracts of propolis that produced from MHI and MGT. Data generate from this study will be a basis of future work on development of Malaysian propolis for health-related products.

Materials and Methods

Chemicals and reagents

DPPH and Folin-Ciocalteu's reagent (Sigma-Aldrich). Sodium carbonate (Na_2CO_3), aluminium chloride ($AlCI_3$), sodium nitrite ($NaNO_2$), and sodium hydroxide (NaOH) were aquired from Merck, Germany. Methanol was used as a solvent for the preparation of samples, toluene, ethyl acetate and formic acid (8: 2: 0.1) used as mobile phase for TLC analysis. All chemicals used were of analytical grade.

Collection and preparation of propolis

Propolis used in this study was collected from AGROPOLIS Apiary, Agriculture Production and Food Innovation Research Institute (AGROPOLIS UniSZA), Universiti Sultan Zainal Abidin. Each sample was cleaned and froze in -20°C, then ground to powder. Propolis extract was prepared by infusing 7 g of crude propolis in 70 mL of 80 % v/v methanol solution for at least 3 days. The extracts were filtered and dried under pressure using rotary evaporator. Crude propolis and extracts were kept cool (-20 °C) prior analysis. Propolis produced by *H. itama* coded as MHI and propolis produced by *G. thoracica* coded as MGT.

Physicochemical analysis

MHI and MGT of propolis were subjected for determination of physicochemical parameters such as moisture, fat, crude fibre, crude protein, carbohydrate and ash content were carried out according to the methods described in pharmacopoeia [17, 18]

Phytochemical screening by Thin Layer Chromatography

MHI and MGT of propolis extracts were screened for the presence of various classes of compounds according to the standard screening method [19] using thin-layer chromatography (TLC) with silica gel G (Merck $60F_{254}$) plates of 0.05 mm thickness. The extracts were dissolved in methanol, while the development of the plate was carried out using mobile systems toluene: ethyl acetate: formic acid (8: 2: 0.1 v/v) for MHI and MGT extracts. After development, the plates were sprayed by various chemical reagents such as anisaldehyde, vanillin-sulphuric acid and iodine for detection of the respective classes of compounds.

DPPH free radical-scavenging activity

The ability of MHI and MGT to scavenge 2,2-diphenyl-1-picrylhydrazyl (DPPH) was determined by DPPH free

radical scavenging activity assay. The scavenging effect of extracts for DPPH was performed based on the method described [20] with a slight modification. Quercetin was used as positive control. One mili Molar of DPPH solution was prepared by diluting 3.94 mg DPPH in 10 mL methanol. 200 µL of standard and sample solution (800, 400, 200,100, 50, 25, 12.5 and 6.25 µg/mL) were added into a 96 well micro plate. Then, 50 µL of 1 mM DPPH solution was mixed into each well and were left at room temperature in the dark place for 30 minutes. After 30 minutes of incubation period, the absorbance was read at 517 nm by Elisa reader spectrophotometer. The blank sample is 200 µL methanol and 50 µL of 1 mM DPPH. All sample extracts were made in triplicate. The ability of different propolis extracts and positive controls to scavenge the DPPH free radical was calculated using the formula, as shown in equation below:

$$\text{Inhibition \%} = [(A_{Blank} - A_{Sample})/ A_{Blank}] \times 100\ \% \quad (1)$$

A_{Blank} is the absorbance of 1 mM of DPPH solution with methanol while A_{Sample} is the absorbance of the propolis sample extracts and positive control solution. The lower absorbance indicates a higher scavenging activity followed by decreasing the intensity of purple to yellow colour. The radical scavenging activities of crude extracts were interpreted via IC_{50} values. The IC_{50} is a concentration that can scavenge the 50 % of DPPH free radical.

Nitric Oxide assay

The nitric oxide (NO) scavenging activity of the extract was measured according to the method described by Ho et al. [21]. 50 µL of propolis extracts were added into 50 µL of 10 M sodium nitroprusside solution in 96-well flat-bottomed plate and then incubated under light at room temperature for 90 min. Finally, an equal volume of Griess reagent (1 % of sulphanilamide and 0.1 % of naphthylethylenediamine in 2.5 % HPO_3) was added to each well to measure the nitrite content immediately at 546 nm. L-ascorbic acid was evaluated as a reference standard. All experiments were carried out in triplicate. The percentage scavenging activity was calculated as described for DPPH assay.

Antidiabetic activity

The enzyme inhibition activity for α-glucosidase was assessed according to the method described by Sancheti et al. [22] with minor modifications to determine the potential of MHI and MGT propolis extract for antidiabetic activity. The reaction mixture contained 50 µL of 0.1 M phosphate buffer (pH 7.0), 25 µL of 0.5 mM 4-nitrophenyl α-D-glucopyranoside, 10 µL of extract sample at various concentrations and 25 µL of α-glucosidase solution (0.2 Unit/mL). This reaction mixture was then incubated at 37 ^{0}C for 30 min. The reaction was terminated by adding 100 µL of 0.2 M sodium carbonate solution. The enzymatic hydrolysis of substrate was monitored by the amount of p-nitrophenol released in the reaction mixture at 410 nm using microplate reader. Individual blanks were prepared for correcting the background absorbance, where the enzymes were replaced with buffer. Controls were conducted in an identical manner replacing the extracts with methanol. Acarbose was used as positive control. All experiments were carried out in triplicates. The inhibition percentage of α-glucosidase was assessed by the following formula:

$$\text{\% Inhibition} = [\ 1 - (\text{sample absorbance} / \text{control absorbance})] \times 100 \quad (2)$$

Statistical analysis

Triplicate determinations, mean and standard deviation were calculated. Calibration curve of standard was obtained for concentration versus absorbance. All data were subjected for analysis using independent variable t-test.

Results and Discussion

Physicochemical evaluation

Bees produce propolis as part of their defense system in order to protect their hive from invaders and microbial attacks. In this study, we collected propolis produced by two different species of stingless bees, *H. itama and G. thoracica* from our Apiary. Even though the location was the same and the distance between hives of these two species is only few meters apart, the physicochemical content such as moisture, fat, crude fibre, protein, soluble extractive and ash content were markedly different as shown in Table 1. MHI contains noticeable high moisture content compared to MGT, ranged from 9.90 – 23.72 %. The lower of moisture content of MGT could prevent bacterial, fungal or yeast growth through storage [23]. The ash values, total ash was found to be in the ranged from

4.11 – 5.99 %, where MGT contain higher value compared to MHI. Ash values used to determine quality and purity of crude samples. It indicates the presence of various impurities like carbonate, oxalate and silicate. MHI had lower percentage of crude fat content in comparison with MGT. However, in contrast, MGT have a lower carbohydrate content but slightly higher in fibre. Meanwhile, protein content of both samples was in close range, 2.17 – 3.87 %. The differences of MHI and MGT physicochemical content might due to vegetation preferences of the bee species [14].

Table 1. Physicochemical analysis of the methanol extracts propolis produced by stingless bees, *H. itama* (MHI) and *G. thoracica* (MGT) (p<0.05)

Parameter	**MHI**	**MGT**
Moisture (%)	23.72 ± 0.62[1]	9.90 ± 11.82
Ash (%)	4.11 ± 0.67	5.99 ± 0.31
Crude fat (%)	21.43 ± 5.39	73.47 ± 2.75
Crude protein (%)	3.80 ± 0.12	2.17 ± 0.15
Crude fibre (%)	44.36 ± 5.07	67.48 ± 1.50
Carbohydrates (%)	49.60 ± 9.19	8.46 ± 10.32

Chemical fingerprint by Thin Layer Chromatography analysis

Propolis is a complex resinous mixture, which contains approximately 50 % resin that composed of flavonoids and related to phenolic acids regarded as the polyphenolic compounds, 30 % wax, 10 % essential oils, 5 % pollen and 5 % various organic compounds [12]. The chemical composition of propolis reportedly depends on the specificity of the local flora at the site collection and also the vegetation preference of stingless bee species. As seen in Table 2, the chemical compositions of propolis were tested by TLC profiling of MHI and MGT in different chemical reagents for detection of the respective classes of compound. There were three reagent used during this step which were iodine, anisaldehyde and also vanillin. TLC plate was stained with iodine vapor to visualize organic compound since iodine has a high affinity for both unsaturated and aromatic compounds such as polycyclic aromatic compounds, phenolic steroid, ester and alkaloids. Anisaldehyde was used to detect aldehyde, phenol, sugar and terpenes compound. When heated, the TLC plate change to light pink color and other functional groups tend to vary with respect to coloration. Vanillin used for the detection of amines, amino acids, higher alcohols, phenols, and essential oils. The plate also visualized by UV light on wavelength 366 nm. The results obtained from determination of the tests illustrated the presence of terpenoids, flavonoids and essential oils were present in both extracts. However, steroids, saponins and coumarins were absence in MGT but presence in MHI. On the other hand, the previous studies by Buenos et al. [24] were showed that the flavonoids were not found on methanol extract but only presence in the ethyl acetate and hexane extracts of propolis. These constituents may contribute to the MHI and MGT propolis therapeutic effect. Overall, from TLC analysis, the chemical composition and chemical fingerprint of propolis produced by *H. itama* are more complex compare to that of *G. thoracica*.

The differences in the phytochemical screening results of propolis might due to the time of harvest, storage, local flora extraction method [25] and the bee species. Besides using TLC method, analytical techniques such as high performance liquid chromatography (HPLC) and gas chromatography (GC), usually coupled to mass spectrometry (MS) were used to obtain molecular weight, structural information and identification [26]. However, the developed TLC method is a straightforward and efficient way for screening propolis samples at preliminary stage and for quality purposes. It is applicable to qualitatively determine biologically active compounds like flavonoids and others constituents in propolis using the specific detection reagent.

Table 2. Phytochemical tests of the methanol extract propolis produced by stingless bees, *H. itama* (MHI) and *G. thoracica* (MGT)

Constituents	Color detected	MHI	MGT	Chemical / Spray reagent
Terpenoids	Pink	+	+	Anisaldehyde
Flavonoids	Blue fluorescence	+	+	Anisaldehyde
Saponins	Dark bluish	+	-	Vanillin-sulphuric acid
Steroids	Bluish green	+	-	Anisaldehyde
Coumarins	Light blue	+	-	UV 365 nm
Essential oils	Red and brown	+	+	Vanillin-sulphuric acid
All compounds	Yellow-brown	+	+	Iodine

DPPH Free Radical Scavenging Activity of MHI and MGT Propolis.

The antioxidant test was conducted to determine the antioxidant potential of propolis extract, using the DPPH scavenging method. The use of DPPH to scavenge radicals has more advantages which easy to use, have high sensitivity and enabled to analyze of large numbers of samples in a short time. In order to measure antioxidant activity, the reduction of DPPH, a stable free-radical was used to evaluate the antioxidant activity of MHI and MGT propolis at concentrations varying from 6.25-800 µg/mL with quercetin as standards. The results show the variation of inhibition percentage. As shown in Figure 1, quercetin has the highest inhibition percentage (antiradical activity) closely followed by MHI while the MGT has the lowest and the differences is statistically significant.

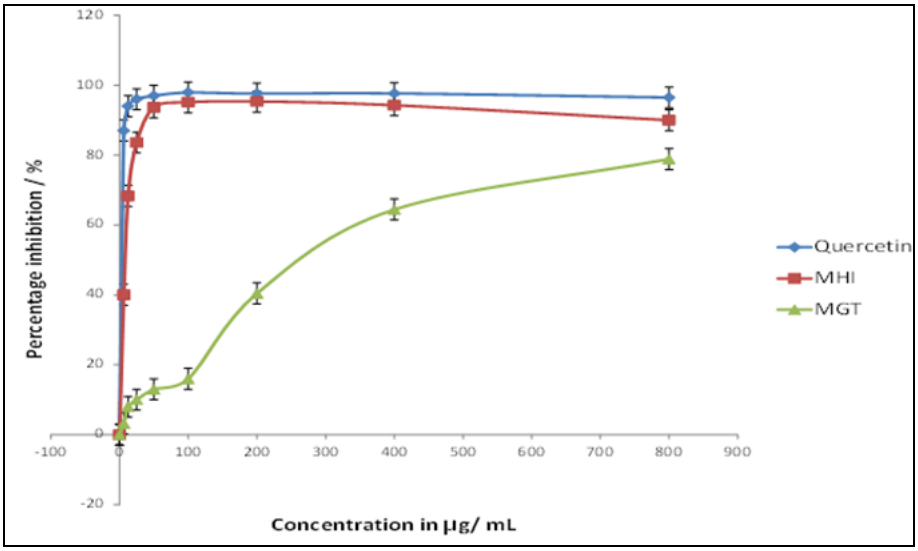

Figure 1. Plot of percentage inhibition against concentration of MHI, MGT and quercetin ($P<0.05$)

The other parameters used for this test is IC_{50} and is defined as the concentration of extract required to capture the DPPH free radical by 50 %. Scavenging activity of MHI is comparable to that of quercetin with IC_{50} of 15 µg/mL and 10 µg/mL, respectively (Figure 2). Meanwhile, MGT only moderately inhibited DPPH scavenging with IC50 of

270 µg/mL (Figure 2). A smaller IC_{50} value of the extract means the higher scavenging activity of the DPPH radical and, therefore, increased activity as an antioxidant. From the results above, propolis produced by MHI shows the higher antioxidant property compared to MGT. The difference in the antioxidant activity might due to the flavonoid content of propolis extracts or other compounds, which are potential antioxidants. As the previous studies by Fuliang et al. [28], the methanol extracts of Peruvian and Netherlands propolis exhibited stronger DPPH free radical scavenging activity than the corresponding water extract. It is due to its phenolic and flavonoid content, which is related to the antioxidant potential. The reasons behind the markedly higher radical scavenging activity exhibited by different types of propolis are probably due to their resin plant origin, climate, and resin collection time by the bees.

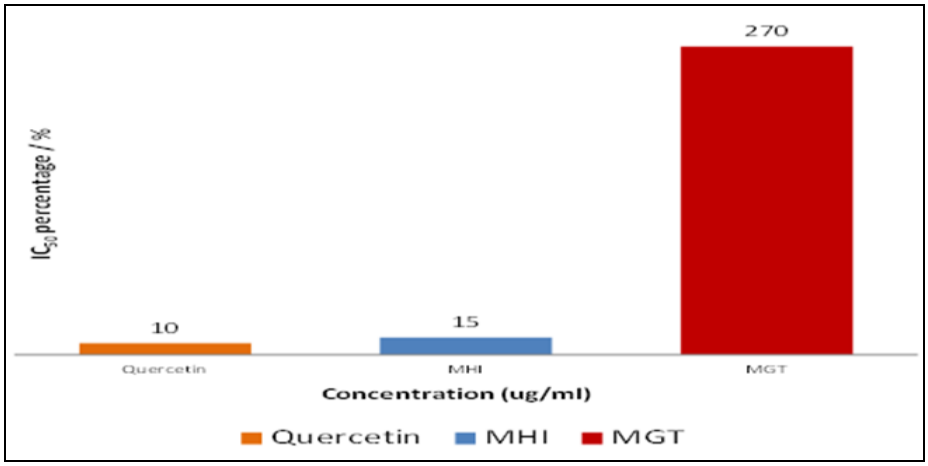

Figure 2. IC_{50} of MHI, MGT and Quercetin by DPPH scavenging method.

Nitric Oxide activity

Nitric oxide is a method to determined the potential of antioxidant that can react with superoxide to form the peroxynitrite anion, which can decompose to produce OH- and NO-. It has also been involved in a variety of biological functions, including neutrotransmission, vescular homeostasis, antimicrobial and antitumor activities. It was based on the principle that sodium nitro-prusside in aqueus solution at physiological pH spontaneously generates nitric oxide which interacts with oxygen to produce nitrite ions that can be estimated using Griess reagent. Scavengers of nitric oxide compete with oxygen leading to reduced production of nitrite ions. Large amounts of NO- may lead to tissue damage [27].

Nitric oxide scavenging activity was performed with MHI and MGT propolis and ascorbic acid as standard compound. The inhibition potential of all samples and standard preparations exhibited dose dependent manner. As shown in Figure 3, ascorbic acid was found more significantly active than both extracts. There is no significant difference between MHI and MGT propolis in the nitric oxide activity. From the graph, it was observed that as concentration increases, the percentage of inhibition scavenging is increasing linearly but constant at 150 µg/mL for all extracts and ascorbic acid (standard preparation). The IC_{50} for ascorbic acid was 30 µg/mL , but there were no scavenging activity at 50 % for MHI and MGT extracts propolis. Previous studies by Myint et al. [27] were found that labdane-type diterpenes, flavonoids and some phenolic compounds possessed potent nitric oxide inhibition activity in water and methanol extracts of Brazilian propolis. That may not be the case for propolis produced by *H. itama* and *G. thoracica*.

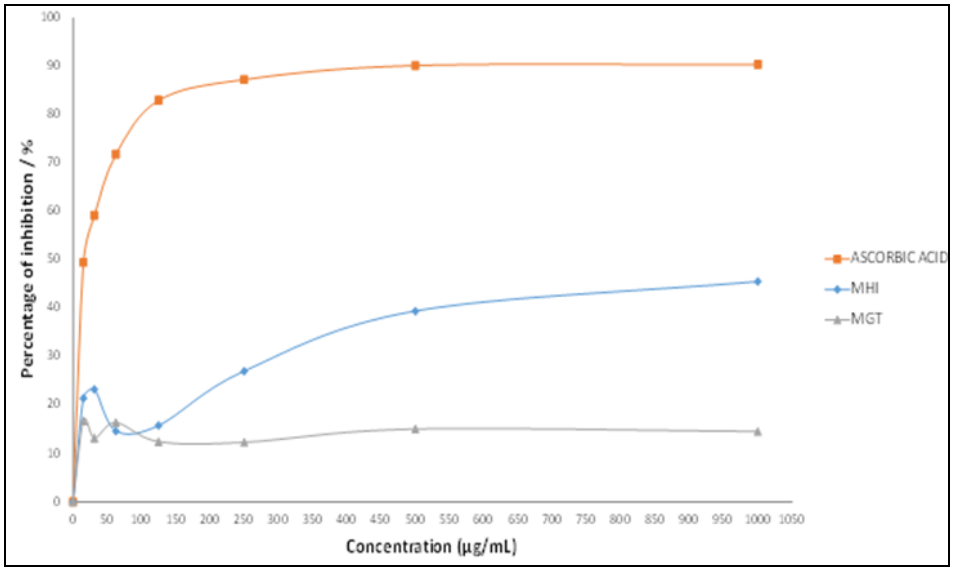

Figure 3. Plot of percentage inhibition against concentration of MHI, MGT and Ascorbic acid (P>0.05)

Antidiabetic activity

In this study, the hypoglycemic potential of both extracts (MHI and MGT) were evaluated by the α-glucosidase inhibition assay. Acarbose was used as positive control. Results were tabulated in Figure 4 and 5 respectively. The IC_{50} was calculated for both extracts and were found significant (P<0.05) than acarbose. These differences in the concentration of propolis extracts may cause the differences in antidiabetic activities between MHI and MGT propolis.The IC_{50} of MHI and MGT were 2.5 µg/mL and 30 µg/mL respectively which were found lower than IC_{50} of acarbose (190 µg/mL). From results, it confirmed that the MHI showed potent antidiabetic potential than MGT and was higher than acarbose (positive control).

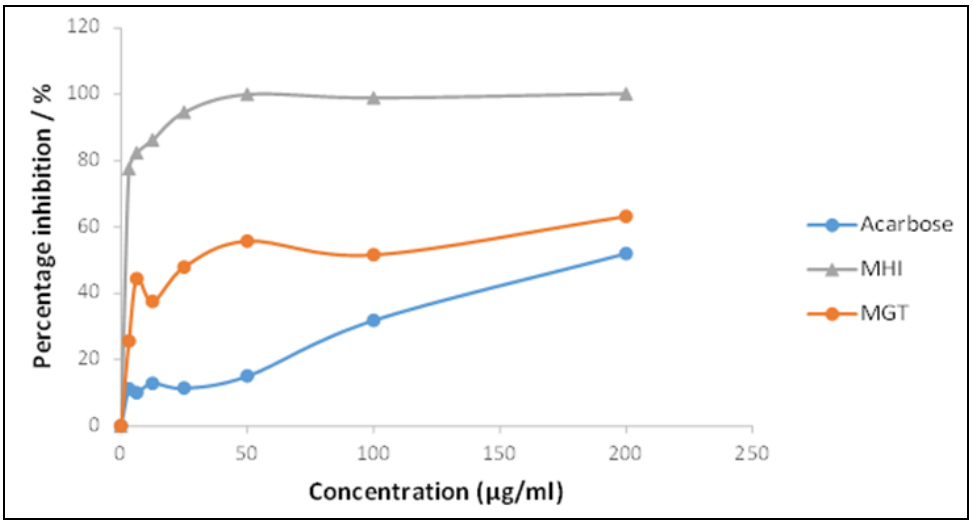

Figure 4. Plot of percentage inhibition against concentration of MHI, MGT and Acarbose (P <0.05)

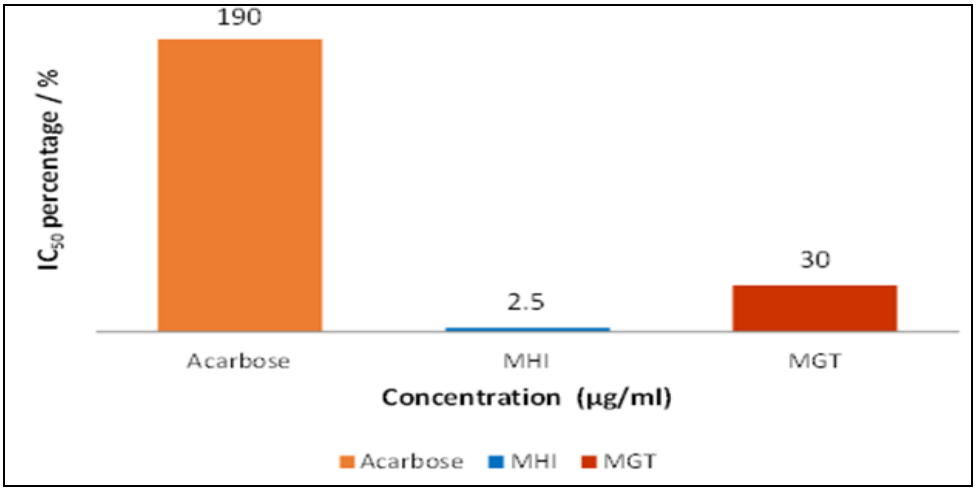

Figure 5. IC_{50} of MHI, MGT and Acarbose by antidiabetic activity

As the previous studies, flavonoids in propolis have an antioxidants activity and are thought to be the compound that is able to lower serum glucose levels through the inhibition of oxidative stress. In addition, the antioxidants activity of propolis can improve insulin receptor signaling in insulin resistant conditions, therefore the insulin sensitivity can be increased [28]. Similarly, result of MHI propolis have higher potential in antioxidant and also antidiabetic activity compare to that of MGT. However, previous reports have demonstrated that a propolis ethanol extract from Brazilian propolis improves insulin sensitivity during the prediabetic and diabetic stages on obese rats [29]. Thus, the chemical composition of propolis was strongly influenced by the source materials, species of bees and also types of the extraction.

Conclusion

From this study, it shows that bee species play role in determining the chemical and biological profile of particular propolis and should put into account in decision of further development for propolis. The data of physicochemical, preliminary phytochemical tests, biological activity and TLC profiling generated in this study will be the basis for authentication, standardization profile and quality control assessment of Malaysian propolis, especially produced by stingless bees, *Heterotrigona itama* and *Geniotrigona thoracia*. Further investigation on identification of marker compounds should be carried out to be use in propolis standardization.

Abstract

Calcium carbonate ($CaCO_3$) microspheres (μ-spheres) are widely used as inorganic templates (or cores) for fabricating nano-engineered microcapsules. Deionized water is commonly used in the fabrication of $CaCO_3$ μ-spheres using precipitation reaction between calcium chloride ($CaCl_2$) and sodium carbonate (Na_2CO_3) solutions under vigorous stirring. However, in the current work distilled water was used throughout the experiments. Furthermore, two simple fabrication approaches, namely membrane filtration and centrifugation approaches, were used in order to understand the effect of different experimental factors on the size and shape of $CaCO_3$ μ-spheres. For the membrane filtration approach, the experimental factors tested included mixing procedure of solutions, stirring speeds, drying techniques, and types of filter paper used. For the centrifugation approach, the experimental factors tested included mixing procedure of solutions, stirring speeds, centrifugation times, drying techniques, and quantity of washing agents used. The size measurements and shape of the $CaCO_3$ μ-spheres were investigated using compound microscopy. Scanning electron microscopy (SEM) was used to observe the fine surface morphological details of the $CaCO_3$ μ-spheres. Overall results indicate that the centrifugation approach can yield better $CaCO_3$ μ-spheres as compared to the membrane filtration approach in terms of narrow size distribution and uniform spherical shape. The fabricated $CaCO_3$ μ-spheres can be used as inorganic templates for fabricating nano-engineered microcapsules.

Keywords: $CaCO_3$ microspheres, scanning electron microscopy (SEM), compound microscopy

Abstrak

Kalsium karbonat ($CaCO_3$) mikrosfera (μ-sfera) digunakan secara meluas sebagai templat bukan organik (atau teras) untuk memfabrikasi mikrokapsul nano-kejuruteraan. Air ternyahion lazim digunakan dalam fabrikasi $CaCO_3$ μ-sfera dengan menggunakan tindak balas pemendakan antara larutan kalsium klorida ($CaCl_2$) dan natrium karbonat (Na_2CO_3) dengan pengacauan yang laju. Namun begitu, dalam kerja-kerja semasa air suling telah digunakan sepanjang eksperimen. Dua teknik fabrikasi yang ringkas, iaitu teknik penapisan membran dan pengemparan telah digunakan untuk memahami kesan faktor eksperimen yang berbeza terhadap saiz dan bentuk $CaCO_3$ μ-sfera. Bagi teknik penapisan membran, faktor – faktor eksperimen yang diuji termasuk prosedur pencampuran larutan, kelajuan pengacauan, teknik pengeringan, dan jenis kertas penapis yang digunakan. Bagi teknik pegemparan, faktor – faktor eksperimen yang diuji pula termasuk prosedur pencampuran larutan, kelajuan pengacauan, masa pengemparan, teknik pengeringan, dan kuantiti agen pembasuhan yang digunakan. Ukuran saiz dan bentuk $CaCO_3$ μ-sfera telah dikaji dengan menggunakan mikroskopi sebatian. Mikroskopi elektron pengimbasan (SEM) digunakan untuk meneliti morfologi permukaan halus $CaCO_3$ μ-sfera. Keputusan kajian menunjukkan bahawa teknik pengemparan mampu menghasilkan $CaCO_3$ μ-sfera lebih baik berbanding teknik penapisan membran dari segi taburan saiz yang kecil dan berbentuk sfera yang seragam. Rekaan $CaCO_3$ μ-sfera boleh digunakan sebagai templat bukan organik untuk fabrikasi mikrokapsul nano-kejuruteraan.

Kata kunci: $CaCO_3$ microsfera, mikroskop elektron pengimbasan (SEM), mikroskopi sebatian

Introduction

Calcium carbonate ($CaCO_3$) microspheres (μ-spheres) have been extensively used as core templates to fabricate nano-engineered microcapsules for drug delivery applications [1, 2]. $CaCO_3$ cores can be easily fabricated and can also be easily dissolved by using ethylenediaminetetraacetic acid (EDTA) after the layer-by-layer (LbL) multilayer self-assembly process [3]. Several different approaches have been used to fabricate $CaCO_3$ μ-spheres or co-precipitated protein-$CaCO_3$ μ-spheres in the nm-μm size range [1, 4–10]. The membrane filtration and centrifugation approaches are two simple and low-cost approaches for fabricating $CaCO_3$ μ-spheres. The membrane filtration approach is based on pressure-driven separation of microspheres from the solution [11]. A vacuum pump can aid in applying pressure (lower than the atmospheric pressure) to the filtration equipment for faster separation. The centrifugation approach is based on centrifugal force-driven sedimentation of microspheres in the solution [12].

Deionized water (with resistivity of 18 MΩ·cm) is commonly used in the fabrication of $CaCO_3$ μ-spheres using precipitation reaction between calcium chloride ($CaCl_2$) and sodium carbonate (Na_2CO_3) solutions under vigorous stirring. However, in the current work distilled water was used throughout the experiments. Furthermore, the easy-to-use membrane filtration and centrifugation approaches were tested in the current work in order to achieve uniformly-shaped $CaCO_3$ μ-spheres with narrow size distribution. Mixing procedure of solutions, stirring speeds, drying techniques, types of filter paper, and centrifugation times are some of the experimental factors that need to be evaluated for their potential to influence the formation of uniformly-shaped and monodispersed $CaCO_3$ μ-spheres [13–15]. Limited details are available in literature regarding the influence of mixing procedure of solutions, stirring speeds, drying techniques, types of filter paper, and centrifugation times on the formation of uniformly-shaped and monodispersed $CaCO_3$ μ-spheres using distilled water. Therefore, the aim of the current work was to gain further knowledge about the influence of experimental factors in preparing uniformly-shaped $CaCO_3$ μ-spheres with narrow size distribution. The knowledge gained from the current work can be used to prepare $CaCO_3$ microtemplates using distilled water for the fabrication of nano-engineered microcapsules.

Materials and Methods

Chemicals

Calcium chloride ($CaCl_2$) (Fisher Scientific UK Ltd., Loughborough, UK), Sodium carbonate (Na_2CO_3) (Nacalai Tesque Inc., Kyoto, Japan) and acetone (RCI Labscan Ltd., Bangkok, Thailand) were purchased and used.

Fabrication of $CaCO_3$ μ-spheres

Two different fabrication approaches, namely membrane filtration and centrifugation approaches, were used in order to prepare uniformly-shaped $CaCO_3$ μ-spheres with a narrow size distribution. In both approaches, precipitation reaction between $CaCl_2$ and Na_2CO_3 solutions was used. The experiments were carried out at room temperature unless specified otherwise.

Membrane filtration approach

The $CaCO_3$ μ-spheres were fabricated by precipitation reaction between $CaCl_2$ and Na_2CO_3 solutions as reported by Petrov et al. [1] with slight modification. Briefly, 20 mL of 0.33 M solutions of $CaCl_2$ and Na_2CO_3 were mixed under vigorous stirring at 900 rpm for 30 s at room temperature. After the stirrer was stopped, the reaction mixture was left without stirring for 10 min. Subsequently, the precipitated $CaCO_3$ μ-spheres were collected and thoroughly washed with 100 mL of distilled water three times followed by acetone one time using membrane filtration system equipped with a filter paper. Finally, the μ-spheres were dried.

Two different mixing procedures, four different stirring speeds, two different drying techniques, and two types of filter paper were carried out in order to understand the effect of these experimental factors on the morphology and size distribution of $CaCO_3$ μ-spheres. The two mixing procedures of solutions used were: Na_2CO_3 solution was added rapidly (directly) to $CaCl_2$ solution and Na_2CO_3 solution was added drop-by-drop (one drop per second) to $CaCl_2$ solution. The four stirring speeds of magnetic stirrer used were: 300 rpm, 600 rpm, 900 rpm, and 1200 rpm

for 30 s at room temperature. The two drying techniques used were: drying in air for 24 h, and drying in oven at 50 °C for 60 min. The two types of filter papers used were: Smith filter paper AO336 with 15-20 μm pore size (Smith Scientific Ltd., UK) and Whatman filter paper with 11 μm pore size (GE Healthcare UK Ltd., UK).

Centrifugation approach

The $CaCO_3$ μ-spheres were fabricated by precipitation reaction between $CaCl_2$ and Na_2CO_3 solutions as reported by Volodkin et al. [16, 17] with slight alteration. Briefly, 20 mL of 0.33 M solutions of $CaCl_2$ and Na_2CO_3 were mixed under vigorous stirring at 900 rpm for 30 s at room temperature. After the stirrer was stopped, the reaction mixture was left without stirring for 10 min. Subsequently, centrifugation washing steps with distilled water for four times were conducted in order to eliminate the unreacted species [18]. The $CaCO_3$ μ-spheres were then washed by centrifugation with acetone twice. Finally the μ-spheres were dried.

Two different mixing procedures, four different stirring speeds, two different drying techniques, two different centrifugation times and two different quantities of washing agents were carried out in order to understand the effect of these experimental factors on the morphology and size distribution of $CaCO_3$ μ-spheres. In the case of first, second, and third experimental factors, parameters similar to the membrane filtration were used. The two centrifugation times (at 1000 rpm) used were: 1 min and 5 min. The two quantities of washing agents (distilled water and acetone) used were: 25 mL and 40 mL.

Characterization of $CaCO_3$ μ-spheres

The shape and size measurements of the $CaCO_3$ μ-spheres were investigated using a compound microscope (Nikon ECLIPSE E100) at 4x, 10x, 40x, and 100x magnification. Powder samples of $CaCO_3$ μ-spheres were used for the compound microscopy experiments. The compound microscope was equipped with Dino-eye (Microscope Eye-Piece Camera) to take the images and DinoCapture 2.0 software to measure the diameters of $CaCO_3$ μ-spheres. The fine surface morphological details of the $CaCO_3$ μ-spheres were observed using a scanning electron microscope (SEM) (JSM-6360 LA JEOL, US).

Data analysis

The statistical analysis to determine the mean and standard deviation of the diameters of $CaCO_3$ μ-spheres was done using SPSS software. Histograms overlaid with a normal distribution curve showing the size distribution of $CaCO_3$ μ-spheres was also done using the same software.

Results and Discussion

For most applications, narrow size distribution and uniform shape of $CaCO_3$ μ-spheres are highly desirable characteristics. In order to achieve the desired μ-sphere characteristics, the experimental factors related with the preparation of μ-spheres using distilled water were studied. For the membrane filtration approach, the experimental factors tested included mixing procedure of solutions, stirring speeds, drying techniques, and types of filter paper used. For the centrifugation approach, the experimental factors tested included mixing procedure of solutions, stirring speeds, centrifugation times, drying techniques, and quantity of washing agents used. The results from the different experimental factors tested (under membrane filtration and centrifugation approaches) in order to understand their influence on the formation of $CaCO_3$ μ-spheres are presented and discussed in terms of shape and size distribution of the μ-spheres in the following sections.

Effect of mixing procedure of solutions

Figures 1a and 1c show the $CaCO_3$ μ-spheres obtained from the rapid addition mixing procedure of solutions that produced spherical shaped μ-spheres. The average size of μ-spheres was 5.93 ± 0.72 μm and 5.33 ± 0.95 μm for membrane filtration and centrifugation approaches, respectively. Compound microscopy results show that the $CaCO_3$ μ-spheres formed clusters when using drop-by-drop addition mixing procedure of solutions (Figures 1b, 1d). The reaction mixture should be mixed rapidly (reactive precipitation) and then left undisturbed for certain time. The solutions were left undisturbed for around 10 min in order to allow the crystal nucleation and growth of $CaCO_3$. The histograms in Figure 2 show that both approaches produced narrow size distributions of $CaCO_3$ μ-spheres; with a positively skewed distribution for the membrane filtration approach.

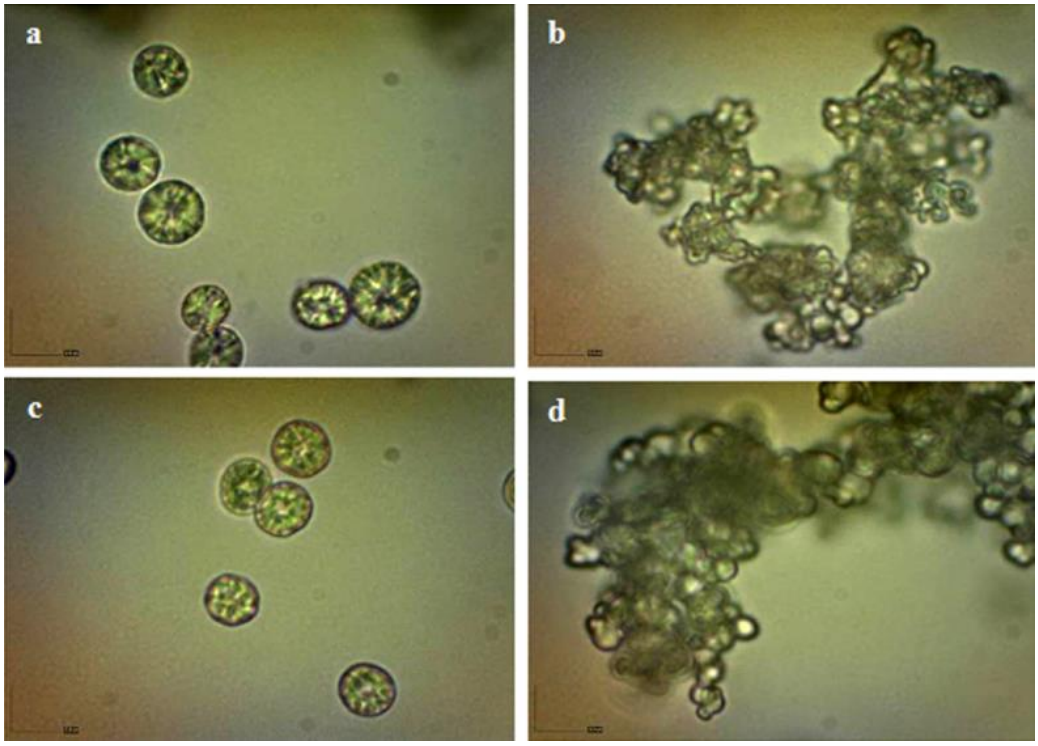

Figure 1. Microscope images of $CaCO_3$ µ-spheres fabricated using different mixing procedures of solutions (a, c) Na_2CO_3 was added directly to $CaCl_2$ and (b, d) Na_2CO_3 was added drop-by-drop to $CaCl_2$. Membrane filtration approach (a, b) and centrifugation approach (c, d) (100x magnification, scale bars indicate 5 µm)

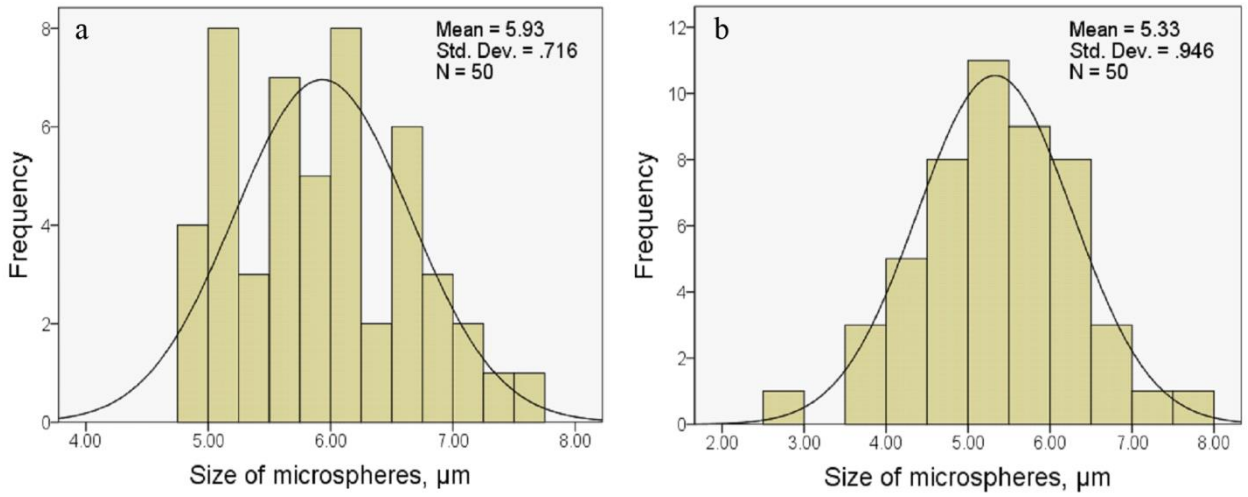

Figure 2. Histograms showing size distribution for $CaCO_3$ µ-spheres fabricated using rapid addition mixing procedure of solutions (a) membrane filtration approach and (b) centrifugation approach

Effect of stirring speed

Compound microscopy images show that the $CaCO_3$ μ-spheres obtained using stirring speeds of 300, 600, and 900 rpm have a mixture of calcite and spherical shapes (Figures 3a, 3b, 3c, 3e, 3f, and 3g). As shown by representative images, it was observed that non-uniform sizes and shapes of $CaCO_3$ μ-spheres were obtained at lower stirring speeds. Uniform shaped $CaCO_3$ μ-spheres were achieved at a stirring speed of 1200 rpm (Figures 3d, 3h), with the average sphere diameters of 4.98 ± 0.57 μm and 7.27 ± 0.78 μm for membrane filtration and centrifugation approaches, respectively. Histograms in Figure 4 show that both approaches produced narrow size distribution of $CaCO_3$ μ-spheres; with a negatively skewed distribution for the centrifugation approach. The results indicate that stirring speed has an effect on the shape and size of the μ-spheres and that higher stirring speed yields better size distribution and spherical $CaCO_3$ μ-spheres, similar to previously reported work [14].

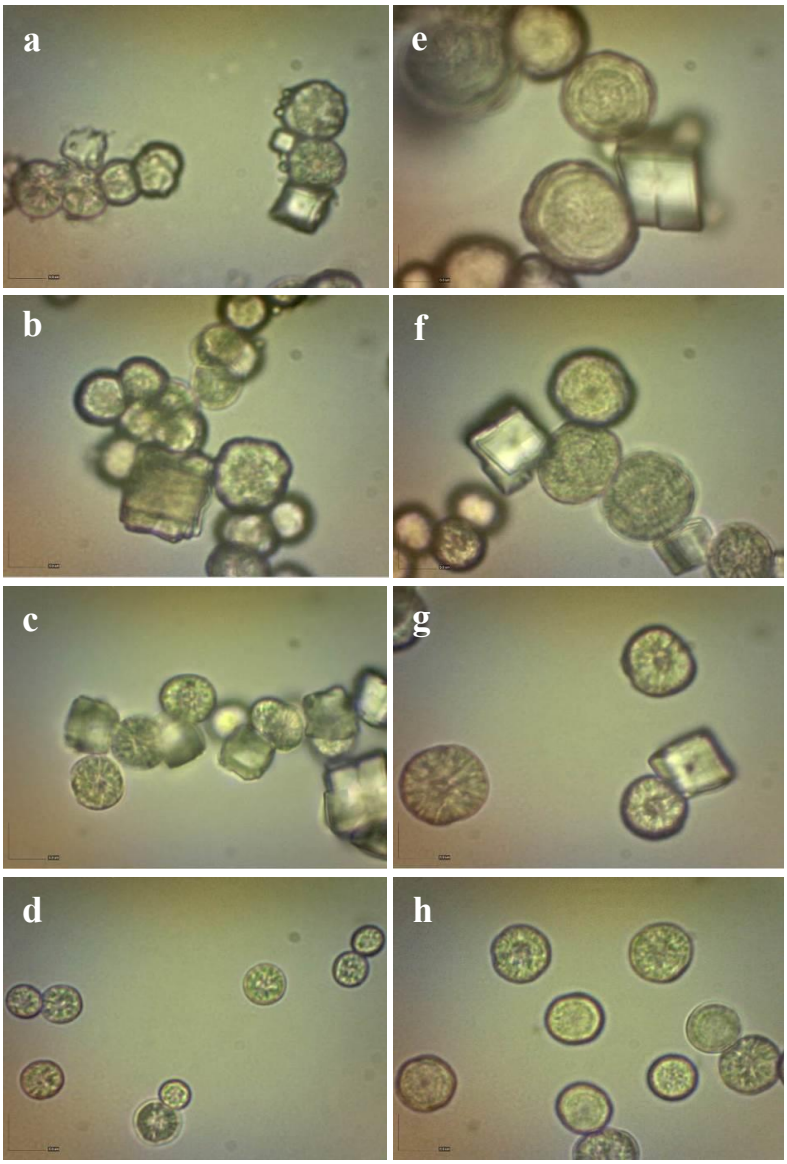

Figure 3. Microscope images of $CaCO_3$ μ-spheres fabricated using different stirring speeds (a, e) 300 rpm, (b, f) 600 rpm, (c, g) 900 rpm and (d, h) 1200 rpm. Membrane filtration approach (a to d) and centrifugation approach (e to h) (100x magnification, scale bars indicate 5 μm)

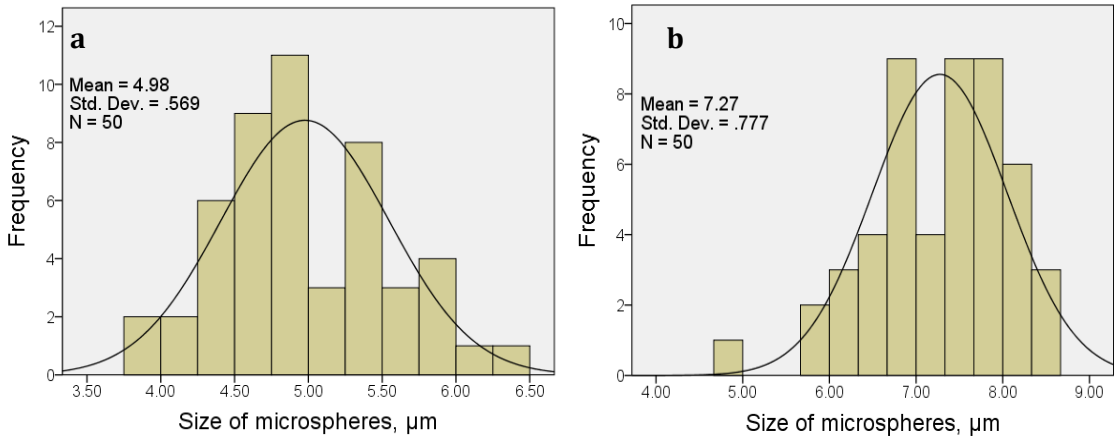

Figure 4. Histograms showing size distribution for $CaCO_3$ µ-spheres fabricated using a stirring speed of 1200 rpm (a) membrane filtration approach and (b) centrifugation approach

Effect of drying technique

The purpose of drying the $CaCO_3$ µ-spheres was to remove physically adsorbed water or acetone from the µ-spheres. Figures 5a and 5c show that spherical shaped $CaCO_3$ µ-spheres were obtained when dried in air. $CaCO_3$ µ-spheres obtained by drying in oven at 50 °C had spherical and calcite shapes (Figures 5b, 5d). The average size of µ-spheres was 6.64 ± 1.64 µm and 5.33 ± 0.95 µm for membrane filtration and centrifugation approaches, respectively. Histograms in Figure 6 show that centrifugation approach produced narrow size distribution of $CaCO_3$ µ-spheres, whereas the membrane filtration approach has a bimodal distribution. The drying technique also influenced the final quantity of $CaCO_3$ µ-spheres. It was observed that the $CaCO_3$ µ-spheres dried in air were heavier than those dried in oven. With the membrane filtration approach, the average weight of $CaCO_3$ µ-spheres obtained by drying in air was 0.95 ± 0.04g and by drying in oven was 0.58 ± 0.13g. Similar results were obtained with the centrifugation approach, where the average weight of $CaCO_3$ µ-spheres by drying in air was 0.50 ± 0.19g and by drying in oven was 0.43 ± 0.15g. Overall, the results indicate that membrane filtration approach yields more quantity of $CaCO_3$ µ-spheres compared to the centrifugation approach, and drying at room temperature provides spherical shaped $CaCO_3$ µ-spheres.

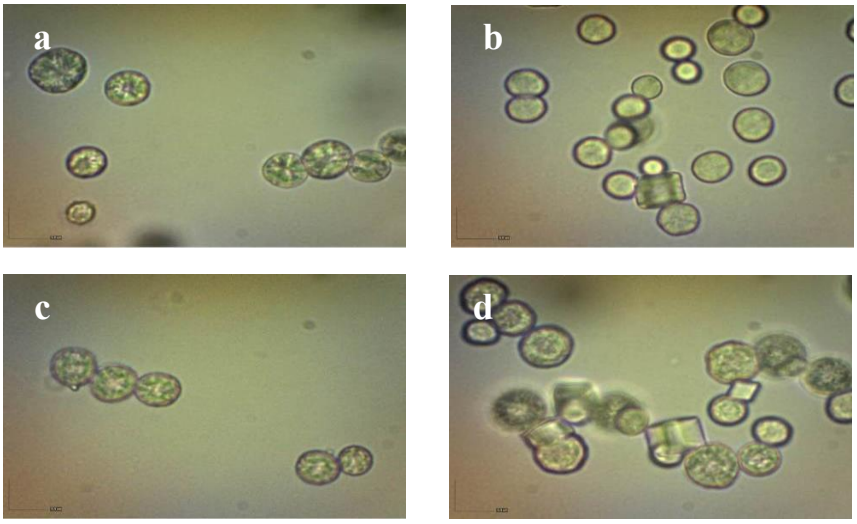

Figure 5. Microscope images of $CaCO_3$ µ-spheres fabricated using different drying techniques (a, c) dried in air and (b, d) dried in oven at 50 °C. Membrane filtration approach (a, b) and centrifugation approach (c, d) (100x magnification, scale bars indicate 5 µm)

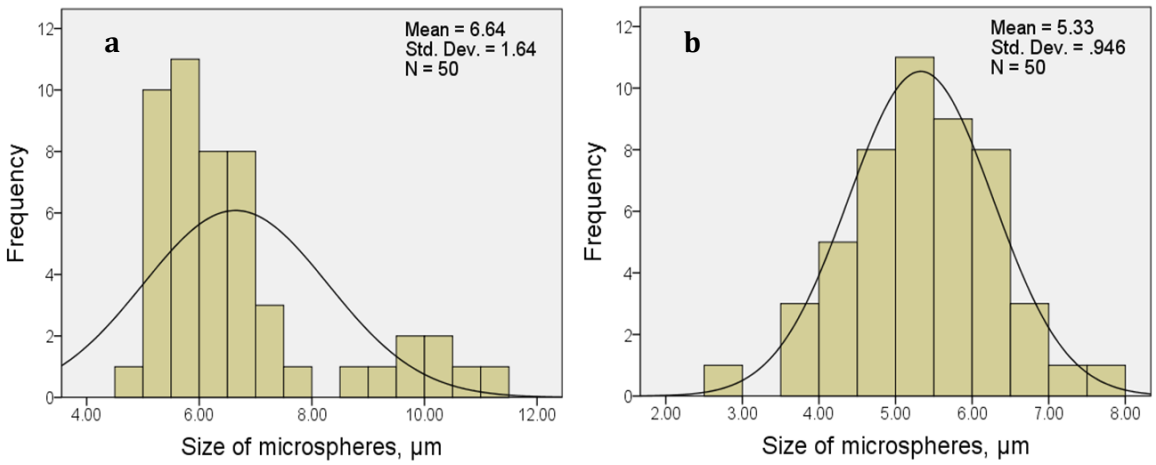

Figure 6. Histograms showing size distribution for $CaCO_3$ µ-spheres fabricated by drying in air (a) Membrane filtration approach and (b) centrifugation approach

Effect of type of filter paper

Figure 7 shows the effect of using different brands of filter paper that have different pore sizes. Compound microscope images show that $CaCO_3$ µ-spheres obtained by using Smith filter paper (with 15-20 µm pore size) had spherical shape and better size distribution (Figure 7a).

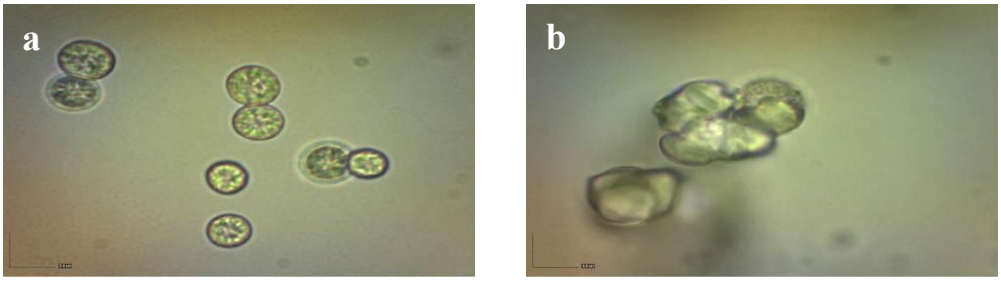

Figure 7. Microscope images of $CaCO_3$ µ-spheres fabricated using different types of filter paper in membrane filtration approach (a) Smith filter paper and (b) Whatman filter paper (100x magnification, scale bars indicate 5 µm)

Images of $CaCO_3$ µ-spheres obtained using Whatman filter paper had irregular particles (Figure 7b). The average size of the µ-spheres was 4.98 ± 0.57 µm by using smith filter paper. Histogram in Figure 8 shows that using membrane filtration system equipped with the smith filter paper yielded a narrow distribution of $CaCO_3$ µ-spheres. The results depict that the smith filter paper used here is more suitable to produce $CaCO_3$ µ-spheres.

Effect of centrifugation time

For centrifugation washing step at 1000 rpm for 1 min, uniform spherical $CaCO_3$ µ-spheres were obtained (Figure 9a); at 1000 rpm for 5 min, agglomeration (clustering) of the $CaCO_3$ µ-spheres was observed (Figure 9b). The average size of the µ-spheres was 5.14 ± 0.68 µm for centrifugation time of 1 min. Histogram in Figure 10 shows a narrow distribution of $CaCO_3$ µ-spheres obtained for centrifugation time of 1 min. The results indicate that a shorter centrifugation time results in spherical shapes and narrow size distribution of $CaCO_3$ µ-spheres.

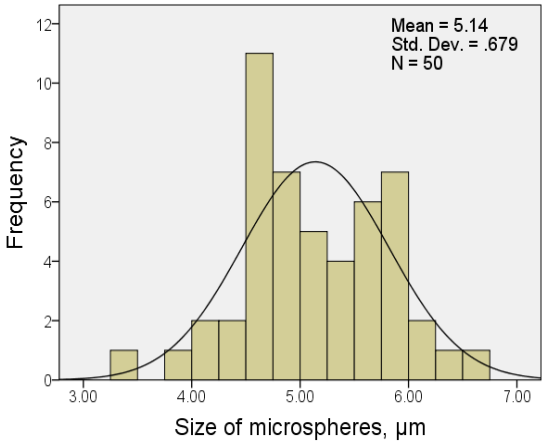

Figure 10. Histogram showing size distribution for $CaCO_3$ µ-spheres fabricated by centrifugation at 1000 rpm for 1 min

Effect of quantity of washing agents

Before drying, the μ-spheres were washed with distilled water and acetone for several times in order to eliminate the unreacted species. Figure 11a shows that spherical μ-spheres with average diameter of 4 ± 0.52 μm were obtained by using 25 mL of washing agents. Figure 11b shows that cauliflower-shaped $CaCO_3$ μ-spheres [19] were obtained by using 40 mL of washing agents. The results might be a consequence of the capacity of the centrifuge tube used; 25 mL of washing agents appeared to be suitable with 50 mL centrifuge tubes used in this study. Histogram in Figure 12 shows narrow distribution of $CaCO_3$ μ-spheres obtained using 25 mL of washing agents.

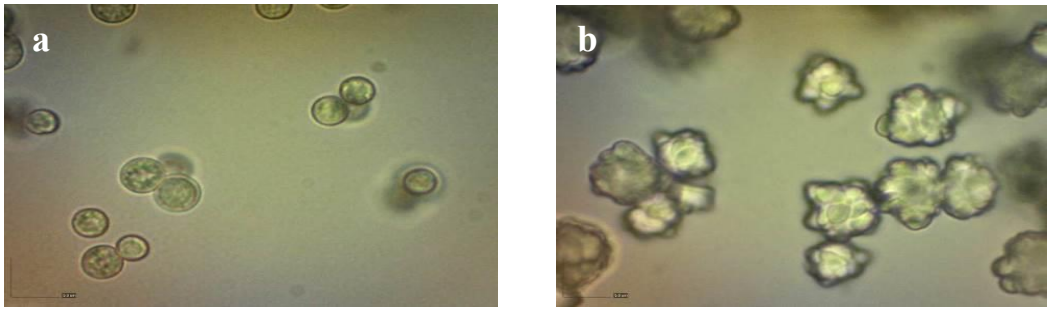

Figure 11. Microscope images of $CaCO_3$ μ-spheres fabricated using different quantity of centrifugation washing agents (a) 25 mL and (b) 40 mL of distilled water and acetone (100x magnification, scale bars indicate 5 μm)

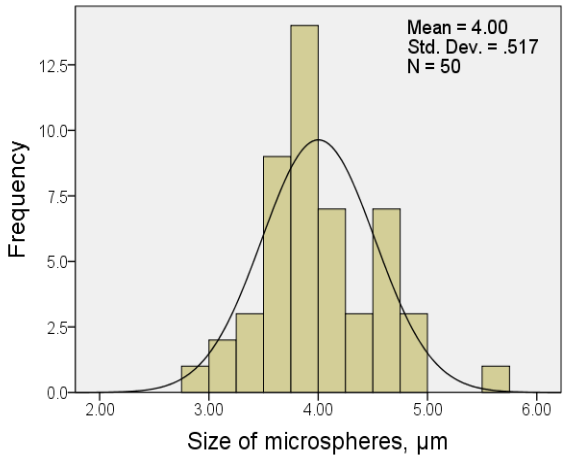

Figure 12. Histogram showing size distribution for $CaCO_3$ μ-spheres fabricated using 25 mL of centrifugation washing agents

Table 1 summarizes the results obtained for the $CaCO_3$ μ-spheres from all the experiments conducted to evaluate the influence of different experimental factors. For each fabrication approach, the experimental factors that yielded the best results were used to fabricate a new set of $CaCO_3$ μ-spheres. For membrane filtration approach (microscopy images shown in Figure 13a) the fabrication conditions used were direct mixing, stirring speed of 1200 rpm, drying in air, and Smith filter paper, whereas for centrifugation approach (microscopy images shown in Figure 13b) the fabrication conditions used were direct mixing, stirring speed of 1200 rpm, drying in air, centrifugation time of 1 min, and 25 mL of centrifugation washing agent. The average size of μ-spheres was 5.14 ± 0.68 μm and 4.81 ± 1.51 μm for centrifugation and membrane filtration approaches, respectively. Based on the final weight of $CaCO_3$ μ-

spheres, membrane filtration approach produced more quantity (average weight of 0.77 ± 0.16g) than centrifugation approach (average weight of 0.59 ± 0.07g). Histograms in Figure 14 show that the centrifugation approach yields better size distribution compared to the membrane filtration approach which has a bimodal distribution. SEM micrographs in Figure 15 show the spherical shaped $CaCO_3$ μ-spheres. The higher magnification micrographs clearly show the typical surface morphology of $CaCO_3$ μ-spheres.

Table 1. Summary of influence of experimental factors on $CaCO_3$ microsphere shape and size

Factor		**Figure**	**Weight (g)**	**Structure/Shape**	**Particle size (μm)**

	40 mL		0.37	Cauliflower-shaped	-[b]

[a]Nearly spherical
–[b]Clustered or agglomeration structure (data not analysed)

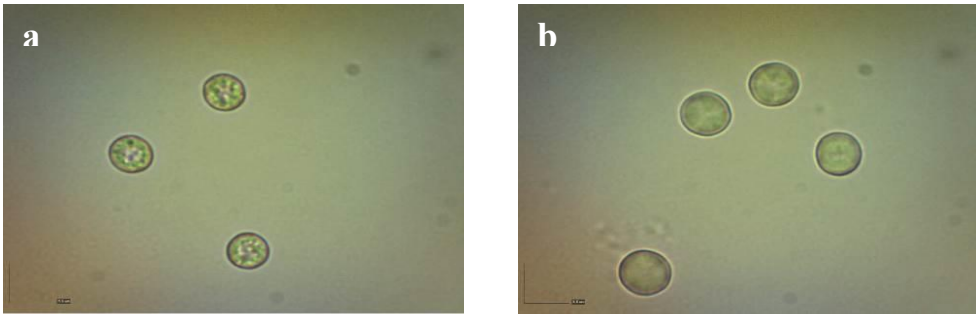

Figure 13. Microscope images of $CaCO_3$ µ-spheres fabricated using (a) membrane filtration approach and (b) centrifugation approach (100x magnification, scale bars indicate 5 µm)

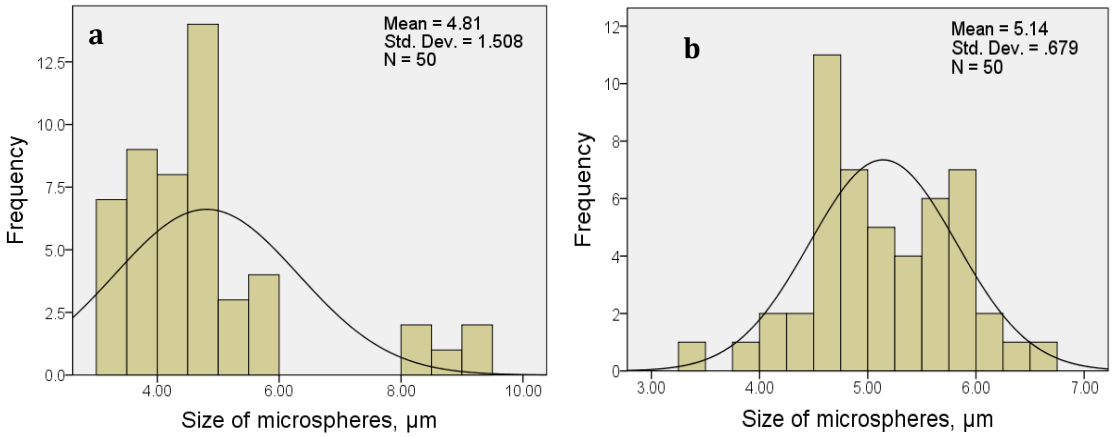

Figure 14. Histograms showing size distribution for $CaCO_3$ µ-spheres fabricated using (a) Membrane filtration approach and (b) centrifugation approach

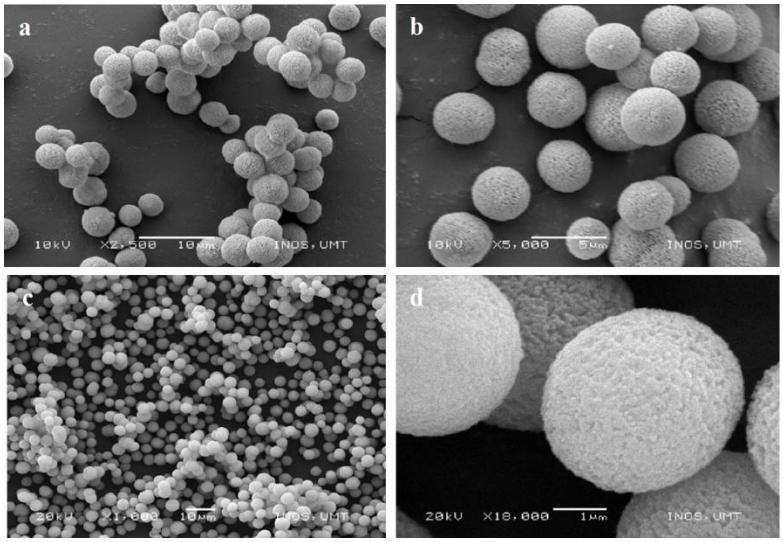

Figure 15. SEM images of $CaCO_3$ µ-spheres (a, b) taken using 10kV, and (c, d) taken using 20kV

Overall, the results indicate that the centrifugation approach can yield better $CaCO_3$ μ-spheres as compared to the membrane filtration approach in terms of uniform spherical shape and narrow size distribution of μ-spheres. These two are the desired characteristics for the $CaCO_3$ μ-spheres that would be used as templates for fabricating nano-engineered microcapsules.

Conclusion

Fabrication of $CaCO_3$ μ-spheres using precipitation reaction between $CaCl_2$ and Na_2CO_3 solutions was carried out using membrane filtration and centrifugation approaches by varying different experimental factors that have important roles in the formation of $CaCO_3$ μ-spheres; with distilled water used throughout the experiments. Better size distribution of $CaCO_3$ μ-spheres was obtained through direct mixing procedure of solutions, 1200 rpm of stirring speed, and drying in air for both the approaches. Also, better size distribution of $CaCO_3$ μ-spheres was obtained through using Smith filter paper in the case of the membrane filtration approach and at 1000 rpm for 1 min centrifugation time, using 25 mL of washing agents in the case of the centrifugation approach. Overall, our results indicate that the centrifugation approach can yield better $CaCO_3$ μ-spheres as compared to the membrane filtration approach in terms of uniform spherical shape and narrow size distribution of μ-spheres. The knowledge from this study will be used to prepare $CaCO_3$ μ-spheres that will act as templates for fabricating nano-engineered microcapsules.

Abstract

Emulsion Liquid Membrane (ELM) process have shown a great potential in wide application of industrial separations such as in removal of many chemicals, organic compounds, metal ions, pollutants and biomolecules. This system promote many advantages including simple operation, high selectivity, low energy requirement, and single stage extraction and stripping process. One potential application of ELM is in the purification of succinic acid from fermentation broth. This study outline steps for developing emulsion liquid membrane process in purification of succinic acid. The steps include liquid membrane formulation, ELM stability and ELM extraction of succinic acid. Several carrier, diluent and stripping agent was screened to find appropriate membrane formulation. After that, ELM stability was investigated to enhance the recovery of succinic acid. Finally, the performance of ELM was evaluated in the extraction process. Results show that formulated liquid membrane using Amberlite LA2 as carrier, palm oil as diluent and sodium carbonate, Na_2CO_3 as stripping agent provide good performance in purification. On the other hand, the prepared emulsion was observed to be stable up to 1 hour and sufficient for extraction process. In conclusion, ELM has high potential to purify succinic acid from fermentation broth.

Keywords: emulsion liquid membrane, purification, succinic acid, formulation, stability

Abstrak

Proses emulsi membran cecair (ELM) telah menunjukkan potensi yang hebat dalam pelbagai aplikasi pemisahan perindustrian seperti pembuangan pelbagai bahan kimia, sebatian organik, ion logam, bahan pencemar, dan molekul biologi. Sistem ini menawarkan banyak kelebihan termasuk operasi yang mudah, sangat selektif, keperluan tenaga yang rendah, dan proses pengekstrakan dan pelucutan dalam satu peringkat. Satu potensi aplikasi ELM adalah dalam proses penulenan asid succinic daripada larutan penapaian. Kajian ini menggariskan beberapa langkah untuk membangunkan proses emulsi membran cecair dalam penulenan asid sussinik. Langkah – langkah tersebut termasuklah formulasi cecair membran, kestabilan ELM, dan pengekstrakan asik sussinik menggunakan ELM. Beberapa pembawa, pelarut, dan agen pelucutan telah ditapis untuk mencari rumusan membran yang sesuai. Selepas itu, kestabilan ELM dikaji untuk meningkatkan perolehan asid sussinik. Akhir sekali, prestasi ELM dinilai dalam proses pengekstakan. Keputusan menunjukkan bahawa rumusan cecair membran menggunakan Amberlite LA2 sebagai pembawa, minyak kelapa sawit sebagai pelarut dan natrium karbonat, Na_2CO_3 sebagai agen pelucutan memberikan prestasi yang baik dalam proses penulenan. Disamping itu, emulsi diperhatikan stabil sehingga 1 jam dan ini mencukupi untuk proses pengekstrakan. Kesimpulannya, ELM berpotensi tinggi untuk mnulenkan asid sussinik daripada proses penapaian.

Kata kunci: emulsi membran cecair, penulenan, asid sussinik, formulasi, kestabilan

Introduction

Two fluid phases can be separated by a barrier called membrane which allow the selective permeation of solute through the barrier [1]. Membrane extraction utilizes either a porous or nonporous polymeric membrane to provide a selective barrier between the feed and the receiving phase. Instead of using solid as membrane material, it is also possible to use liquid as a membrane. Liquid membrane technology is widely applied in different potential area like wastewater treatment, textile industries, electroplating, pulp and paper, pharmaceutical, mining, semiconductor, dairy, food and beverage processing, biotechnology industries, and tanning and leather industries [2-4].

The liquid membrane extraction or commonly known as emulsion liquid membrane (ELM) was introduces as an alternative technique to the liquid-liquid extraction and to the separation by solid polymeric membranes. Basically, ELM is double emulsion produced by emulsifying two immiscible liquid phase (i.e. water droplet in oil or vice versa). Then, the resulting emulsion is dispersed into another external feed phase containing solute to be recovered or removed. The driving force of the solute transport through the membrane is simply the concentration gradient.

ELM offers numerous advantages because of high transport efficiency, economical, relatively low energy consumption, and high extraction efficiency due to large mass transfer surface area available. Besides, ELM also one of the most efficient techniques for separation and concentration process for low concentration of solute [5]. In addition, ELM process involve combination of extraction and stripping process [6]. This combination can remove the equilibrium limitation between the organic and aqueous phase. Besides, with the use of appropriate carrier for transport mechanism, specific molar recognition can be achieved.

An ELM process includes four main steps: (1) emulsification, (2) dispersion and extraction, (3) settling, and (4) demulsification (breaking of the emulsion). In the first step, emulsion is prepared by emulsifying internal phase and membrane phase. Then, the prepared emulsion is dispersed into the external feed phase containing solute to be extracted. After that, settling process is allowed to occur to separate emulsion and feed solution. Then, the membrane phase is recovered by demulsification process.

One potential application of ELM is in the purification of succinic acid from fermentation broth. Generally, succinic acid fermentation broth contains many components especially acetic acid as major by-product. Therefore, in this study, an ELM process was developed for selective separation of succinic acid from simulated solution. Important aspects regarding the ELM process is its formulation in terms of the emulsification procedure, the choice of surfactants, carrier, stripping agent and diluent, which decide whether the process is successful or not. Besides that, stability also plays an important role for successful ELM process. The emulsion should be stable enough to resist leakage during extraction, but not too stable so that the emulsion can easily demulsified.

This paper will present the investigation of liquid membrane component selection, stability study and several parameter of succinic acid extraction such as stripping agent concentration, carrier concentration and treat ratio.

Materials and Methods

Materials

Amberlite LA2 as carrier was obtained from Merck Company. Amberlite LA2 used, was mixture of straight-chain secondary amine mixture (374 g/mol). Trioctylamine (TOA) (>93 % assay) and tridodecylamine (TDA) (>95 % assay) were purchased from Merck. Kerosene as diluent was purchased from Sigma Aldrich. Palm oil, also as diluent used in this study was ordinary cooking oil (BURUH) acquired from supermarket. Sodium hydroxide (NaOH) (98 % assay) was purchased form J.T. Baker, while Sodium carbonate, Na_2CO_3 (99.5 % assay) was purchased from Merck. Sorbitan Monooleate (Span 80) (with more than 60 % oleic acid composition) as surfactant was purchased from Sigma Aldrich. Polyethylene glycol sorbitan monooleate (Tween 80) and Cocamide diethanolamine (DEA) was purchased from Sigma Alderich and Chemicalland21 respectively. In addition, succinic acid (SA) (99.0 % assay) and acetic acid (AA) (99.7 % assay) were purchased from Sigma Aldrich and J.T. Baker, respectively. All these solutions and reagents were used directly as received without further purification.

Methods

In formulation, ELM components including carrier, diluent and stripping agent was screened by liquid-liquid extraction process. The experiment was conducted by mixing an equal volume of organic solution and with simulated aqueous feed solution at 320 rpm using mechanical shaker. The solution was then poured carefully into separating funnel for phase separation. Sample of aqueous phase at the bottom was taken for succinic and acetic acid concentration measurement. Similar procedures was repeated for screening diluent and stripping agent. Extraction and stripping performance was evaluated using Equation 1 and 2 respectively.

The selected formulation was then used to study ELM stability. An equal volume of liquid membrane and stripping solution was emulsified at 5000 rpm using homogenizer. The emulsion formed was transferred into measuring cylinder and then stored at room temperature. The volume of different phase separated was recorded as a function of time. Similar procedure was repeated for different parameter.

In extraction study, the prepared emulsion was dispersed into feed phase of simulated succinic acid solution. The mixture was then agitated at 600 rpm for 3 minutes using a motor stirrer. The mixture was then separated in separating funnel. The aqueous phase at the bottom was taken for analysing. The performance of extraction was evaluated using Equation 1.

$$Amount\ extract\ (g/l)\ =\ \frac{[A]_{i(aq)} - [A]_{f(aq)}}{[A]_{i(aq)}} \tag{1}$$

$$Amount\ strip\ (g/l) = [A]_{fs(aq)} \tag{2}$$

where, $[A]_{i(aq)}$ is the initial acid concentration in external aqueous phase (g/l); $[A]_{f(aq)}$ is the acid concentration in aqueous extrenal phase after extraction (g/l); $[A]_{fs(aq)}$ is the acid concentration in aqueous stripping phase after stripping (g/l).

Besides that, distribution ratio (D) and separation factor (α) for the extraction of succinic and acetic acid were determined using Equation 3, 4, and 5.

$$D_{SA} = \frac{[SA]_{org}}{[SA]_{aq}} \tag{3}$$

$$D_{AA} = \frac{[AA]_{org}}{[AA]_{aq}} \tag{4}$$

$$\alpha_{\frac{SA}{AA}} = \frac{D_{SA}}{D_{AA}} \tag{5}$$

where D_{SA} is the distribution ratio of succinic acid; D_{AA} is the distribution ratio of acetic acid; $\alpha_{SA/AA}$ is the separation factor of succinic over acetic acid.

Results and Discussion

ELM formulation for Succinic Acid

The experimental results for liquid membrane component screening are shown in Table 1. The first parameter in liquid membrane formulation is carrier screening. The selection of suitable carrier is very crucial for the ELM system to perform well and selectively form complex with desired solute. Secondary or tertiary amine are generally typical carrier for carboxylic acid [6]. In this study, TOA, TDA and Amberlite LA2 from amine group were used to extract succinic acid. The current study clearly shows that Amberlite LA2 gives the best performance for succinic acid extraction (19.98 g/l) compared to TOA (10.99 g/l) and TDA (3.20 g/l). This is due to the Amberlite LA2 is one of the secondary amine, while TOA and TDA are both tertiary amine. Secondary amine can easily form complex with succinic acid and form ammonium salt. The process of complex formation involved the ion pair

association between the acid radical and the alkylammonium cation. Since Amberlite LA2 is a secondary amine, it can easily react with acid radical by losing the H bonding. This finding in line with the results found by Ricker (1978) who reported that the secondary amine shows better extractability compared to tertiary amine. Besides, highest value of separation factor was obtained using Amberlite LA2 as the carrier. This means that Amberlite LA2 not only can extract high amount of succinic acid, but it also selectively forms complex with succinic acid over acetic acid. Therefore, the use of Amberlite LA2 was preferred for the ELM formulation to separate succinic and acetic acid and used in the following section.

Table 1. Results of liquid membrane component screening

Parameters	**Variables**	**SA extract (g/l)**	**AA extract (g/l)**	**Selectivity,** $\alpha_{SA/AA}$
Carrier	TOA	10.99	1.40	2.15
	TDA	3.20	0.48	8.48
	Amberlite LA2	19.98	0.42	23.81
Kerosene/palm oil %	100/0	18.45	0.07	134.73
	70/30	20.89	0.70	17.79
	50/50	20.11	0.42	27.73
	30/70	22.22	0.28	57.82
	0/100	21.39	0.41	34.10
		SA stripped (g/l)		
Stripping agent	NaOH	7.58	-	-
	Na_2CO_3	16.34	-	-

The influence of diluents on separation of succinic and acetic acid also tabulated in Table 1. The present study shows that similar amount of succinic acid was extracted using different composition of kerosene and palm oil between 18 – 22 g/l of succinic acid. The results indicate that the composition of kerosene and palm oil did not give much effect on succinic acid extraction. Nevertheless, there was a really large different on the selectivity of succinic acid, where kerosene gives the best selection of succinic acid with 134.73 separation factor value. However, kerosene is not environmentally friendly and the toxicity effect of kerosene will be harmful to human. Hence, it is highly desirable to replace it with another material, such as palm oil. According to the results in Table 1, the combination of 30/70 kerosene to palm oil also leads to high separation factor (57.82) followed by a comparatively separation factor using pure palm oil (34.10). The 30/70 kerosene to palm oil provide larger separation factor, but the combination can complicate the extraction process and kerosene is still being used although in a small proportion. Therefore pure palm oil is selected as possible diluent in this study. This is because the valuable property in palm oil over kerosene seen as renewable, nontoxic and readily available. Hence, pure palm oil is considered as diluent in next study.

In the ELM system, the succinic acid extraction is governed by pH difference between the external feed and internal receiving phase. Therefore, alkaline solution such as NaOH and Na_2CO_3 were screened in this study as stripping agent for succinic acid extraction. The results indicate there is almost no acetic acid stripped in the process due to very small amount of acetic acid is extracted in the loaded organic phase. The amount of succinic acid stripped using Na_2CO_3 is 16.34 g/l compared to NaOH which is only 7.59 g/l. This is because Na_2CO_3 dissociates, and forms 2 moles of sodium ion in comparative to NaOH that gives only 1 mol. Therefore, more succinic acid will be stripped using Na_2CO_3. The result of this study seems to be consistent with other research, who reported that Na_2CO_3 show better performance than NaOH in stripping process of succinic acid [8].

ELM stability study: *Effect of organic to internal ratio*

Organic to internal phase ratio is important in order to achieve optimal emulsion stability. Table 2 represents stability of prepared emulsion showing various stage of phase separation. The most unstable emulsion was formed by 1/1 organic to internal ratio where the internal droplets dispersion did not last long and about 27 % of aqueous phase was separated just within 10 minutes. This is because the nature property of the palm oil and the existing natural surface-active agent called stearin influence the oil/water interface and modify the structure of the interfacial film and hence affect its stability [9]. Therefore, less droplets was formed for 1/1 ration. Increasing the ratio of O/I to 3/1 cause increasing in emulsion stability due to increase in the membrane phase layer around the internal droplets [10]. Besides, increasing the organic fraction will also increase the surfactant content in the emulsion, results in better droplet formation, increase mechanical resistance of the membrane and prevent coelescence of the dispersed droplet. Thus, more stable emulsion with greater amount of droplets was formed. Hence, 3/1 of O/I ratio is highly preferable to produce a stable emulsion.

Table 2. Effect of organic to internal ratio on emulsion stability

O/I ratio	Aqueous phase separated (%)		
	10 min	30 min	60 min
1:1	26	36	40
2:1	10	16	30
3:1	0	1	5

Effect of homogenizer speed

Application of mechanical energy can make one of the liquid breaks into droplets and disperse in the other and form emulsion. The influence of homogenizer speed on the performance of water in oil emulsion stability was presented in Table 3. Result indicates that the water in oil emulsion stability significantly increase as increasing homogenizer speed from 5000 to 7000 rpm. This is because increasing the homogenizer speed produce higher number of droplets with greater interfacial area, thus stabilize the emulsion. A study by Sulaiman et al. [11] also found that higher homogenizer speed increase emulsion stability. Further increase the speed to 9000 shows that the stability is lower than that of 7000 rpm. This is due to the droplets tend to coalesce among each other, thus enlarging their size which leading to the breakage of the droplet. At 12000 rpm homogenizer speed, a highly viscous, "mayonnaise-like" emulsion was formed. The reason for this is due to foaming mechanism, where air-bubbles are incorporated into the emulsion phase, and lead to a more rigid system. Therefore, homogenizer speed at 7000 rpm is preferable in this study in producing stable emulsion.

Table 3. Effect of homogenizer speed on emulsion stability

Homogenizer speed (rpm)	Aqueous phase separated (%)		
	10 min	30 min	60 min
5000	0	0.96	7.69
7000	0	0.96	3.85
9000	0	0.96	5.77
12000	0	0.96	0.96

Effect of emulsifying time

Table 4 demonstrate the effect of emulsification time on water in oil emulsion stability. For 3 minutes emulsification time, about 2 % of aqueous phase was separated from the emulsion in 10 minutes storage. This indicates that short emulsifying time produce unstable emulsion because of the organic membrane and aqueous internal solution was not well homogenized. Additions of emulsification time to 5 minutes produce more stable emulsion, where it starts to break after 30 minutes. This is due to smaller internal droplets formed, thus leading to stable emulsion because smaller droplets take more time to coalesce [12]. However, an extending the emulsification time up to 10 minutes and above decrease the stability of water in oil emulsion due to high shear exposure and causing emulsion breakage. The breakage phenomena because of prolonged emulsification time also observed by Othman et al. [13]. Thus, 5 minutes emulsification time is sufficient for the production of most stable emulsion.

Table 4. Effect of emulsifying time on emulsion stability

Emulsifying time (min)	**Aqueous phase separated (%)**		
	10 min	**30 min**	**60 min**
3	2	15	21
5	0	0.96	3.85
10	2	15	20
15	4	13	21
20	0	15	22

Effect of surfactant blend

Surfactant blend have synergistic effects in enhancing emulsion stability. Compared to individual emulsifiers, appropriate surfactant combination produce a greatly enhanced emulsion stability [9]. Basically, the addition of a co-surfactant can further reduce interfacial tension, also through adsorbing in the w/o interface thereby minimizing the repulsion of the hydrophilic head-groups of the surfactants, which contributes to a more efficient packing of the surfactants at the interface and reduces water droplet size. Result shows better stability was observed when HLB is increased. This indicate that Span 80 is compatible with Tween 80. This is due to similarity structure between both surfactant, since Tween 80 is a derivative from Span 80. Due to the compatibility structure, the film of Span 80 be better solvent for the Tween 80 on the mixed film, therefore form a phase that resist breakage. Hence, the emulsion is more stable. Figure 4 shows emulsion at HLB 8 and HLB 15 remain unseparated. However, emulsion at HLB 15 using only Tween 80 favours oil in water emulsion. Thus, combination of Span 80 and Tween 80 at HLB 8 will be considered for the next experiment.

Table 5. Effect of surfactant blend on emulsion stability

HLB	**Aqueous phase separated (%)**		
	10 min	**30 min**	**60 min**
4.3	0	18	20
5	0	0	4
6	0	17	20
7	0	12	18
8	0	0	0
15	0	0	0

ELM extraction study

The experimental results for succinic acid extraction efficiency are shown in Table 6. Effect of stripping agent concentration is shown in Table 6 varying from 0.01 to 2M of Na_2CO_3. The amount of succinic acid extracted increase when stripping agent concentration was increase from 0.01 to 0.5 M. The highest succinic acid extracted was 31.5 g/L. This is because of the tendency of the internal phase to strip succinic acid was increased and this delays the accumulation of succinic complex in the membrane layer. Further increase in Na_2CO_3 concentration reduces succinic acid extraction performance. This might be due to leakage of the succinic acid extracted and internal stripping agent through the membrane to the external. On the other hand, highest selectivity was obtained when using 0.50 M Na_2CO_3. It shows that at this stripping agent concentration, high amount of succinic acid was extracted. Furthermore, the system favors succinic acid than acetic acid to be extracted. Hence, 0.5 M Na_2CO_3 was selected as the best stripping agent concentration in this process.

Table 6. Results on succinic acid extraction

Parameters	Variables	Amount of succinic acid extracted (g/l)	Amount of acetic acid extracted (g/l)	Selectivity $\alpha_{SA/AA}$
Na_2CO_3 (M)	0.01	2.12	2.21	0.20
	0.10	2.51	2.96	0.18
	0.50	31.54	1.75	15.02
	1.00	9.19	2.45	1.08
	2.00	3.49	2.98	0.26
Amberlite LA2 (M)	0.005	7.79	3.63	0.50
	0.05	33.79	3.96	15.79
	0.50	31.97	3.11	14.24
	1.00	18.38	2.48	3.16
Treat ratio	1:1	32.45	1.38	43.95
	1:2	33.57	3.72	16.34
	1:3	33.79	0.57	184.83
	1:4	35.02	4.29	21.94
	1:5	28.47	0.76	41.28

Besides that, Table 6 also shows effect of carrier concentration on succinic acid extraction. Succinic acid was slightly extracted when 0.005 M of Amberlite LA2 was used. This indicates amount of carrier was insufficient for extraction process. Increasing the Amberlite LA2 concentration to 0.05 increase the succinic acid extraction up to 33.8 g/L from 40g/L succinic acid solution. An increased in succinic acid extraction occur due to the fact that the concentration of carrier in the organic membrane phase phenomenologically increases the solute concentration at the interface and thus increasing the driving force for extraction. However, the extraction performance was reduced when Amberlite concentration increased beyond 0.05M. This is due to excess of free carrier in the organic membrane phase. The excessive concentration of carrier cause higher viscosity of membrane, thus reduce the mass transfer of solute into the internal phase. On the other hand, highest selectivity at 15.79 was obtained at 0.05 M Amberlite LA2 concentration, which means succinic acid is the most favorable compared to acetic acid under this condition. Therefore, 0.05 M Amberlite LA2 was chosen as the optimum carrier concentration due to highest amount of succinic acid extracted and highest selectivity.

This study also varies treat ratio from 1:1 to 1:5. The amount of succinic acid extracted was slightly increased from treat ratio 1:1 to 1:4. At high treat ratio (1:1 to 1:2), larger mass transfer area can be obtained because higher number of emulsion globule was formed. However, with the help of surfactant hydration, this condition cause

continuous water movement into the internal aqueous phase and leads to emulsion breakage. This breakage therefore reduce succinic acid extraction at high treat ratio. This results is in line with Sulaiman et al. [11], who reported emulsion breakage occur at high treat ratio. Further reducing the treat ratio to 1:5 reduce the succinic acid extraction performance because of the reduction in the dispersibility of the emulsion. This cause smaller mass transfer surface area. As a result, the extraction efficiency shows a decreasing trend. Besides that, succinic acid extraction also may be reduced due to the emulsion breakage, owing to the increasing osmotic pressure difference between the external and ELM phase. Despite the highest succinic acid extracted when treat ratio 1:4 is applied, result of shows that the value is smaller than selectivity in treat ratio 1:3. This indicates that more acetic acid also extracted in the system. In addition, the emulsion breakage also higher compared to 1:3. Hence, 1:3 of treat ratio was selected as optimum condition.

Conclusion

The finding of this study provides an approach for selective extraction of succinic acid toward acetic acid. It can be concluded the best liquid membrane was formulated using Amberlite LA2 as carrier, palm oil as diluent, and Na_2CO_3 as stripping agent. Besides, all the parameter has shown a significant effect on the stability of water in palm oil emulsion. The most stable emulsion was recorded at 7000 rpm homogenizer speed, 5 minute emulsification time, and 3 % (w/v) span 80, and HLB value of 8 with combination of Span 80 and Tween 80. Meanwhile, up to 33.9 g/L succinic acid was extracted under promising conditions which are 0.5 M Na_2CO_3, 0.05 M Amberlite LA2, and 1:3 treat ratio.

Abstract

Agriculture waste is potentially useful as an alternative material to absorb and attenuate electromagnetic interference (EMI). This research highlights the use of coconut shell powder (CSP) and coconut shell activated carbon (CSAC) as raw materials with epoxy resin and amine hardener composite to absorb microwave signals over frequency of 1 – 8 GHz. In order to investigate the suitability of these raw materials as EMI absorbing material, carbon composition of the raw materials is determined through CHNS Elemental Analysis. The surface morphology of the raw materials in term of porosity is investigated by using TM3000 Scanning Electron Microscope (SEM). The complex permittivity of the composites is determined by using high temperature dielectric probe in conjunction with Network Analyzer. From the result, the Carbon% of CSP and CSAC is 46.70% and 84.28% respectively. In term of surface morphology, the surface porosity of CSP and CSAC is in the range of 2 µm and 1µm respectively. For the dielectric properties, the dielectric constant and the dielectric loss factor for CSP and CSAC is 4.5767 and 64.8307and 1.2144 and 13.8296 respectively. The materials more potentially useful as substitute materials for electromagnetic interference (EMI) absorbing are discussed.

Keywords: agricultural wastes, dielectric properties, carbon composition

Abstrak

Sisa pertanian mempunyai potensi untuk digunakan sebagai bahan alternatif untuk menyerap atau melemahkan gangguan elektromagnatik (EMI). Kajian ini menekankan kepada penggunaan serbuk tempurung kelapa (CSP) dan karbon teraktif tempurung kelapa(CSAC) sebagai bahan mentah dengan campuran resin epoksi dan komposit penguat amina untuk menyerap gelombang mikro dalam frekuensi 1 – 8 GHz. Bagi mengkaji kesesuaian bahan mentah sebagai bahan penyerap gelombang mikro, komposisi karbon dalam bahan mentah ditentukan mengunakan analisis unser CHNS. Liang permukaan bahan mentah pula dikaji mengunakan mikroskop pengimbas elektron TM3000 (SEM). Ketelusan kompleks bagi bahan campuran diukur menggunakan prob dielektrik suhu tinggi dan alat analisis rangkaian. Daripada keputusan yang diperolehi, peratusan karbon dalam CSP dan CSAC adalah sebanyak 46.70 % dan 84.28 %. Manakala dari segi liang permukaan pula, keliangan CSP dan CSAC masing – masing berada dalam lingkungan 2um dan 1um.Bagi sifat dielektrik, pemalar dielektrik untuk CSP dan CSAC masing – masing adalah 4.5767 dan 64.8307. Bagi pembelauan dielektrik, nilai untuk CSP dan CSAC masing – masing adalah 1.2144 dan 13.8296. Isu bahan yang lebih berpotensi untuk digunakan sebagai bahan penyerap gangguan elektromagnatik (EMI) dibincangkan.

Kata kunci: sisa pertanian, sifat dielektrik, komposisi karbon

Introduction

Recently, researchers have focused to identify the agricultural wastes (organic materials) as a new absorbing material. Agricultural waste is made up of organic compounds from living plant like oil palm shell, rice husk, and coconut shell. Many natural substances (agricultural wastes) are used as base materials to make activated carbon. The most common being used in absorbing material are sugarcane, rice husk, ground nut shell, oil palm shell, coconut shell, corncobs, durian shell, soybean oil cake [1-6]. At present, coconut wastes are used in horticultural and agricultural applications [7]. Carbon is the main element to absorb unwanted electromagnetic signals [8-12].

The French chemist Antoine-Alexandre-Brutus Bussy who in a 1822 is the first publication suggested that porosity was important to the adsorptive properties of activated carbons. Optical microscopy and scanning electron microscopy (SEM) have demonstrated enormous potential for use in the study and characterization of activated carbons because of their ability to directly view the micro-structure of activated carbons [13,14]

Dielectric properties are the main characteristic that determines a material to absorb energy. The dielectric properties (ε) are derived from transmission line theory [15-17] and are expressed as complex permittivity, shown in Equation 1:

$$\varepsilon = \varepsilon' - j\varepsilon'' \tag{1}$$

where ε is define as dieletric properties, ε' is define dieletric constant and ε'' define as dieletric loss factor.

Dielectric constant (ε') is the real part of the complex permittivity whereas the imaginary part of the complex permittivity is called the dielectric loss factor (ε'').The dielectric constant and dielectric loss factor effect the ability of a material to act as microwave absorber. The dielectric constant defines the ability of a material to store the microwave energy while the dielectric loss factor defines the ability of a material to convert and dissipate the stored microwave energy to heat. In other words, microwave absorber prefers materials that possess higher thermal conductivity because when the thermal conductivity increases, the ability of these materials to dissipate heat also increase.

In this paper, the potential of CSP and CSAC with epoxy resin and amine hardener composite will be investigated.

Materials and Methods

Material preparation

For the coconut shell source, it was economically important to use a readily available agricultural waste by product. To manufacture coconut shell powder, the shells of fully matured nuts are first cleaned of the adhering pithy matter. The matured coconut shells were taken from Kuala Ibai, Terengganu, Malaysia. The coconut shell is sanded using sanding machine in order to get the coconut shell powder. The readymade CSAC powder was bought from Tan Meng Keong Sdn. Bhd company, Perak Darul Ridzuan, Malaysia.

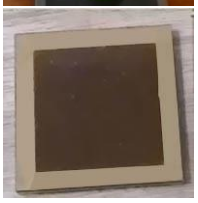
Material characterisation

The carbon composition of the CSP and CSAC is determined by using ultimate analyses through CHNS Elemental Analysis. The CHNS elemental analysers provide a means for rapid determination of carbon, hydrogen, nitrogen and sulphur in organic matrices [18,19]. In order to investigate the surface morphology of CSP and SCAC materials in term of porosity, sample was investigated by using TM3000 Scanning Electron Microscope. For SEM measurements, the samples were prepared by coated with a thin layer of platinum [5-20].

Composite preparation

The raw material was mix with epoxy resin matrix and the composites were prepared in weight ratio 80: 20 (80 % for raw material, 20 % of epoxy resin). Sample 1, the CSP composites were stirred by using IKA RW20 Digital Stare for 1 hour. Sample 2 was prepared in similar manner but using CSAC. The mixture was poured in 30mm x

30mm x 5 mm rectangular planner moulds. Fabrication of sample 1 can be done through the steps summarized in Figure 1 below.



Step 1		Sanding process of matured and cleaned coconut shell
Step 2		Collection of coconut shell powder
Step 3		The coconut shell powder mixing with resin and hardener in weight ratio 80:20
Step 4		The coconut shell powder composites were stirred by using IKA RW20 Digital Stirer for 1hour
Step 5		The composite were filled and fabricate using mould.

Figure 1. Fabrication of composite sample

Dielectric Properties Measurement

Several popular measurement techniques are the transmission line techniques (waveguide, coaxial and free-space), impedance, dielectric probe and cavity methods [21]. Amongst these techniques, high temperature dielectric probe techniques are chosen to determine of the complex permittivity of the coconut shell powder and coconut shell activated carbon polymer composite dielectric properties measurement. The high temperature dielectric probe is performed by contacting the probe into the samples. The high temperature probe measurement procedure, which is done by contacting the probe to a flat surface of a sample, is shown in Figure 2. The fields at the probe end "fringe" into the material and change as they come into contact with the MUT.

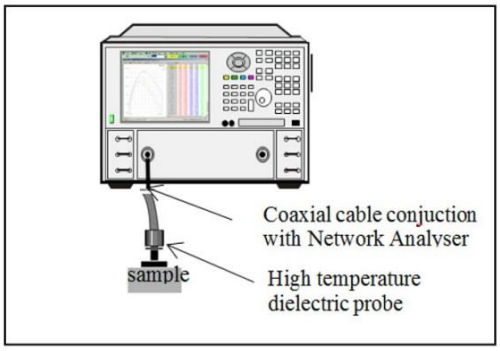


Figure 2. Measurement techniques for CSP and CSAC composites: High Temperature Dielectric Probe Technique

Results and Discussion

Carbon composition

The carbon composition of the CSP and CSAC is determined through CHNS Elemental Analysis. The CHNS Elemental Analysis determines the percentages of Carbon, Hydrogen, Nitrogen and Sulphur [22]. The result of elemental analysis of CSP and CSAC is presented in Table 1.

Table 1. The CHNS Elemental Analysis of CSP and CSAC

Material	Total Mass (mg)	Carbon		Hydrogen		Nitrogen		Sulphur		Oxygen
		%	mg	%	mg	%	mg	%	mg	(by diff)
CSP	2.0120	46.70	0.94	3.174	0.064	0.171	0.003	1.036	0.021	48.92
CSAC	2.0140	84.28	1.697	0.478	0.010	0.222	0.005	1.084	0.022	13.94

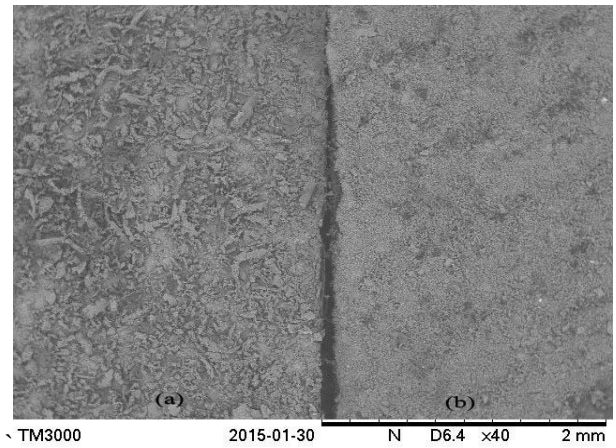
As presented in Table 1, the carbon % of CSP and CSAC is 46.70 % and 84.28 % respectively. The CSP has lower carbon content compare to CSAC. The high composition of carbon in the coconut shell as presented from the elemental analysis indicates a good precursor material for porous carbon [23].

CSAC have higher carbon content compared to CSP because to produce activated carbon from coconut shells, the overall process utilizes the pyrolysis of coconut shells into char, followed by steam activation in a fluidized bed reactor (FBR). The resulting activated carbon is 97% pure.

Surface Morphology

SEM morphologies in Figure 3 and Figure 4 shown reveal details of activated porosity development of CSP and CSAC.

The most important property of the activated carbon is its adsorptive capacity, which in general is proportional to the surface area [24, 25]. Carbon's highly porous nature provides a large surface area for absorption. The application of activated carbon in absorption processes mainly depends on the surface chemistry and pore structure of porous carbon [26]. While, Li et al. said that activated carbon having porous structure and high surface area where the pore structure is importance for optimal performance for absorbing material [27]. CSAC is an excellent quality high surface area material [28].



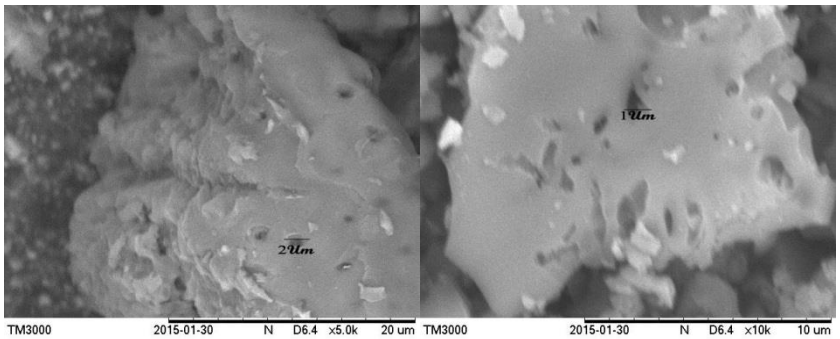


Figure 3. SEM morphology on composite surface (a) CSP; (b) CSAC

(a) (b)

Figure 4. SEM morphology on particle porosity (a) CSP; (b) CSAC

In Figure 4, presence of mesopores is detected in CSP and CSAC where the porosity is in the range of 2um and 1um respectively.

Dielectric Properties

The result of dielectric properties of CSP and CSAC over frequency of 1-8 GHz is presented in Table 2.

Figure 5 (a) and (b) show the dielectric properties that were measured from CSP and CSAC composites. The dielectric constant and dielectric loss factor vary when the frequency increased from 1GHz to 8GHz. It can be observed that the dielectric properties of the CSAC composite are higher compared to the CSP composite. This is due to the high carbon composition in the CSAC compared to the raw CSP.

Table 2. Dielectric properties for CSP and CSAC

Frequency (GHz)	Sample Composite	Dielectric Properties		
		Dielectric Constant (ε')	Dielectric Loss Factor (ε'')	Loss Tangent ($\tan\delta$)
1	CSP	5.1244	0.5200	0.1015
	CSAC	64.8307	18.0791	0.2789
2	CSP	5.0726	0.7029	0.1386
	CSAC	60.8409	14.7596	0.2426

Conclusion

From this experiment, we investigate the potential of CSP and CSAC composites as EMI absorbing material in term of carbon composition, surface morphology and dielectric properties. Both CSP and CSAC composites show desirable potential to be used as EMI absorbing material, in term of carbon as dominant element, mesopores porosity and thermal conductivity. From the result, CSAC composite possess better carbon composition, surface morphology and thermal conductivity compared to CSP composite.

Abstract

Soil carbon is the carbon held within the soil, primarily in association with its organic content. The total soil organic carbon study was determined in a plot at Bukit Jeriau forest in Bukit Fraser, Pahang, Malaysia. The aim of this study is to determine the changing of soil organic carbon between wet season and dry season. Soil organic carbon was fined out using titrimetric determination. The soil organic carbon content in wet season is 223.24 t/ha while dry season is 217.90 t/ha. The soil pH range in wet season is between 4.32 to 4.45 and in dry season in 3.95 to 4.08 which is considered acidic. Correlation analysis showed that soil organic carbon value is influenced by pH value and climate. Correlation analysis between clay and soil organic carbon with depth showed positively significant differences and clay are very much influenced soil organic carbon content. Correlation analysis between electrical conductivity and soil organic carbon content showed negative significantly difference on wet season and positively significant different in dry season.

Keywords: organic carbon, Fraser's Hill, forest, soil

Abstrak

Karbon tanah adalah nama generik bagi karbon yang wujud di dalam tanah, terutamanya dalam pencampuran kandungan organiknya. Satu kajian kandungan karbon organik di dalam tanih telah ditentukan di satu plot berukuran 1 hektar persegi di Hutan Simpan Bukit Jeriau, Bukit Fraser, Pahang, Malaysia. Tujuan kajian ini adalah untuk menentukan perbezaan kandungan karbon organik dalam tanah antara musim basah dan musim kering. Kandungan karbon organik ditentukan dengan menggunakan kaedah pentitratan.Jumlah kandungan karbon organik pada musim basah adalah sebanyak 223.24 t/ha manakala pada musim kering pula sebanyak 217.90 t/ha. Julat pH pada musim basah adalah 4.32 hingga 4.45 manakala pada musim kering adalah dari 3.95 hingga 4.08, dalam lingkungan berasid. Nilai pH pada musim kering mengalami penurunan. Analisis korelasi mendapati nilai pH dan iklim memberi kesan kepada kandungan karbon organik. Ujian korelasi antara lempung dengan kandungan karbon organik menunjukkan terdapat pebezaan signifikan positif. Ini menunjukkan kandungan lempung mempengaruhi kandungan karbon organik dalam tanih. Ujian korelasi kekonduksian elektrik dengan kandungan karbon organik menunjukkan perbezaan signifikan yang negatif pada persampelan musim basah manakala perbezaan signifikan positif pada musim kering.

Kata kunci: karbon organik, Bukit Fraser, hutan, tanih

Introduction

Organic are the terms use to describe the materials that associated with or derived from living organisms. The amount of organic matter in soil is often used as an indicator of the potential sustainability in a soil system. Soil organic matter are playing important part in nutrient cycle and repairing soil structure. Organic carbon in soil is important to ensuring good health in soil environment and critical in supplying the needs of the ecosystem [1,2]. Recently, research on soil organic carbon becoming important because of terrestrial organic carbon is critical factor to understanding carbon emission in which can causing climate change [3]. Organic carbon in soil are part of soil organic component, including others important elements such as hydrogen, oxygen and nitrogen. Organic in soil is derived from plants and animals that gradually decomposes. Soils constitute a significant reservoir of carbon (C) in both organic and mineral forms and can play an important global role, by mitigating or contributing carbon to the atmosphere [4,5]. Globally, soils contain more than two thirds of the total C stored in vegetation and almost twice the amount in the atmosphere while forest soils (including peaty soils) contain approximately 69 % of the total forest C pool [6]. With a small change in soil organic carbon, it can show a significant change for CO2 in atmosphere [7]. Carbon absorbance into the soil is a way that can decrease carbon accumulation in atmosphere which can lower the risks of climate changes. From that, the result show where soil organic carbon is very important to predict the effects and brings on global environment [8,9]. Field survey are a good ways to evaluate soil organic carbon including in the high altitude area such as Fraser Hill.

Carbon stored form the organic carbon in soil is highly sensitive to land use changes [10,11]. Organic carbon contain in soil are decrease with decreasing of organic matter inputs, while it increasing in organic carbon oxidation cause of aggregates disruption, and increasing the aeration. Many factors can indicate the stabilization of organic carbon in soil, the important factors are clay content, pH, hydrology, climate, and organic matter inputs. Some of these factors are fixed and depended on soil characteristics while some are depended on climate and land use management. Soil organic carbon storage are controlled by balanced from input from vegetation and decomposition output [12,13]. Organic carbon storage in soil are high in high altitude are because of high in carbon concentration (organic carbon per area) [14]. With unique climate and less human activity, Fraser Hill are ideal place to run a research on determine the soil organic carbon for the higher altitude area. Research on soil organic carbon changes are important for us to understand the relationship of its content in forest and their changes effect on global in the future [15].

Materials and Methods

Study area

Fraser Hill is very popular as a highland vacation and situated on 1500 m from sea level. This area is located on Titiwangsa range in Peninsular Malaysia which is formed by igneous formation activities from late Triassic to early Jurassic [2,15]. Annual rainfall distribution is 2624 mm with average 208 wet days. The area receives 20mm to 410mm of rainfall each month, typically low during the first quarter, and very high during the last quarter of the year. The temperature is cool, ranging from 18 °C – 22 °C annually with high humidity ranging from 85 – 95 % every month. The surrounding vegetation is lower montane forest [16]. Study site is one hectare plot located in Jeriau Forest, Fraser Hill, Pahang (Figure 1).

Soil samplings were done on one hectare plot (100m x 100m) where it has been divided into 9 subplots. To represent both dry and wet season, the soil sample was taken once for each season. The dry and wet season was determined using annual average rainfall at the nearest station and Malaysia annual rainfall data. Soil samples were taken from each subplot (Figure 2) by profile deep from 0 – 20 cm, 20 – 40 cm, 40 – 60 cm, 60 – 80 cm, and 80 – 100 cm. Research plot were located at 03°43’ 33.5” N, 101° 43’ 076” E to 03° 43’ 34.3” N, 101° 43’ 07.0” E and 03° 43’ 32.7” N, 101°43’ 05.6” E to 03° 43’ 32.9” N, 101°43’ 06.3” E. Each soil sample was taken to laboratory to be air dried and sieved using 2 mm sieve. Samples were then ready for analysis.

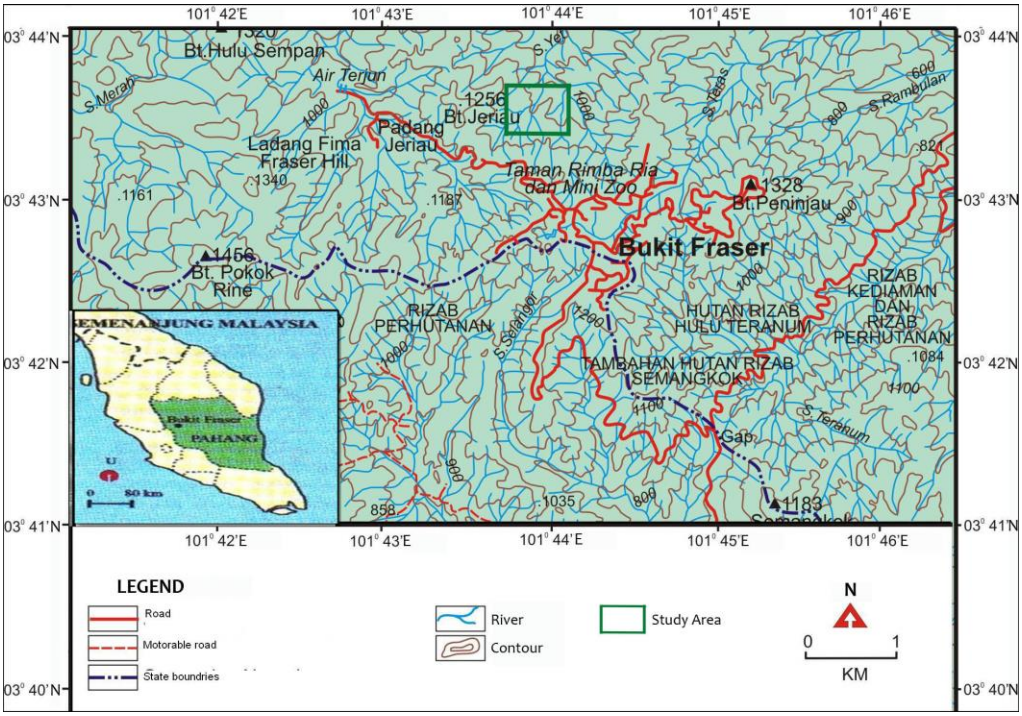

Figure 1. The map of study area

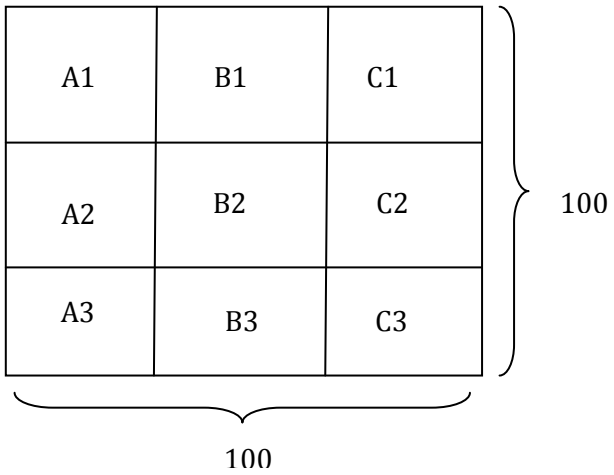

Figure 2. Research plot and subplots

Soil particle size distribution

20g soil are inserted into 600 ml beaker. Then, 50 ml of hydrogen peroxide (H^2O^2 - 30vol.) are pouring into it and heated on the sand bath with the temperature 60 – 70 °C until the mixture become less than 100 ml. Then, samples were transferred into Erlenmeyer flask and 5% sodium hexametaphosphate (20 ml) were added before shaking it in a period of 2 hour on reciprocating shaker. Then, the samples were transferred into 1000 ml beaker with the adding of water. Sub-sample size < 20µm and < 2µm were collected using pipette. The remaining samples were transferred into 600 ml beaker and the samples are slowly being washed until it's clear. The remaining was inserted into oven

overnight at 105 °C. The samples when through sieved to determine the size and weighed to determine the soil particles distributions.

Measurement of pH and conductivity

Determinations of pH were using soil: water ratio of 1:1.2.5 [17]. pH value were read with pH meter that has been calibrated [18]. Soil electrical conductivity was determined using saturated gypsum extract. The remaining of filtered of mixtures were determined using conductivity meter which has been calibrated.

Determination of organic carbon content

Soil organic carbon was determined using Walkley & Black method [19]. An amount 0.5g soil sample were weighed and inserted into 500 ml Erlenmeyer flask. Then, 10 ml of Potassium Dichromate, 1.0 N $K_2Cr_2O_7$ were inserted and shake to mix it. Then, 20 ml sulphuric acid, H_2SO_4 (98 %) was poured into the mixture. The mixtures were left for 30 minutes to cool it. After that, 3 g of sodium fluoride (NaF) were added with 100 ml of distilled water. Ten drop of ferroin indicator were added which made the mixtures turned into orange solution. The mixtures were titrated with 0.5 N ammonium sulphate, until it turned into bright green [18]. The totals of FAS were recorded. The same operations were used to determine blank value with no sample was added. The formula to calculate the content of organic carbon in soil expressed as equation 1 below:

$$\text{Carbon content (KC)} = B \times A \times D \times C \quad (1)$$

where as KC is define as carbon content in ton, B is define as soil bulk density, (g^{cm-3}), A is define as area (m^2), D is define as soil depth (m) and C is percentage (%) of carbon organic.

Results and Discussion

Soil particle size distributions in study area were dominated by sandy and clayey soil (Table 1). Sand content on soil surface (0 – 20cm) were range from 39 % to 56 % with average value is 49 %. Soil texture becoming more sandy and less clayey with the increasing the depth. With sandier texture, water movements are high compare to clayey texture. According to Bationo and Buerkert [20], clay and silt type play an important role in the stabilization of organic compounds and small variations in soil texture could have large effects on soil organic carbon. With increasing clay content, it can decreased carbon output because of its stabilization effect on soil organic carbon.

Table 1. Soil particles size distribution

Sample	Depth (cm)	Sand (%)	Clay (%)	Silt (%)	Texture
A1	0 – 20	45	36	19	Sandy caly

	80 – 100	70	11	19	Loamy sand

According to Table 2, soil organic carbon content were decreasing with increasing soil depth with the highest soil organic carbon content in depth of 0 – 20 cm for both seasons. The percentage of organic carbon content in wet seasons were higher than dry season at the depth 0 – 20 cm and 20 – 40 cm, while at the depth 40 – 60 cm, 60 – 80 cm, and 80 – 100 cm the percentage of soil organic carbon were higher in dry season. These differences were attributed to differences in belowground allocation of biomass among vegetation types, and tree dominated systems had higher inputs of organic matter than other types at the surface of the soil [21]. There was obvious changing in soil organic carbon concentration until 60 cm depth. After 60 cm depth, soil organic carbon concentration slowly reduces until 100 cm depth. The difference in soil organic carbon concentration at this depth is due to vegetation and hydrology [22]. Water moving downwards carries dissolved organic carbon to deeper soil horizons, where it is preserved from complete mineralization, gradually the transported compounds are reabsorbed to soil particles and contribute to carbon storage deeper in the soil profile. The difference of soil organic carbon content between both seasons is 5.33t/ha (Figure 3).

Table 2. The average soil organic carbon content with depth

Depth (cm)	% OC Wet season	Bulk density (gm^{-3})	TOC, (t/ha)	% OC Dry season	Bulk density, (gm^{-3})	TOC, (t/ha)
0 – 20	4.93	1.04	102.54	4.18	1.03	86.38
20 – 40	2.95	1.04	61.36	2.78	1.03	57.41
40 – 60	1.31	1.03	26.99	1.72	1.03	35.44
60 – 80	1.05	1.04	21.84	1.14	1.03	23.53
80 –100	0.51	1.03	10.51	0.74	1.02	15.14
		Total	223.24		Total	217.90

% OC = percentage of organic carbon in soil; TOC = Total organic carbon

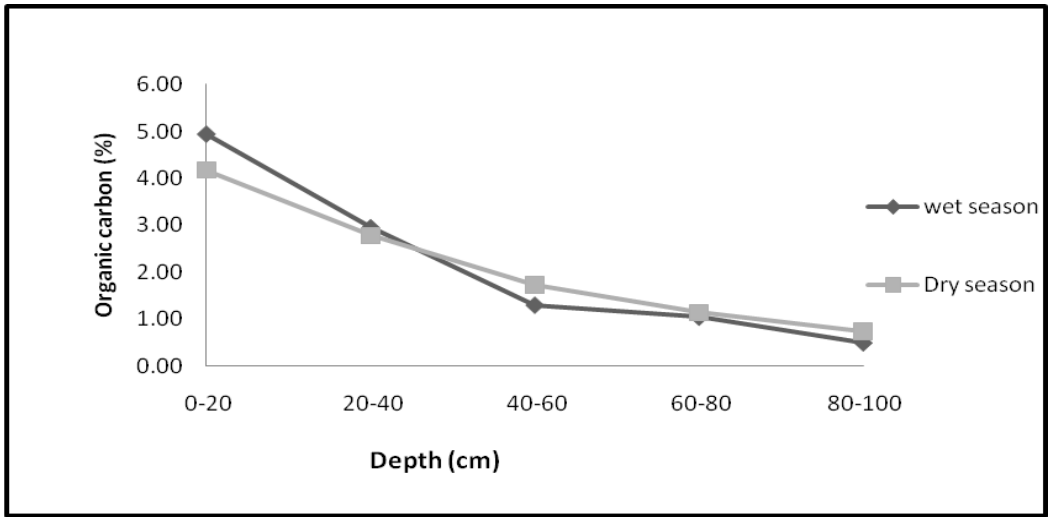

Figure 3. Seasonal soil organic carbon content with depth

Correlation analysis between clay and organic carbon content were significant different on both seasons. Wet season were positively significant at 0.01 (n = 30, r = 0.594**), while on dry season also positively significant at 0.01 (n = 45, r = 0.688**). Soil organic carbon concentration were high at upper soil profile and become lesser at the deep profile. Particle size distribution analysis showing clay content increase with depth. Carbon content and status in the

soil are closely associated with clay and silt contents and clay type, which influences the stabilization of organic carbon [20]. Increasing clay content can provide the stabilization of organic carbon in soil and slowing down decomposition process by microbes [11,23]. In this study, soil organic carbon concentrations were high at high clay area. High clay content can increase plant productivity through water holding capacity in which adding carbon input into the soil [24].

Figure 4 show the value of pH versus depth on both seasons. pH values were stable on both seasons at all station. On dry season pH value were ranging from 3.95 – 4.08 and during wet season it ranging from 4.32 –4.45. Relatively, pH values were lower at depth 0 cm to 40 cm. From 40 cm to 100 cm deep, the changing values were low on both seasons. pH value are related to decomposition of organic matter in which it can affect pH value and also increase organic carbon content in soil. This is also related with the low organic carbon concentration in deeper soil profile, meaning soil organic carbon content increase with decreasing pH value. Correlation analysis between pH and soil organic carbon on dry season were negatively significant at 0.015 (n = 45, r = - 0.378*). There is no significantly different on wet season.

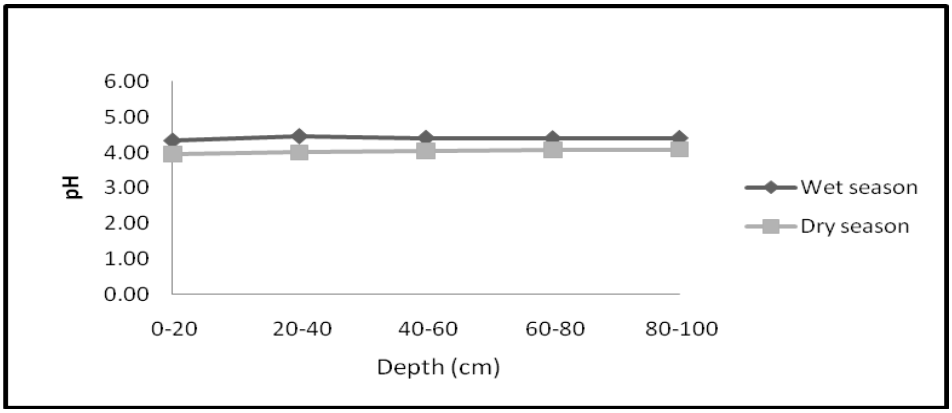

Figure 4. An average of pH value in soil samples

Electrical conductivity (Figure 5) values were stable at every depth on both seasons. During wet season, the highest electrical conductivity was measured at 0 – 20 cm deep with the value 2.65mS/cm and lowest value was 2.52mS/cm at 60 – 80cm deep. During the dry season, highest electrical conductivity value was 2.56mS/cm at 0 – 20 cm deep and at depth of 40 – 60cm the lowest value recorded at 2.33m^S/cm. Electrical conductivity in soil are influenced by soil texture (especially clay), water content and soil water holding capacity, dissolved ion in soil capillary. Soil electrical conductivity value increased with increasing of clay content and water content. According to Officer et. al. [25], the soil zone with high electrical conductivity value are high in clay and organic material content. Correlation analysis between electrical conductivity and soil organic carbon content on wet season showing significantly positive at 0.05 (n = 45, r = 0.315*) and on dry season were significantly negative at 0.01 (n = 45, r = - 0.583**). It showed that electrical conductivity influenced by the value of soil organic carbon content. Correlation analysis between electrical conductivity with pH showing negatively significant on dry season at 0.05 (n = 45, r = - 0.353*) but on wet season, there is no significantly different. It means on dry season, salt content in soil have small influence on pH value but not in wet season.

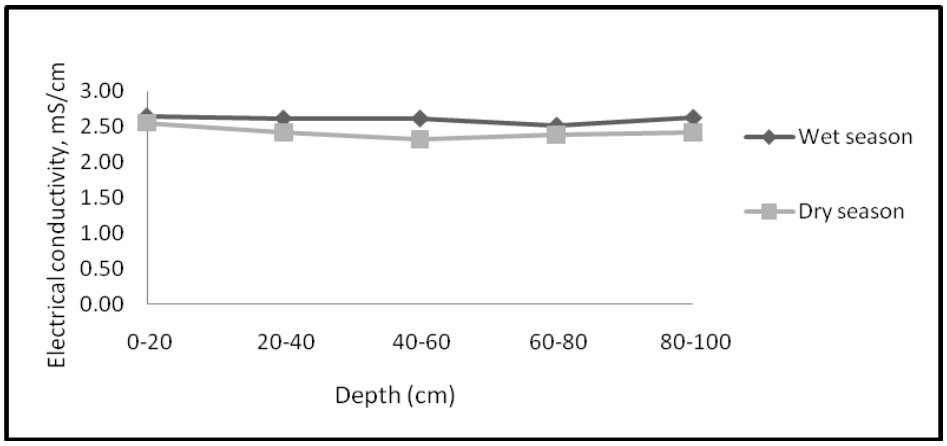

Figure 5. Measurement of electrical conductivity in soil samples

Conclusion

Soil organic carbon content were slightly higher in wet season compared to dry season with the different value of 5.34 t/ha. Soil organic carbon content is decreasing with depth on both seasons. The value of soil organic carbon decreasing drastically from high organic matter in higher soil profile and lower in deeper soil profile. pH value in dry season were acidic than wet season. Soil electrical conductivity values were stable and not much significantly different on both seasons. The average soil electrical conductivity value on wet season is 2.61m^S/cm and during dry season is 2.42m^S/cm.

Abstract

This study focuses on activated carbon preparation from spent mushroom farming waste (SMFW) via chemical activation using Box-Behnken design (BBD) of Response Surface Methodology (RSM). Potassium hydroxide (KOH) functions as activating reagent and it plays an important role in enhancing the activated carbon porosity. Three input parameters and two responses were evaluated via this software generated experimental design. The effects of three preparation parameters of impregnation ratio, activation time and activation temperature as well as two responses of carbon yield and iodine number were investigated. The optimum conditions for preparing activated carbon from SMFW was found at SMFW: KOH impregnation ratio of 0.25, activation time of 30 min and activation temperature of 400 ^{o}C which resulted in 28.23 % of carbon yield and 314.14 mg/g of iodine number with desirability of 0.994. The predicted results were well corresponded with experimental results. This study is important in economical large scale SMFW activated carbon preparation for application study of adsorption process for metal treatment in wastewater with minimum chemical and energy input.

Keywords: activated carbon, spent mushroom farming waste, Box-Behnken design, response surface methodology

Abstrak

Kajian ini memfokuskan penyediaan arang teraktif daripada sisa tanaman cendawan terpakai melalui reka bentuk box-behnken (BBD) dari kaedah gerak balas permukaan (RSM). Potasium hidroksida (KOH) berperanan sebagai agen pengaktifan dan penting untuk meningkatkan liang arang teraktif. Tiga parameter input dan dua respon telah dinilai oleh perisian ini yang dihasilkan oleh rekabentuk eksperimen. Kesan daripada penyediaan tiga parameter iaitu nisbah pemadatan, masa pengaktifan dan suhu pengaktifan serta dua respon iaitu hasil arang teraktif dan nilai iodin telah disiasat. Keadaan optimum dalam penyediaan arang teraktif telah didapati pada nisbah SMFW: KOH iaitu 0.25, tempoh pengaktifan selama 30 min dan suhu pengaktifan 400 °C, di mana ia menghasilkan jumlah maksimum arang teraktif sebanyak 28.23 % dan nilai iodin yang boleh diterima iaitu sebanyak 314.14 mg/g dengan ketepatan 0.994. Keputusan yang telah diramalkan adalah seiring dengan keputusan eksperimen. Kajian ini adalah penting dalam penyediaan arang teraktif secara berskala besar dengan ekonomi daripada sisa tanaman cendawan terpakai untuk kajian proses penjerapan terhadap rawatan logam dalam air sisa dengan input bahan kimia dan tenaga yang minimum.

Kata kunci: karbon teraktif, sisa tanaman cendawan terpakai, reka bentuk Box-Behnken, kaedah gerak balas permukaan

Introduction

Activated carbon (AC) is a carbonaceous material with large surface area and high porosity. The surface area and pore size distribution are important factors in determination of AC performance. The macropores act as the entrance to the AC, while the mesopores and micropores responsible for adsorption process determined by iodine number. Iodine number is important parameter to indicate the quality of carbon porosity by measuring the amount of iodine adsorbed (in milligrams) by 1 g of carbon using standard method of ASTM D4607-94. On the other hand, the percentage yield in activated carbon preparation plays a major role in continuous supply for application.

Generally, optimization of AC preparation is via traditional method. However, response surface methodology (RSM) has been found to be a useful tool to optimize AC preparation. Box–Behnken design (BBD) is one of RSM method with an independent quadratic design. It does not contain an embedded factorial or fractional factorial design. In this design, the treatment combinations are at the midpoints of edges of the process space and at the center. The BBD is favourable due to its less number of experiments with variable parameter consuming less time.

Most of the study had reported in multiple input parameters such as impregnation ration (IR), activation time and activation temperature. Precusors from agricultural wastes such as flamboyant (*Delonix regia*) pods [1], *Prosopisafricana* seed hulls [2], *Borassus aethiopum* shells [3] and coconut husk [4] have been studied. Spent mushroom farming waste (SMFW) is a low cost agricultural based material, abundantly available and is a renewable resource. The SMFW consists of sawdust and rice husk majorly. Previous study using sawdust as AC by Foo & Hameed [5] and Moodley et al.[6] and rice husk as AC by Khan et al.[7], Chen et al.[8], Kumagai et al.[9] and Ding et al.[10] have generated highly porous carbonaceous carbon. These reports showed that both components of sawdust and rice husk are suitable as a potential precursor. Thus, SMFW has been selected as precursor for this study as there is lack of literature study on utilization of sawdust and rice husk combination medium of SMFW AC preparation and application.

The aim of this study is to optimize SMFW AC preparation parameters of impregnation ratio (IR) between KOH and SMFW, activation time and activation temperature. The analysis involve multiple responses of percentage yield and iodine number via BBD of RSM method.

Materials and Methods

Materials

Spent mushroom farming waste (SMFW) used for preparation of activated carbon was provided by C&C Mushroom Cultivation Farm, Johor, Malaysia.

Characterization of the activated carbon

The AC surface morphology was analyzed using Field Emission Scanning Electron Miscroscope (FESEM) of ZEISS Supra 40VP at voltage of 5 kV and 12000 magnifications. The Fourier Transform Infrared (FTIR) spectra were analyzed using Series 100 PerkinElmer Fourier Transform Infra-Red (FTIR) spectroscopy in the range of 400 – 4000 cm^{-1} for surface functional groups identification. Thermogravimetric analyzer (TGA) TA Model SDT Q600 V8.3, under nitrogen gas atmosphere with heating condition following the ASTM D2974 was conducted.

Activated carbon preparation via Box-Behnken Design

The preparation of AC from SMFW was accomplished using sodium hydroxide (KOH) as activating agent. The SMFW was impregnated with the KOH for 24 hours respectively. The slurry was then dried at 80 ^{0}C for 24 hours. The impregnate precursor was carbonized in furnace. The produced char was washed with hydrochloric acid and distilled water to remove residual KOH and dried at 80 ^{0}C. Finally, the prepared AC was sieved to size of 150 micrometer and kept in drying cabinet prior to use. The experiments were applied using parameter set by BBD of RSM method. The variables studied were (i) $x1$, KOH: SMFW impregnation ratio; (ii) $x2$, activation time and (iii) $x3$, activation temperature. The experimental sequence was randomized in order to minimize the effects of the uncontrolled factors [3]. The two responses were carbon yield (Y_1) and iodine number (Y_2). Each response was used to develop an empirical model which correlated the response to the three activated carbon preparation parameters.

The percentage of activated carbon yield was calculated as equation (1). Iodine test was conducted according to ASTM D4607method and calculation as shown in equation (2) below:

$$\text{Percentage yield (\%)} = \frac{\text{Weight of activated carbon}}{\text{Weight of dried SMFW}} \text{ x } 100 \quad (1)$$

$$\frac{X}{M} = \frac{[A-(DF)(B)(S)]}{M} \quad (2)$$

where X/M is defined as iodine adsorbed per gram of carbon (mg/g), A is defined as normality of iodine solution × 12693, DF is defined as dilution factor (2.2), B is defined as normality of sodium thiosulfate solution × 126.93, S is defined as sodium thiosulfate used for every titration (mL) and M is defined as weight of activated carbon used.

Results and Discussion

Characterization of the activated carbon

The SEM image of SMFW AC is shown in Figure 1. The SMFW AC has a rough surface with different size of pores. The large irregular structure of pores in the AC external surface indicated the macropores with linkage of mesopores and micropores rooting inside the internal structure of AC. Formation of the pores corresponded to the formation of metallic potassium (K) through activation process using KOH as activating agent. Intercalation of K in the carbon structure widened the existing pores and developed new porosity essential for adsorption process.

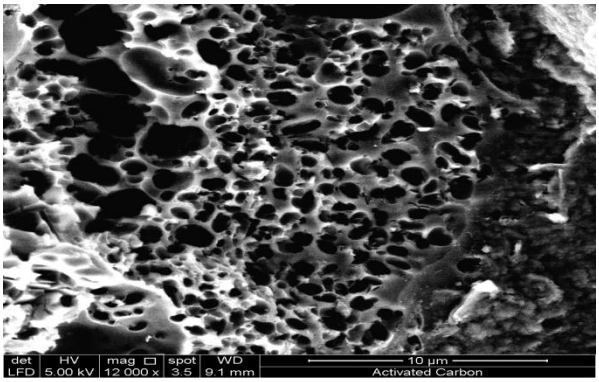

Figure 1. SEM image of SMFW activated carbon

Figure 2 shows the FTIR image of SMFW AC to determine the AC surface chemistry of functional groups. From the spectra, the band at 3405 cm^{-1} was attributed to the hydrogen bond between –OH in the AC surface or –OH in water molecule [11]. Besides, band at 1384 cm^{-1} was attributed to stretching vibration of C-N bond [12] and band at 1714 cm^{-1} was attributed to the C=O stretching bond of ketone [13]. The N-H stretch bond at band 3500 cm^{-1} represented amine group in the AC.

Figure 3 demonstrates the TGA/DTG curve thermogravimetry (TG) of AC and its derivatives represented by green line and blue line respectively. The TGA curve showed three phases of AC weight loss. The first stage was the moisture elimination of 3.4 % below temperature of 200 ^{0}C. Next, second stage weight loss of 26 % was due to the degradation of hemicelluloses, cellulose and lignin occurred at temperature 200 – 500 ^{0}C [14]. According to the previous study by Yang et al. [15], hemicelluloses started to degrade at 220 ^{0}C and completed at 315 ^{0}C while degradation of cellulose occurred between 315 – 390 ^{0}C. Stronger structure of lignin degraded in a wider temperature range than the other two components. The third stage involved weight loss according to the weight loss of 51.2 % volatile matter at temperature 500 – 900 ^{0}C. The same results have been reported in literature by Gao et al. [14], Zhang et al. [16] and Domingueza et al. [17]. The DTG curve of Figure 4 shows a significant change occurred due to the weight loss of AC starting of the degradation of hemicelluloses, cellulose and lignin. This was

explained by the fact that hemicelluloses and cellulose compounds have the structure of branching chain of polysaccharides without aromatic compound, which are easily volatilized. Meanwhile, lignin consists of various –O- and C-C functional groups and aromatic structural units [18].

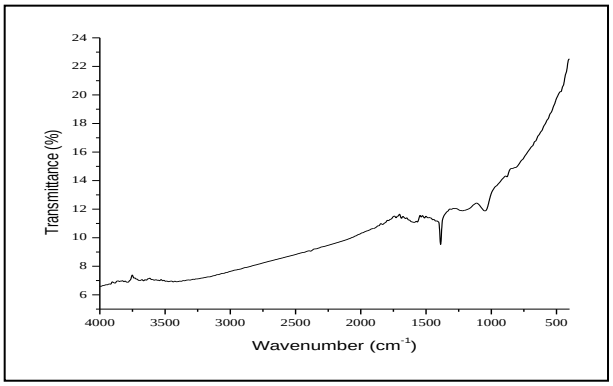

Figure 2. FTIR image of SMFW AC

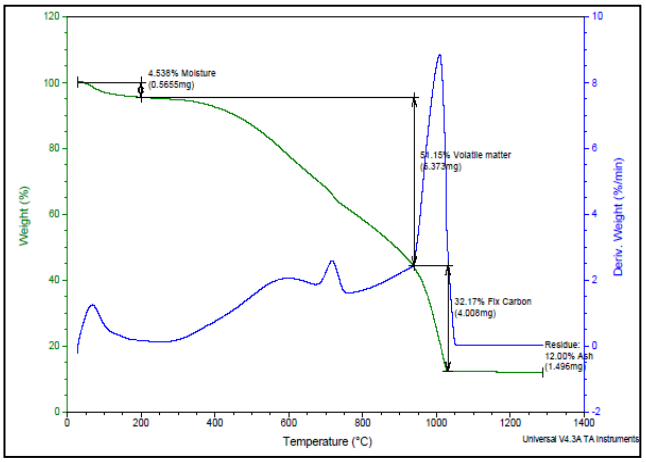

Figure 3. TGA/DTG image of SMFW AC

Optimization of parameters on carbon yield

Figure 4 (a – c) illustrate the 3-D response surface plots of percentage yield on AC as a function of three process parameters of impregnation ratio, activation time and activation temperature.

Figure 4 (a) shows the effect of impregnation ratio and activation time on the percentage yield. There are only little effect of time on yield. However, decreasing of yield with increasing ratio was observed which was due to increase of the carbon burn-off. Increased the impregnation ratio has resulted increased the weight loss of releasing the volatile matter from the intensifying dehydration and elimination reactions [4]. This is supported by Muthanna et al.[19] using Siris seed pods. Figure 4 (b) shows the effect of impregnation ratio and activation temperature on the percentage yield. When the ratio and temperature increased, the percentage yield of carbon was decreased. This was due to higher elimination of tars in the pores. Sentorun-Shalaby et al. [20] reported that at higher activation temperature, activation of apricot stones became more extensive and resulted in a lower solid yield with a more

widened porous structure. Figure 4 (c) shows the effect of activation time and activation temperature on the percentage yield. As the temperature increased, the percentage yield of carbon was decreased. Meanwhile, activation time did not have significant effect on the percentage yield since heating duration of AC only affect it's surface area. This is supported by Tan et al. [4] study on coconut husk AC.

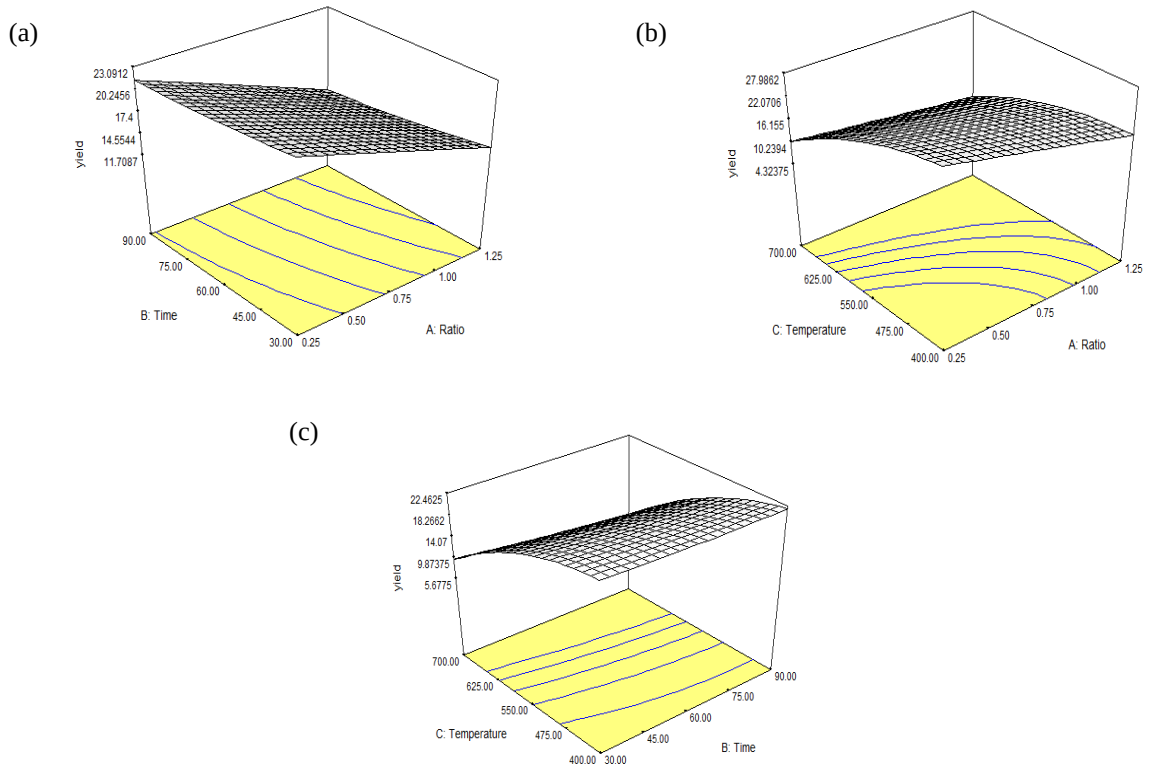

Figure 4. (a) Response for the effect of ratio KOH: SMFW and activation time on percent yield, (b) Response for the effect of ratio KOH: SMFW and activation temperature on percent yield and (c) Response for the effect of activation time and activation temperature on percent yield

Optimization of parameter on iodine number

Figure 5(a – c) illustrate the 3-D response surface plots of iodine number for AC as a function of three process parameters of impregnation ratio, activation time and activation temperature. Figure 5(a) shows the effect of impregnation ratio and activation time on the iodine number of the prepared AC. The iodine number increased with increased of the impregnation ratio. The impregnation ratio plays an important role in the formation of pores and promotes catalytic oxidation simultaneously. The KOH served to increase porosity of AC, thus resulted the raised in iodine number. This is supported by Abechi et al. [21] using KOH-kernel shell. Figure 5(b) shows the effect of impregnation ratio and activation temperature on the iodine number of prepared AC. As the activation temperature and impregnation ratio increased, the value of iodine number was increased. High temperature would increase the C–KOH reaction rates, thus resulting in increasing devolatilization and development of the pore structure in the char. Muthanna et al. [19] reported similar observation using AC from Siris seed pods. Figure 5(c) shows the effect of activation time and activation temperature on the iodine number of carbon. Since both the activation time and activation temperature increased, the value of iodine number was also increased. Tham et al.[22] reported that longer activation time had generated more micropores and mesopores in the AC produced from durian shell.

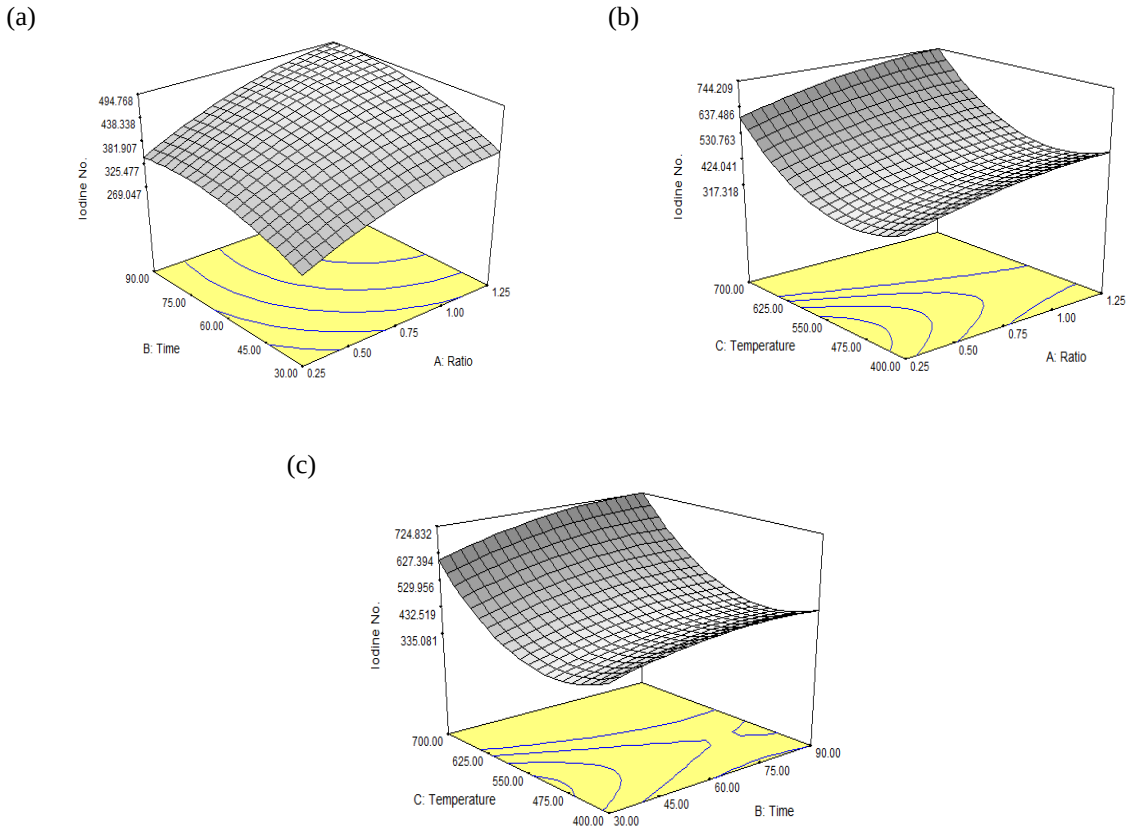

Figure 5. (a) Response for the effect of ratio KOH: SMFW and activation time on iodine number, (b) Response for the effect of ratio KOH: SMFW and activation temperature on iodine number, and (c) Response for the effect of activation time and activation temperature on iodine number.

Comparisons between experimental data and predicted data of Box-Behnken design

Final empirical models in terms of coded factors for carbon yield (Y_1) and iodine number (Y_2) are shown in equation (3) and (4), respectively.

$$Y_1 = 17.48 - 4.56xx1 - 1.13xx2 - 7.27xx3\text{-}0.045xx1^2 + 0.26xx2^2 - 2.83xx3^2 - 0.30xx1xx2 + 1.55xx1xx3 - 0.84\ xx2xx3 \quad (3)$$

$$Y_2 = 433.10 + 66.64xx1 + 45.65xx2 + 120.13xx3 - 26.86xx1^2 - 33.10xx2^2 + 144.64xx3^2 + 8.20xx1xx2 + 6.56xx1\ xx3 + 14.11xx2xx3 \quad (4)$$

Figure 6 shows the comparison between the experimental and predicted value of percentage yield and iodine number of AC. It was observed that there were good agreement between the experimental and predicted values of percentage yield and iodine number, which indicated the excellent reliability of the model with high R^2 of 0.9804 and 0.9333 respectively.

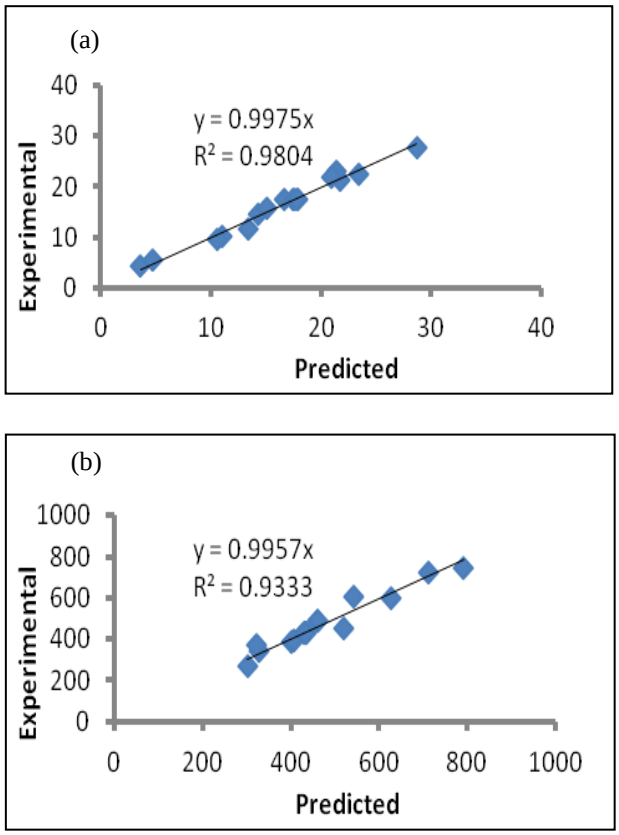

Figure 6. (a) Relationship between actual and predicted value of percentage yield of activated carbon, and (b) Relationship between actual and predicted value of iodine number of activated carbon.

Conclusion

Preparation of AC via Box-Behnken design of Response Surface Methodology was evaluated. The analysis of percentage yield and iodine number using this method generated optimum condition of impregnation ratio, activation time and activation temperature at 0.25, 30.04 min and 400 ^{0}C respectively. Experimental result was well fitted to predicted result with high R^2 of 0.9804 for percentage yield of AC and 0.9333 for iodine number. This method is applicable for industrial practice in AC production which involves multiple input and responses with minimum chemical and energy input, contribute on green technology.

Abstract

Studies on the removal of frequently used herbicide for controlling broad-leafed weeds, Paraquat Dichloride (PQ) has been carried out intensively. Waste from steelmaking industries (Electric Arc Furnace (EAF) slag) and natural zeolite (clinoptilolite) were used as the starting materials. Preparation of an adsorbent involved two steps, namely extraction iron oxide (IO) from slag and precipitation of IO onto clinoptilolite. Characterization of NZIC were done using Fourier Transform Infrared spectroscopy (FTIR), Scanning Electron Microscopy (SEM), single-point Brunauer Emmett Teller (BET) surface area analysis, Vibrating Sample Magnetometer (VSM) and pH at zero point charge (pHzpc). The NZIC showed a lower magnetic saturation at 8.13 emu/g compared to maghemite at 29.5 emu/g. The BET surface area of NZIC was 146.29 m^2/g, larger compared to the individual surface area of clinoptilolite and maghemite which are 37.84 and 17.84 m^2/g respectively. Adsorption of PQ onto clinoptilolite and NZIC were investigated using a batch experiment. Surface characteristic of NZIC was investigated by pHzpc experiment showing that at pH 8.2 its electric surface charge is zero. Optimum parameters for adsorption of PQ in water were found at pH 12 with 0.01 g/10 mL of NZIC and equilibrium time of 20 minutes. Desorption experiment revealed that NZIC have a good recovery in repetitive usage for PQ removal in water.

Keywords: waste, clinoptilolite, iron oxide, paraquat, adsorption

Abstrak

Kajian ke atas penghapusan racun rumpai yang sering digunakan untuk mengawal tumbuhan berdaun besar, Paraquat Diklorit (PQ) telah dijalankan secara intensif. Sisa daripada industri keluli dan zeolit asli (klinoptilolit) telah digunakan sebagai bahan mentah. Elektrik relau arka (EAF) sanga mengandungi logam oksida berharga seperti oksida besi (IO) yang merangkumi 37% (w/w) sanga. Kajian ini memberi tumpuan untuk mengekstrak IO dan pemendakan ke atas klinoptilolit. Penyediaan Zeolit-Besi Oksida Komposit (NZIC) melibatkan dua langkah mudah iaitu pengekstrakan IO dari sanga EAF dan pemendakan IO ke atas klinoptilolit. Pencirian NZIC telah dilakukan dengan menggunakan Fourier Transform Inframerah Spektroskopi (FTIR), Imbasan Elektron Mikroskopi (SEM), analisis kawasan permukaan Brunauer Emmett Teller (BET), Vibrating Sample Magnetometer (VSM) dan pH di caj titik sifar (pHzpc). NZIC menunjukkan ketepuan magnet yang rendah iaitu pada 8.13 emu/g berbanding maghemite dengan ketepuan magnet 29.5 emu/g. Kawasan permukaan BET untuk NZIC adalah 146.29 m^2/g, lebih besar berbanding dengan kawasan permukaan individu klinoptilolit dan maghemite, 37.84 dan 17.84 m^2/g masing-masing. Penjerapan PQ ke atas klipnotilolit dan NZIC telah disiasat menggunakan eksperimen kumpulan. pHzpc untuk NZIC adalah pada pH 8.2 di mana caj permukaannya adalah seimbang. Parameter optimum untuk penjerapan PQ dalam air didapati pada pH 12 dengan 0.01 g/10 mL NZIC dan keseimbangan masa iaitu 20 minit. Eksperimen penyaherapan menunjukkan NZIC mempunyai kadar pemulihan yang baik dalam penggunaan berulang-dalam penyingkiran PQ di dalam air.

Kata kunci: sisa, klinoptilolit, ferum oksida, paraquat, penjerapan

Introduction

Paraquat (1,1'-dimethyl-4,4'-bipyridinium) is a highly effective herbicide used to control weeds and grass in agricultural area. Commonly, farmers tend to spray the diluted herbicides to the plant area and eventually the excess PQ may reach the source of fresh water by leaching from soil. Paraquat (PQ) is hydrophilic compound and it is highly soluble in water. Paraquat is classified as toxic to human and environment. The maximum concentration level (MCL) of PQ in drinking water is 20 µg/L according to United States Environmental Protection Agency (USEPA). Hence, efficient method for pesticides removal in water is constantly being researched. Various techniques has been research including adsorption [1, 2] and advanced oxidation process (AOP) via catalyst and Fenton [3-5]. Adsorption is considered a feasible method for pesticides removal due to its simplicity, cost-effectiveness and high removal.

The use of agricultural and industrial waste as precursors in the preparation of adsorbent constantly studied. In this study, electric arc furnace (EAF) slag and clinoptilolite were used as the starting materials for the production of an adsorbent. Natural zeolite namely clinoptilolite is a cation exchanger and have high selectivity properties. The selectivity and size exclusion of zeolite offers more effective removal of PQ. The performance of synthetic and natural zeolite in removing contaminants is not much different [6]. Zeolites also reduce the effect of NOM in adsorption of contaminant in real water sample [7].

The EAF slag is a highly available material from steel-making industry wastes and comprised of many valuable metal oxides such as Zinc (Zn), Iron (Fe), Calcium (Ca), Copper (Cu) and Manganese (Mn) [8]. Numerous works have been reported on the recovery of these valuable materials from slag. For example, Saufi [8] extracted Fe to use to enhance its carbon nanotube (CNT). On the other hand, Shawabkeh [9], Fallman [10] and Orhan [11] studied on maximizing Zinc, Chromium and Barium recovery from slag. In this work, iron was extracted from EAF slag and precipitated onto clinoptilolite to produce an adsorbent for the removal of PQ in water.

Materials and Methods

Raw material

Electric arc furnace slag was collected from Antara Steel Mills (M) Sdn.Bhd and clinoptilolite was purchased from Shafzan Feed and Fertilizer. Both raw materials were ground and sieved to a particle size of 75 µm prior to use. Clinoptilolite was first activated by agitating in 2M sodium chloride (NaCl) solution [12]. Paraquat standard was purchased from Fluka Analytical and used without further purification. Stock solution of PQ was prepared by dissolving standard paraquat in double distilled water. The working solution of PQ was prepared by series of dilution from the stock solution prepared.

Preparation of Natural Zeolite-Iron Oxide Composite (NZIC)

The NZIC was prepared via two simple steps. First, iron oxide (IO) was extracted from EAF slag, followed by the precipitation of iron (hydr)oxide onto clinoptilolite. Powdered EAF slag was added to ammonium chloride (NH_4Cl) solution and the mixtures were refluxed for 2 hours. A desired amount of clinoptilolite was added to the filtrate solution to make a 3 to 1 amount of clinoptilolite to iron oxide. Concentrated sodium hydroxide (NaOH) was added dropwise to the filtrate with an aid of sonication. The mixture was stirred for another 2 hours until homogenous suspension was obtained. Synthesized product was filtered, washed and dried overnight in an oven at 70˚C. Final product was calcined in a box furnace at 500°C for two hours at a temperature rate of 10 ˚C/min.

Characterization of NZIC

Fourier Transform Infra-red (FTIR) spectroscopy (Perkin Elmer, Spectrum One) was used to analyse the functional groups found in the clinoptilolite and NZIC prepared at a spectral range of 4000 cm^{-1} to 400 cm^{-1}. The morphology of clinoptilolite, maghemite and NZIC were observed using Scanning Electron Microscopy (SEM) (Phenom G2 Pro). Effect of surface area of clinoptilolite, maghemite and NZIC were studied using single-point Brunauer Emmett Teller (BET) surface area analysis. Magnetic properties of maghemite and NZIC were analysed using Vibrating

Sample Magnetometer (VSM) at room temperature. Zero point charge (zpc) of NZIC was determined by pH at zero point charge (zpc) experiment [13].

Removal of Paraquat in water by NZIC

Adsorption experiment for study on effect of time, adsorbent dosage and pH in paraquat removal by NZIC were conducted in a batch mode study. The experiment take place in thermostat orbital shaker (Lab Companion) and experiments were repeated to ensure the reproducibility of the result is obtained. Adsorption and desorption experiment were done using 10 mg/L PQ standard solution followed by desorption with distilled water. Initial and final concentration of PQ was quantified using calibration curve of PQ standard, analysed by UV-Vis spectrophotometry (UV-Vis-Perkin Elmer Lambda25 Spectrophotometer) at maximum absorption wavelength of 257 nm.

Results and Discussion

Characterization of NZIC

Fourier Transform Infra-red

Spectra of clinoptilolite, maghemite and NZIC in Figure 1 showed an intense peak at 1028 cm^{-1} indicates the presence of internal vibration of tetrahedral Si-O and Al-O. At 450 cm^{-1} band showed the vibration of O-Al-O or O-Si-O bonds. The existence of in-plane-bending vibration of water (H_2O) and OH bending in clinoptilolite and maghemite observed at 1637 cm^{-1} and 3447 cm^{-1} respectively were due to moisture in the sample preparation. Low band at wavenumber of 600 and 790 cm^{-1} found at spectrum of maghemite and NZIC were attributed to the characteristics band of iron oxide [14].

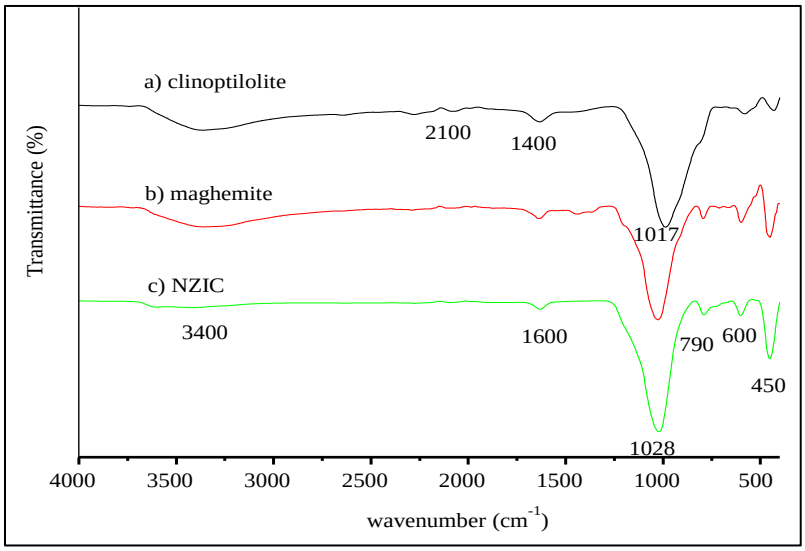

Figure 1. IR spectra of a) clinoptilolite, b) maghemite, and c) NZIC

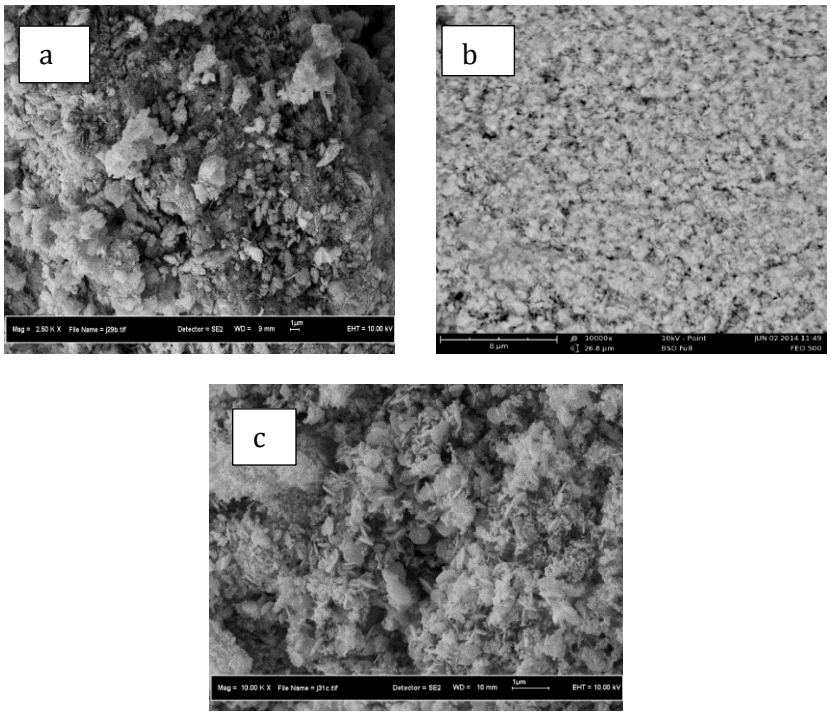
Scanning Electron Microscopy micrograph

SEM images of clinoptilolite, maghemite and NZIC were shown in Figure 2. Micrograph in Figure 2a showed an irregularly shaped of clinoptilolite. Maghemite poses a prismatic and flake-like shape as observed in Figure 2b. Maghemite was scattered around clinoptilolite in Figure 2c showing the effective effect of dispersive by sonication in preparation of NZIC procedure.

Magnetic saturation

Figure 3a showed the hyteresis loop for maghemite and NZIC analysed by VSM at room temperature indicate curve for paramagnetism materials. Magnetic saturation of maghemite and NZIC were 29.55 and 8.13 emu/g respectively. Magnetic curve of maghemite and NZIC showed small loop indicating the remaining of magnetic reflux in the sample eventhough magnetic force is zero. Figure 3b suggested that NZIC in water was attracted effectively when external magnetic field was introduced. The decreasing effect of magnetic saturation in NZIC sample was due to small amount of maghemite in per gram of NZIC as well as the presence of non-magnetic material, clinoptilolite in NZIC..



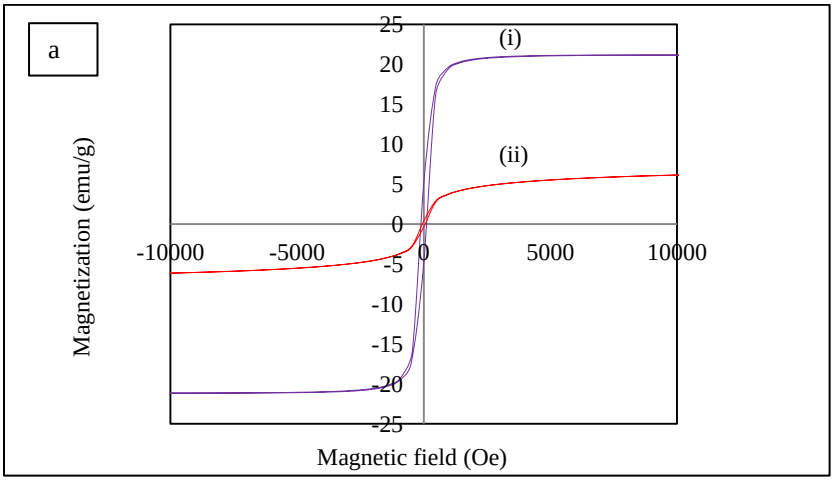


Figure 2. Micrograph of a) clinoptilolite, b) maghemite, and c) NZIC

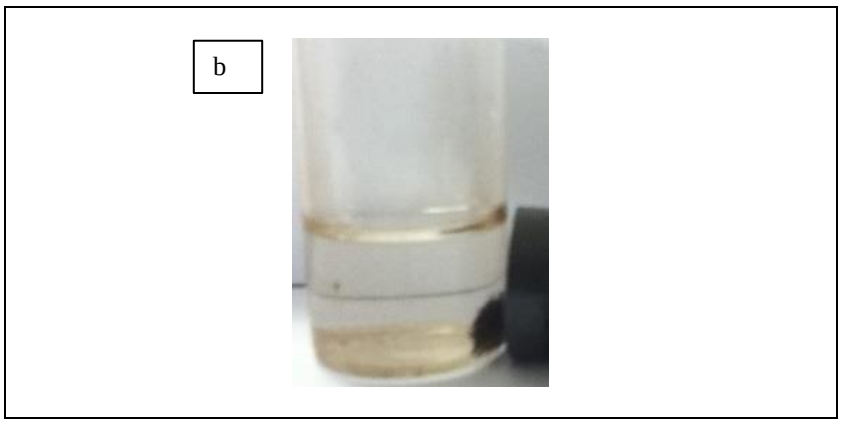

Figure 3. a) Magnetization curve of i) maghemite and ii) NZIC at 300 K, and b) magnetic attraction of NZIC towards external magnetic application

Surface area

The surface areas of raw materials, clinoptilolite and EAF slag as well as maghemite and NZIC were presented in Table 1. Iron oxide showed a small surface area due to the agglomeration effects and its mutual magnetic attraction. By modification of maghemite with clinoptilolite, the surface area increase almost four fold. The larger surface area of an adsorbent, then the bigger active site available for adsorption to take place.

Table 1. Surface area of clinoptilolite, EAFS, iron oxide and NZIC

Sample	**Clinoptilolite**	**Raw EAFS**	**Maghemite**	**NZIC**
Surface area, m^2/g	37.84	3.02	9.62	146.29

pH at zero point charge

The pH at zero point charge (pH_{zpc}) for NZIC was determined by mixing 0.15 g NZIC in 0.01 M concentration of NaCl and varying the pH of the solution from pH 2-13. After 24 hours agitation, the resulting mixtures were analysed for its pH. The plot of initial and final pH in Figure 4 showed an intersection of the two curves at pH 8.2. At this point, the NZIC surface charge is considered neutral. The adsorption of PQ depends on the pH of solution as PQ exists in its cationic form in water. At lower pH, surface of NZIC was saturated with hydronium ions (H_3O^+), thus high competition of these positively charge paraquat (PQ^+) and H_3O^+ decreased the adsorption of PQ.

Paraquat removal by NZIC

Figure 5 shows the plots of PQ removal by clinoptilolite, maghemite and NZIC against time. Adsorption of PQ by clinoptilolite and NZIC (3:1) were rapid at first and reached plateau after 20 minutes contact time. The equilibrium time of PQ removal was attained at the 20th minutes. From the graph in Figure 5, maghemite showed a very low adsorption, means that maghemite was not a good adsorbent. Although the surface area of NZIC was higher than clinoptilolite, but, the removal of paraquat by clinoptilolite was slightly higher than NZIC. As observed in Figure 5, low removal of PQ is observed despite a high surface area of NZIC. This is due to the existence of maghemite in NZIC.

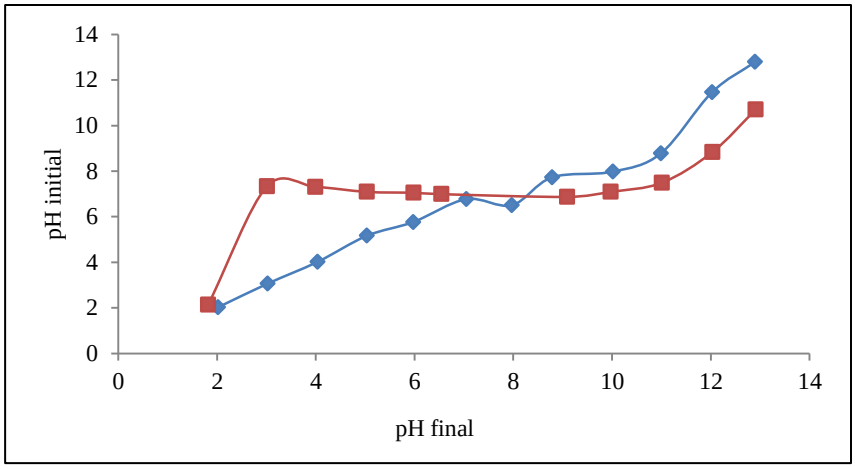

Figure 4. The pH at zero point charge of NZIC

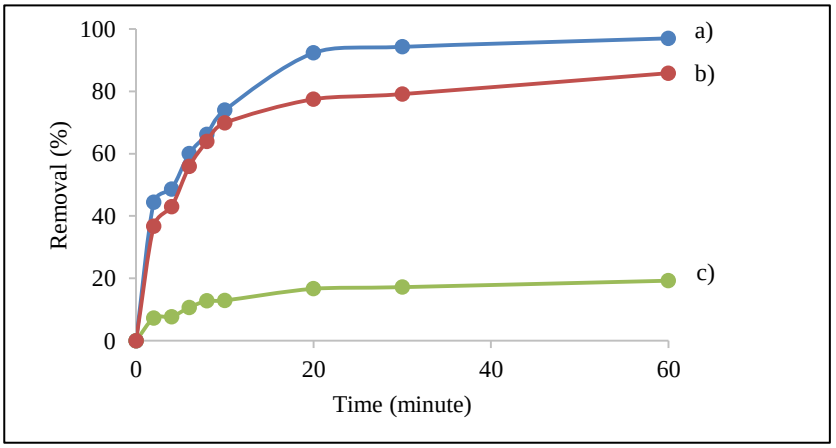

Figure 5. Comparison on the PQ removal by a) clinoptilolite, b) maghemite and c) NZIC (initial PQ concentration = 10 mg/L, Adsorbent dosage = 0.01 g, pH = neutral)

Plot in Figure 6 indicates that paraquat uptake increased with increasing pH. Maximum PQ uptake was obtained at pH 12. The removal of PQ is highly dependent on initial solution pH. This condition interrelated with the nature of PQ in water. The pK_a value of cationic PQ is 9 – 9.5 [14]. At higher pH than pH_{zpc}, higher concentration of hydroxide ions (OH^-) was present on NZIC surface. Hence, NZIC acquired a negatively surface charge at higher pH and cationic PQ easily attached to the surface of NZIC via attraction force.

Figure 7 shows that NZIC have a good recovery of PQ in desorption experiment. At first adsorption-desorption experiment, 99% of PQ was adsorbed and desorbed into the solution. The performance of PQ removal after second and third time repetitive usage was decreased to 86%. This small decreasing in percentage removal of PQ showed that the stability of these adsorbent for repetitive usage.

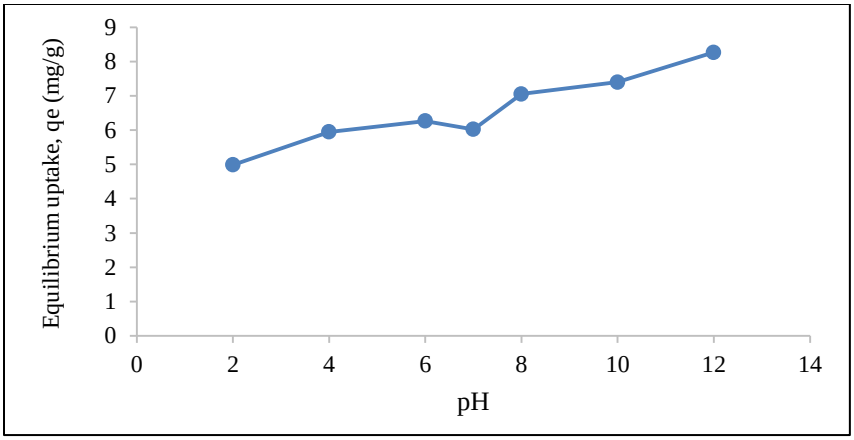

Figure 6. Effect of pH on PQ uptake by NZIC (initial PQ concentration = 10 mg/L, Adsorbent dosage = 0.01 g, pH=12)

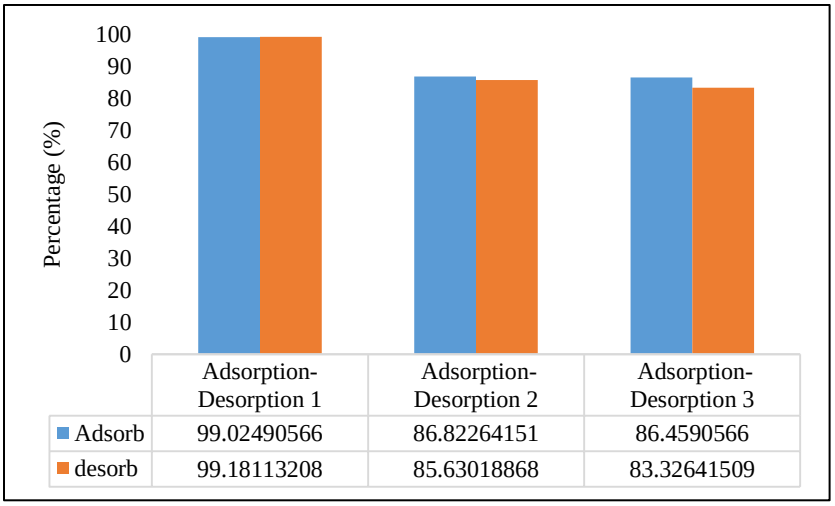

Figure 7. Repetitive adsorption of PQ onto NZIC (initial PQ concentration = 10 mg/L, Adsorbent dosage = 0.01 g, pH = 12)

Conclusion

Preparation of NZIC was done by extraction of iron oxide (IO) from slag and precipitation of IO onto clinoptilolite. Magnetization analysis of NZIC revealed the ability of maghemite in NZIC as a magnetic separator when external magnetic field was applied. Preliminary study showed that clinoptilolite have higher removal percentage of paraquat (96%) compared to NZIC (86%) due to nature of maghemite which is not a good adsorbent. Optimum parameters for adsorption of 10 mg/L PQ in water were found at pH 12 with 0.01 g of NZIC with equilibrium time of 20 minutes. Desorption experiment demonstrate that NZIC as a stable adsorbent for repetitive usage for PQ adsorption.

Abstract

Antifreeze proteins (AFPs) are synthesized by various cold-adapted organisms to enable them to survive in subzero environment. The unique role of AFPs recently attracted enormous interest to develop them as commercial products. In this work, we have studied the antifreeze activity of short helical protein fragments (peptides) instead of the entire antifreeze protein of Antarctic yeast *Glaciozyma antarctica*. Several short peptide segments were designed according to amino acid sequence of helical region of AFP-1 *G.antarctica*, which are assumed to be involved in its antifreeze activity. We have demonstrated that short peptide segments derived from yeast AFP possess antifreeze activity and result in modification of the ice crystals growth rates and habits. This strategy has enabled the preparation of short AFP with high antifreeze activity in large amount of quantities at a low cost further opens the chance of developing the commercial potentials of AFPs.

Keywords: Antarctic yeast, antifreeze protein (AFP), *Glaciozyma antarctica*, ice recrystallization inhibition (IRI)

Abstrak

Protein antibeku (AFPs) disintesis oleh pelbagai adaptasi-sejuk organisma untuk membolehkan ia bertahan di persekitaran suhu bawah takat beku. Peranan unik AFPs telah menarik minat yang besar bagi tujuan produk komersil. Di dalam kajian ini, kami telah mengkaji aktiviti protein antibeku berlingkar yang pendek (peptida) daripada protein antibeku Antartika yis *Glaciozyma antarctica*. Beberapa segmen peptida pendek direka mengikut jujukan asid amino berlingkar AFP-1 *G.antarctica*, yang dianggap terlibat dalam aktiviti antibeku. Kami telah menunjukkan bahawa segmen – segmen peptida pendek yang diperolehi daripada yis AFP mempunyai aktiviti antibeku dan menyebabkan pengubahsuaian kadar pertumbuhan dan tabiat hablur ais. Strategi ini telah membolehkan penyediaan AFP pendek dengan aktiviti antibeku yang tinggi dalam jumlah kuantiti besar pada kos yang rendah seterusnya membuka peluang untuk membangunkan potensi komersial AFPs.

Kata kunci: yis Antartika, protein antibeku (AFP), *Glaciozyma antarctica*, perencatan penghabluran ais (IRI)

Introduction

The effect of sub-zero temperatures on organisms can cause extensive damage due to the presence of ice crystals. If freezing persists, intracellular water passes into extracellular spaces and leads to cell dehydration. Despite this,

various species such as plants, fish, insect, bacteria and fungi are able to survive in the coldest and most southerly continent of the world, Antarctica, where it was once thought conditions would render it uninhabitable. DeVries [1] and his colleagues [2] were the first to reveal the mechanisms through which species of a thriving marine inhabiting the polar oceans at freezing temperatures are able to survive. Although these species have high levels of salt ions as compared to temperate species, the presence of these ions accounted for only about half of the observed water freezing point depression in their body fluid. From the analyses, it is clear that the primary defense in these organisms is attributed to a class of highly specialized biomolecules known as antifreeze proteins or AFPs [3].

Antifreeze activity has been speculated to be a result of ice recrystallization inhibition process. AFPs inhibit the growth of ice crystals by binding to ice surfaces and disrupt the normal propagation of the ice crystal by restricting the growth in the areas where AFPs cover the ice surface [4]. This leads to a curvature of the surface of the ice crystal, increasing the ratio of the surface area to volume, and resulting in a ratio which is no longer thermodynamically supportive of spontaneous ice growth. The potential for an ice crystal to grow is therefore arrested by this mechanism [5]. Most exciting is that AFPs are now leading to promising commercial applications such as improving the texture of ice-cream [6], extending the half-life of frozen dough [7] and as far as cryosurgery [8]. Another interesting development in the application of AFPs is their potential for the cryopreservation of cells, tissues and membranes from damage at low, but not freezing temperatures [9].

There are five types of AFPs which have already been identified: AFP type I, II, III and IV. Type I AFPs are known as amphipathic α-helical structure with alanine-rich sequence sized between 3.3 kDa to 9 kDa -R, type II AFPs with molecular mass ranging from 11 kDa to 24 kDa exists as large globular proteins comprising multi-cysteine residue in their structure [10-12], type III AFPs are recognized as β-sandwich globular proteins with molecular weight around 6 kDa [13-16], type IV AFPs are rich with glutamate (E) or glutamine (Q) residues in sequence form a bundle of with α-helical [17], while type V AFPs were recently reported and known as hyperactive proteins isolated from insects [18].

Instead of using an antifreeze protein, this study will focus on application of the peptide segments of AFP. Because of the simpler structure of antifreeze peptides over antifreeze proteins, it can be used as “molecular tools” to investigate each sequence in peptide structure which performs a function in the antifreeze protein [19]. The α-helical structures are believed to play a major role in inhibiting of ice crystal in Type-I AFPs, and this require the binding of hydrophobic face helices with water crystals [20]. These facts led us to design and study antifreeze activity of short peptides isolated from Antarctic yeast, *Glaciozyma Antarctica* that produced an 18 kDA of AFP I. The predicted three-dimensional structure of AFP I display several α-helical conformations in its structure expected to have biological activity as their native protein.

Materials and Methods

Peptides

Peptide 1, peptide 1m, peptide 2, peptide 3, peptide 4 and peptide 4m, were bought from GL Biochem, Shanghai, China. Each peptide was supplied HPLC purified >90% purity and was used without further purification. The molecular weight of each peptide was analyzed using ESI LC-MS.

Peptide design

Four peptides namely peptide 1, 2, 3 and 4 were derived from α-helical regions in the predicted structure of *G. antarctica* AFP-1. Further modifications were made in peptides 1 and 4 by introducing salt bridges in their structure to improve their α-helical conformation. A scrambled peptide was designed based on the systematic scrambling of peptide 1m and was used as a negative control. Their sequences are shown in Table 1. Structure of the design peptides were then predicted using online server; PEP-FOLD [21]. The basic principle behind PEP-FOLD is that the three dimensional model is built based on the concept of hidden Markov model (HMM) derived structural alphabet (SA) of 27 four amino acids letters. The SA letter profiles of each peptide sequences were first predicted and subsequently assembled with the fragments according to the sOPEP coarse-grained force field.

Antifreeze activity determination

Ice crystals growth in 30 % sucrose solution was studied using a temperature-controlled freezing stage (Model THM 600 Linkham Scientific Instrument, UK) connected with a temperature controller unit (Model TMS 94, Linkham Scientific Instrument, UK). The freezing stage was incorporated on top of the conventional microscope stage (Olympus BX51, USA). In ice recrystallization experiment, 1.5 µL mixture of 1 mM peptide solution and 30 % sucrose (1:1 ratio) was sandwiched between two microscope glass coverslip. The sample was added inside the freezing stage and the temperature was adjusted from 20°C to – 40°C at the rate of 100°C/min. The temperature of the sample was then slowly increased from – 40°C to – 6°C at the rate 10°C/min and was maintained for 3 hours. The irruptive of ice recrystallization phase was occurred, generating a very fine of ice nuclei with different size in different sample. A reduce number and growth of ice crystals size in peptide solution after 3 hours incubation period would be indicative of the peptide efficiency in inhibiting ice crystal growth [23]. The sample microscopic images were captured at the end of incubation period at 100x magnification. The mean size of the ice crystals formed was calculated using the Cell^F software.

Results and Discussion

The ability of Antarctica yeast *Glaciozyma antarctica* to survive in freezing temperature is believed by employing antifreeze proteins. Currently, only AFP-1 gene sequence has been successfully characterized and expressed from the yeast [22]. The large antifreeze protein (AFP) from this *antarctica* yeast shows very low homology as compared to other AFP genes [23]. Interestingly, the predicted three-dimensional structure of AFP-1 sequence shows the presence of several α-helical conformations in its structure. Garner and Harding [20] put forward the idea to design small structured peptides with antifreeze properties and suggested that the α-helical structures which contained both hydrophilic and hydrophobic region are important and may responsible for the antifreeze activity [24].

Peptides 1, 2, 3 and 4 were designed representing the helices presence in the AFP-1 while peptide 1m and 4m were modified version of peptide 1 and 4. The solubility of peptides 1, 1m, 3, 4 and 4m in an unbuffered solution at pH 5.0 was good. However, peptide 2 was dropped from this study due to poor insolubility in water. Modification were made in peptides 1 and 4 sequences and produced peptides 1m and 4m to improve helical structure formation by the use of lactam bridges, which might form at positions either *i, i*+4 or *i, i*+7 between basic and acidic residues. In addition, peptide solubility in water will increase in the presence of more basic and acidic amino acids in the peptide sequence. Besides, it has been recently reported that, reducing the helicity content of AFP results a reduction of the antifreeze activity [24]. Therefore, through the amino acids sequence alterations, the fixed α-helical structures of modified peptides are predicted to be more stable and consequently exhibit higher antifreeze activity.

The three dimensional structure of peptides are predicted to exists as single, amphipathic, α-helix by PEP-FOLD. The prediction can only provide an indication of how certain peptide conforms in an aqueous solution. According to the results, peptide 1m is structurally predicted being more straightforward helix, while both peptides 3 and 4m are structurally less straightforward since there are slightly helical twist can be seen in their structure. As shown in Figure 1, the cross-section view of 3D conformation clearly shows the amino acid distribution in the peptides structure. All peptides have hydrophobic face in their structure. A clear distinct region of hydrophilic and flat

hydrophobic region may be observed in peptide 1m (Figure 2). Although the exact mechanism which attributed to the action of antifreeze by these peptides is remain elusive, it is expected that it may follow a mechanism similar to that of antifreeze activity of type-1 AFPs as found in organisms that live in freezing temperatures [25]. It is well accepted that flat-faced proteins in hydrophobic region may contribute to the binding mechanism of these proteins to ice crystals [20].

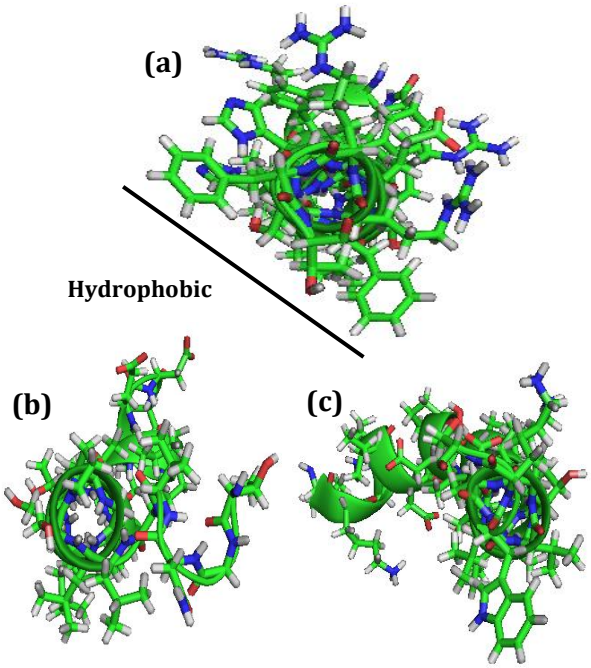

Figure 1. Cross-section view of 3D conformation of (a) peptide 1m, (b) peptide 3 and (c) peptide 4m, using PEP-FOLD and PyMOL showing hydrophobic region. Carbon: green, hydrogen: white, nitrogen: blue, oxygen: red, sulphur: yellow.

Throughout this work, to ensure on the accuracy of antifreeze activity determination, all peptide samples used were dissolved in unbuffered solution at pH 5.0, as salt presence in a solution would elevate the antifreeze activity due to its ability to reduce the freezing point [26]. In this work, to obtain a quantitative estimation of antifreeze activity, ice recrystallization inhibition (IRI) was investigated by observing the ice crystals size after 3 hours of incubation time at – 6°C at low peptides concentration. Figure 2 and Table 2 show IRI results for 1 mM of designed peptide. To investigate the ability of the peptides in ice growth inhibition, the results were compared with a negative control, namely scrambled peptide. The results obtained show that, all five designed peptides could not completely arrest the ice crystal growth. Nevertheless, by comparing IRI results of negative control, diminutive ice crystal size can be clearly seen. The designed peptides demonstrated moderate growth of ice crystals growth. The order of antifreeze activity of peptides at 1 mM concentration based on the size of ice crystal growth was found to be highest in modified peptide 1m and peptide 4m followed by peptide 1, peptide 4 and peptide 3. Interestingly, both modified peptide (peptides 1m and 4m) able to arrest ice growth better than their original peptide (peptides 1 and 4) due to the mutations of Leu19Glu and Gln19Lys in their sequence.

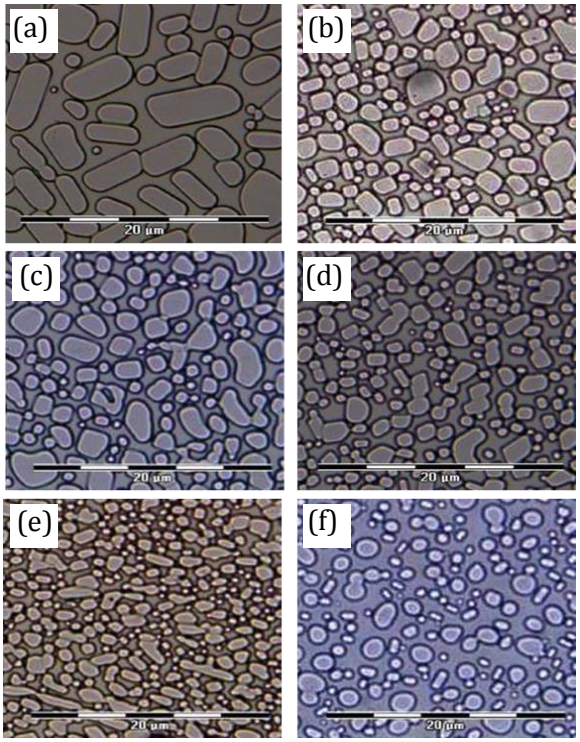

Figure 2. Ice recrystallization inhibition (IRI) of 1 mM peptide assays results. The growth of ice crystals were observed after 3 h incubation at the temperature of -6 °C. (a) scrambled peptide, (b) peptide 1, (c) peptide 3, (d) peptide 4, (e) peptide 4m, (f) peptide 1m.

Table 2. Mean of ice crystal size in 30% sucrose solution containing peptide

Sample	**Mean ice crystal diameter ± SD (µm)**
30% sucrose + 1 mM peptide 1	6.37 ± 2.61
30% sucrose + 1 mM peptide 3	9.27 ± 4.61
30% sucrose + 1 mM peptide 4	7.66 ± 2.94
30% sucrose + 1 mM peptide 1m	4.50 ± 2.42
30% sucrose + 1 mM peptide 4m	5.57 ± 2.21
30% sucrose + 1 mM scrambled peptide	17.22 ± 3.42

The results reported here appear to support the hypothesis that short helical fragments of antifreeze protein should be able to mimic the biological activity of its parent protein by modifying the ice crystals growth and habit. The short designed peptides appear to have similar adaptability which required for antifreeze activity. It was also evident that the hydrophobicity and straightforwardness of helical peptide were crucial for their ice crystal modification capabilities [3]. In this respect, modified peptides (peptide 1m and 4m) possessing a high degree of helicity due to the formation of salt bridges between acidic residues and basic residues exhibited the greatest inhibitory activity than less helical peptide.

Conclusion

As a conclusion, our results proved that a well-conserved α-helical with distinctive hydrophobic and hydrophilic region in the peptide structure, reinforcing the antifreeze activity. The antifreeze activity was found to be peptide 1m > peptide 4m > peptide 1 > peptide 4 > peptide 4. The success of our strategy of using short segments of yeast AFP may enhance potential to develop applications using the short antifreeze peptide properties via routine design and synthesis in cost-effective commercial production.

Abstract

Quantitative Structure-Activity Relationship (QSAR) study was performed on 10 isatin derivatives which were reportedly used as corrosion inhibitors. Dragon software was used to calculate the molecular descriptors. Partial least square (PLS) method was used to run the regression analysis between the descriptors and the corrosion inhibition efficiencies (IE) of the inhibitors. A predictive QSAR model was developed with a correlation coefficient (r^2_{cal}) of 0.9676. The model validity was assessed through internal and external validation. The results show that cross-validation regression coefficient (r^2_{cv}) and prediction regression coefficient (r^2_{pred}) are 0.8163 and 0.9189, respectively. The model was used to predict the IE for ten isatin derivatives. The results confirm a good stability and predictive ability of the model. Dragon-based descriptors provide a very good description of the corrosion inhibition properties of the inhibitors. The results of the QSAR study were found to be consistent with the experimental data.

Keywords: QSAR modeling study, corrosion inhibition, isatin derivatives, partial least square

Abstrak

Kajian hubungan aktiviti-struktur kuantitatif (QSAR) dilaksanakan ke atas 10 terbitan isatin yang dilaporkan diguna sebagai perencat kakisan. Perisian Dragon digunakan untuk mengira pemerihal molekul. Kaedah kuasa dua terkecil separa (PLS) digunakan untuk melaksanakan analisis regresi antara pemerihal dan keberkesanan perencatan kakisan (IE) terhadap perencat kakisan. Ramalan model QSAR dibangunkan dengan pekali kolerasi (r^2_{cal}) bernilai 0.9676. Kesahan model dinilai melalui pengesahan dalaman dan luaran. Keputusan menunjukkan bahawa pekali regresi kesahan-silang (r^2_{cv}) dan pekali regresi ramalan (r^2_{pred}) adalah masing-masingnya 0.8163 dan 9189. Model tersebut digunakan untuk meramal IE bagi 10 terbitan isatin. Keputusan mengesahkan kestabilan dan kemampuan ramalan yang baik terhadap model. Pemerihal berasaskan Dragon memberi penerangan yang baik tentang sifat perencatan kakisan bagi perencat-perencat kakisan. Keputusan kajian QSAR ini adalah konsisten dengan data eksperimen.

Introduction

Steel is the main constructional material and has several types with variety of mechanical properties. It has extensive applications in industries because of its low cost and excellent mechanical properties [1-3]. However, it is prone to corrosion and raises a serious concern since it costs a huge loss in properties and safety problems [4]. Therefore, prevention of corrosion or at least reduction in its rate has been widely studied. Heterocyclic organic compounds containing nitrogen, sulfur, oxygen or phosphorous in their molecular structures are the most reported inhibitors of the steel corrosion especially in acidic corrosive media [5, 6]. The performance of the corrosion inhibitors is based on their adsorption onto metal surface. The adsorption of the inhibitors forms a protected film and reduces the corrosion rate [7]. Many experimental and theoretical studies have been done to study the efficiency of many corrosion inhibitors. However, experimental measurements are costly and time consuming. Therefore, theoretical methods have become more desirable since they may overcome disadvantages of running experiments [8, 9]. For example, quantitative structure activity relationship (QSAR) is a modeling technique which is applied in many disciplines of chemistry [10].

In QSAR modeling, molecular descriptors are calculated based on the molecular structures of the compounds. The traditional method is to calculate the descriptors using quantum chemical calculations. In addition, other techniques such as Molconn-Z, CODESSA and Dragon software are used to calculate molecular descriptors [11]. A number of 4885 molecular descriptors can be calculated using Dragon software [12]. Multiple linear regressions (MLR) and partial least square (PLS) are the most applied regression methods in QSAR modeling. Various variable selection methods such as stepwise regression (RS), genetic algorithms (GA), genetic algorithme-partial least square (GA-PLS) [13, 14], and interval partial linear square (IPLS) [15, 16], were proposed to specify the most relevant variables.

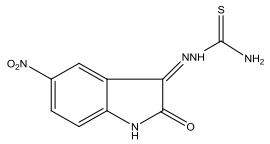
This study aims to develop a reliable QSAR model using data of newly synthesized isatin derivatives as corrosion inhibitors for Q235A steel in 3 M HCl. Apart from quantum chemical calculations, Dragon software was used in this work to calculate molecular descriptors based on the molecular structures.

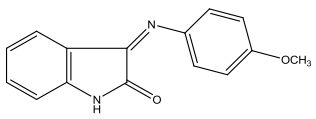
Materials and Methods

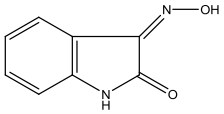
Dataset

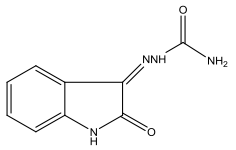
The dataset consists of ten isatin derivatives used as corrosion inhibitors of Q235A steel in acid medium (Table 1) [17]. The corrosion inhibition efficiency sorted in decreasing order from 70.4 to 15.9 %. The dataset was split into 70 % training set and 30 % test set.

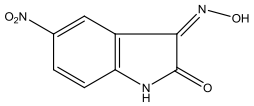
Table 1. Inhibition efficiencies and molecular structures of isatin derivatives collected from Ref. [17]

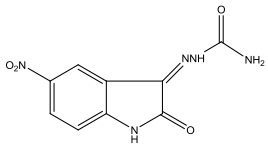


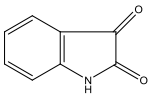


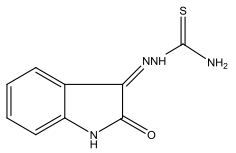


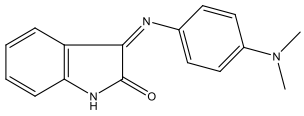


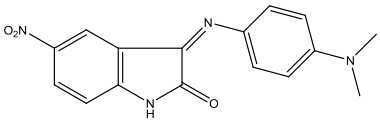












No.	Structure	Inhibition efficiency, IE (%)
Training set		
1		67.7
2		66.8

Calculation of descriptors and variable selection

Prior to descriptors calculation, molecular structures of the inhibitors were drawn with the Chem3D software and optimized using the MM2 followed by the Molecular Orbital Package (MOPAC) module. The Dragon software Version 6.0 [12], was used to calculate the descriptors using the optimized structures. The total number of the calculated descriptors was 2754. A variable selection was applied. One of the highly correlated descriptors pairs with $R \geq 0.90$ was randomly excluded. Descriptors with at least one missing value were then excluded yielding a reduced set of 227. Then descriptors with more than 90% equal values or with zero values were manually eliminated yielding a final set of 165 descriptors. The final set of descriptors was subjected to variable selection using IPLS selection method. The IPLS method was used to select a subset of variables. The selected variables subset could produce reliable models with better prediction ability compared to the use of all dataset variables. The variable selection and models building were performed using PLS Toolbox 6.2 (Eigenvector Research Inc.) in Matlab 7.6.0.324 (R2008a).

Statistical evaluation of the QSAR models

The QSAR model was evaluated in terms of its stability and predictive ability using several statistical parameters. The statistical parameters included correlation coefficient (r^2_{cal}), cross-validation regression coefficient (r^2_{cv}), prediction regression coefficient (r^2_{pred}), root-mean-square error of calibration (RMSEC), root-mean-square error of cross-validation (RMSECV), and root-mean-square error of prediction (RMSEP).

Results and Discussion

IPLS-based model

A set of three significant descriptors were selected from the final set (165 descriptors) using IPLS selection method. The descriptors were used to develop QSAR models. The selected descriptors are HATS3u, R3s and De. The HATS3u (Leverage-weighted autocorrelation of lag3/unweighted) descriptor is a type of GETAWAY descriptors. The R3s (R maximal autocorrelation of lag 3/weighted by I-state) descriptor is also one of GETAWAY descriptors. GETAWAY descriptors are 3D geometrical descriptors which calculated from atomic Cartesian coordinate's values. GETAWAY descriptors were designed to match the 3D-molecule geometry, relatedness of atom, and chemical information [18]. The De (D total accessibility index/weighted by Sanderson electronegativity) descriptor is one of WHIM (weighted holistic invariant molecular) descriptors. WHIM descriptors are molecular descriptors based on statistical indices calculated on the projections of the atoms along principal axes. WHIM descriptors are developed to extract 3D molecular information related to molecular size, shape, symmetry, and atom distribution with respect to invariant reference frames [19,20]. Table 2 shows the correlation matrix of the selected descriptors. It is clear that there is no inter-correlation between the descriptors. Several QSAR models were developed using PLS regression and the best model was selected based on statistical parameters. The best IPLS-based model for modeling the inhibition efficiency of isatin derivatives as a function of a set of three significant descriptors is presented by the Equation (1). The correlation coefficients r^2_{cal}, r^2_{cv}, and r^2_{pred} of the model are 0.9676, 0.8163, and 0.9189, respectively. The values of root-mean-square errors RMSEC, RMSECV, and RMSEP are lower than that of other developed models by the same method. This is an indication of higher prediction ability of the proposed model.

$$\text{IE}\,\% = 61.3368 + 63.4336(\text{De}) + 112.0971(\text{HATS3u}) - 14.7415\,(\text{R3s}) \quad (1)$$

whereas r^2_{cal} = 0.9676, r^2_{cv} = 0.8163, r^2_{pred} = 0.9189, RMSEC = 3.5874, RMSECV = 8.8106 and RMSEP = 18.3132

Table 2. Inter-correlation matrix of descriptors presents the model

Descriptor	De	HATS3u	R3s
De	1		
HATS3u	-0.249	1	
R3s	-0.289	0.230	1

Outliers detection

Detecting and then removing outliers is to enhance the prediction ability of the model. The possibility of the existence of outliers in the dataset was studied by plotting of standardized residuals against predicted values (Figure 1). A compound was considered as an outlier when the standardized residual was greater than 2 or less than -2 [21]. Figure 1 shows the outlier plot of the model. Only one compound has standardized residual higher than 2 which was excluded as an outlier.

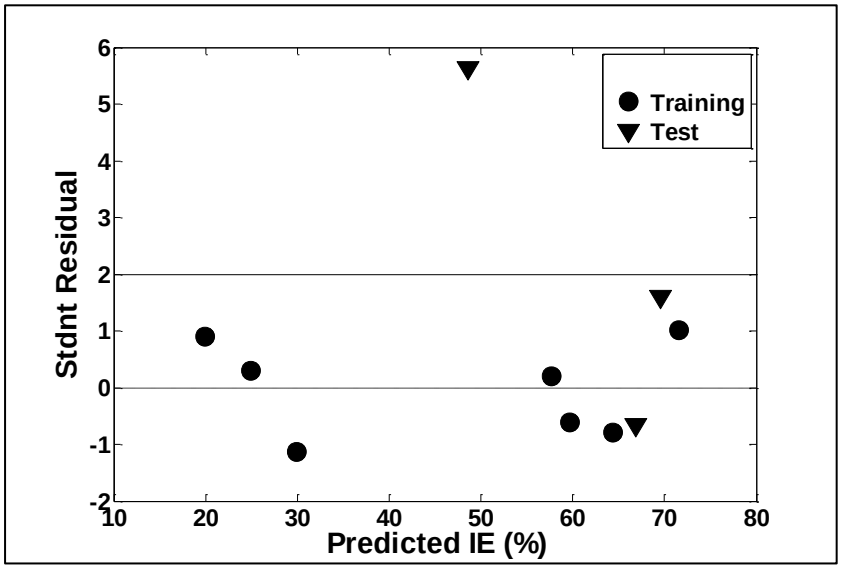

Figure 1. Plot of standardized residual versus predicted values

Model interpretation

Significant descriptors (i.e. HATS3u, R3s and De) were found to be useful to build reliable QSAR models. The proposed QSAR model was used to predict the corrosion inhibition efficiency (IE %) of the dataset compounds. Figure 2 displays a plot of predicted against the experimental values. The plot shows that the QSAR model has a high correlation coefficient. This indicates a good correlation between the experimental and predicted values. According to the statistical parameters, the developed model has high r^2_{cal} and r^2_{cv} of 0.9676 and 0.8163, respectively. Furthermore, the values of RMSEC, RMSECV are lower than that of other developed models by the same method. The result indicates high stability and predictive ability of the proposed model.

Model validation

The stability and predictive power of the model were validated using both internal and external validation. Internal validation was carried out using cross-validation leave-one-out. Internal validation provides internal check on the model. The cross-validation regression coefficient r^2_{cv} is 0.8163. The external validation was conducted by the prediction of test set efficiencies. The predicted efficiencies are in a good agreement with the experimental values. The prediction regression coefficient r^2_{pred} is 0.9189. The results indicate a high ability of the model to predict corrosion inhibition efficiency of new structurally relevant compounds. Further validation was performed to check the robustness of the model using a Y-randomization test. The training set was shuffled several times. The PLS regression was performed to each randomized dataset. The obtained values of r^2_{cal} ranged from 0.0418 to 0.2896. The low r^2_{cal} values indicate that the model is not due to a chance correlation.

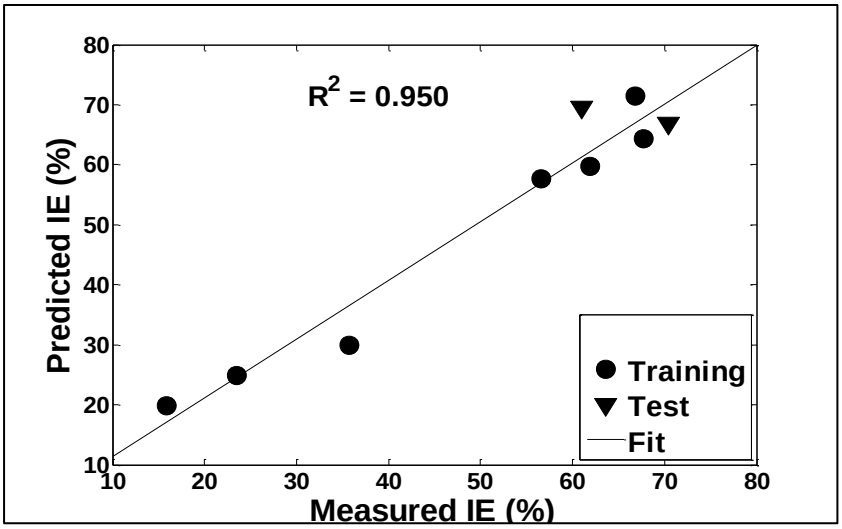

Figure 2. Plot of predicted and measured IE (%)

Conclusion

Dragon software was used to calculate the molecular descriptors. A QSAR model was built using PLS regression method. According to the statistical assessment and validation results, the proposed model reveals high stability and predictive power. Three significant descriptors (i.e. R3s, HATS3u and De) were used to develop a QSAR model. The descriptors contributed significantly to describe the corrosion inhibition properties of the inhibitors. Therefore, the use of Dragon software provides more opportunities to enrich the corrosion area with new descriptors. The computational methods used in this study are useful for developing predictive QSAR models with potent ability to predict and design novel and potential corrosion inhibitors.

Abstract

Interspecies, inter-tissue and interspatial dissimilarities of trace metals in particular body parts of *Saccostrea cucullata*, *Thais clavigera* and *Nerita chameleon* from the east Johor coastal waters were compared. Metals of interest includes Pb, Cd, Zn, Cu, Mn, Co, Se and Sr. Bivalve mollusk *S. cucullata* evidenced to be a worthy bioindicator for Zn and Cu while the two gastropod molluscs, *T. clavigera* for Cd and Se, and *N. chameleon* for Pb, Mn and Sr. The prominent concentration of metals originate in *T. clavigera* may be the outcome of biomagnification transfer from the *S. cucullata* on which they feed while for *N. chameleon*, it might be resulting from their herbivorous feeding behavior on algae on rocks which they graze. The metal accumulation patterns indicate consistent enrichment of essential metals in soft tissue. Values of operculum to tissue ratio (OTR) and shell to tissue (STR) higher than unity in *T. clavigera* indicate that operculum had higher affinities for Pb, Mn and Se while shell had higher affinities for Co and Sr. In *N. chameleon*, values of OTR and STR higher than unity displayed that operculum and shell had similar higher affinities for Co and Sr and Cd, Co and Sr, respectively. Significant interspatial variations ($p< 0.05$ and $p< 0.01$) in trace metals were noted. Assessment of metal concentration with maximum permissible limits of toxic metals in food shown the values were well within safety levels, except for Zn in *S. cucullata* that need to be monitored.

Keywords: heavy metals, intertidal mollusks, body parts, safety level

Abstrak

Perbezaan logam surih antara spesis, antara tisu dan antara kawasan dalam bahagian badan tertentu *Saccostrea cucullata*, *Thais clavigera* dan *Nerita chameleon* dari perairan pantai Johor timur telah dikaji. Logam yang menjadi perhatian termasuklah Pb, Cd, Zn, Cu, Mn, Co, Se dan Sr. Moluska bivalvia *S. cucullata* terbukti berpotensi menjadi bioindikator bagi Zn dan Cu manakala kedua-dua moluska gastropoda, *T. clavigera* bagi Cd dan Se, dan *N. chameleon* bagi Pb, Mn dan Sr. Kepekatan logam yang menonjol dari *T. clavigera* kemungkinan terhasil dari pemindahan biomagnifikasi dari *S. cucullata* yang dimakan manakala bagi *N. chameleon*, ia berkemungkinan terhasil dari tabiat pemakanan secara herbivor ke atas alga di atas batu. Corak pengumpulan logam menunjukkan kepekatan logam perlu yang konsisten dalam tisu lembut. Nilai ratio operculum kepada tisu (OTR) dan ratio kulit ke tisu (STR) lebih tinggi dari paduan dalam *T. clavigera* menunjukkan operculum mempunyai affiniti yang tinggi bagi Pb, Mn dan Se manakala kulit pula mempunyai affiniti yang tinggi bagi Co dan Sr. Dalam *N. chameleon*, nilai OTR dan STR lebih tinggi dari paduan menggambarkan bahawa operculum dan kulit mempunyai persamaan affiniti yang tinggi bagi Co dan Sr dan Cd, Co dan Sr, masing-masing. Variasi antara kawasan yang signifikan ($p<0.05$ and $p<0.01$) dalam logam surih telah dicatatkan. Pemeriksaan kepekatan logam dengan tahap maksimum yang dibenarkan bagi logam berat menunjukkan nilai masih lagi di bawah tahap selamat, kecuali Zn dalam *S.cucullata* yang perlu diberi perhatian.

Kata kunci: logam berat, intertidal moluska, bahagian badan, had selamat

Introduction

Heavy metals in the aquatic system can be naturally formed by the slow leaching from soil to water, typically at low levels in the parts per billion ranges and producing serious effects on social health [1]. They remains in solution for a long time before being removed to the sediments of the sea floor, a route of reverse weathering, which removal mechanisms consist of inorganic precipitation and reactions between dissolved materials and solid particles, as well as biological process like bioaccumulation of bacteria and phytoplankton and larger organisms [2]. Although many metals were recognized to have vital biological roles in low concentration, e.g. Cu, Zn, Mn, Fe; all these elements have the potential to be toxic to certain organisms above threshold concentration. Specific metal might alter into the persistent force of the metallic compounds with high toxicity, which leads to bioaccumulation in the organism's body, being magnified in the food chain and eventually threatening social health.

Much attention has been paid to the capability of marine organisms, especially molluscs to accumulate metallic toxicants from the marine environment where it lives. Goldberg [3] was the first to initiate the ``Mussel Watch Program" in which the bivalves were used as a surveillance tool of coastal pollution. Biomonitoring is a scientific technique in evaluating environment health based on sampling and analysis of an individual organism's tissue and fluids. This method, which comprises human contacts to natural and synthetic chemicals, takes advantage of the facts that chemicals that have entered the organisms leave indicators reflecting this exposure. Compared with other invertebrate groups like arthropods and especially vertebrates, molluscs exhibit only a limited ability to excrete pollutants directly via their kidneys or other excretory organs and tissues, to metabolize organic chemicals, and physiologically to inactivate toxic heavy metals such as by the formation of and binding to metallothioneins [4]. As a consequence, molluscs achieve higher bioaccumulation factors for many toxicants than other groups. Observing of heavy metal contamination and bioavailabilities by the diverse parts of molluscs is remarkable since it might lessen the imprecisions of defining the heavy metal levels by using the total soft tissues [5].

The use of bioindicator organisms to study heavy metal pollution in the Malaysian environment has acknowledged extensive attention. Bivalves and gastropod were frequently used by a number of researchers while fishes were primarily used for health concern related to fish consumption by human. Since the molluscs are accessible along the coastal areas of Peninsular Malaysia and are easily collected, it can therefore be suggested to be good monitoring agents for chemicals pollution. The objectives of this study were to discover the heavy metals bioavailability in selected body parts of *S. cucullata*, *T. clavigera* and *N. chameleon* from rocky shore sites along the coastal waters of the east Johor and to provide an insight in their safety levels for human and environment monitoring. Data of *S. cucullata* was acquired from a study by Fuad et al. [6] for comparison.

Materials and Methods

Study Area

Table 1 and Figure 1 displayed map of sampling locations, coordinates and species collected for this study. Five sampling sites with the abundant numbers of *S. cucullata*, *T. clavigera* and *N. chameleon* population on natural rocky structures were sampled. Not all species were present in sufficient numbers at all sites. *S*amples of relatively same size were hand collected during low tide. All samples were placed in plastic bags, sealed, labeled and stored at 4 – 6 °C during transportation to the laboratory where the samples were rinsed with running Mili-Q water (18.2 Ω) to remove sediment and salt particles prior to store frozen.

After allometric parameter measurement and tissue extraction, extracted tissues were freeze-dried before being weighed again in order to evaluate the water content and conversion factor. Freeze-dried samples were then minced to a homogenous powder and kept at room temperature until analysis. Please note that only soft tissue was extracted from rock oyster.

The analytical procedure was based on Shazili et al. method [7] with little modification. Measurement was carried out using Inductive Coupled Plasma Mass Spectrometry (ICP-MS) Elan 9000 in its standard configuration. Results

were quantified via an external calibration curve generated from the responses obtained from multiple dilutions of a multi-element calibration standard that was prepared from multi-element standards stock solution (Merck). The results were blank corrected and expressed as μg g^{-1} dry weight. Glassware used was immersed in 10% nitric acid (HNO_3) solution in advance for contamination prevention.

Table 1. Sampling locations, coordinates and species collected from east Johor coastal waters

No	Sampling location	Coordinate	Species collected
1	Sungai Rengit	N 01^0 20.985', E 104^0 13.256'	*S. cucullata*, *T. clavigera*, *N. chameleon*

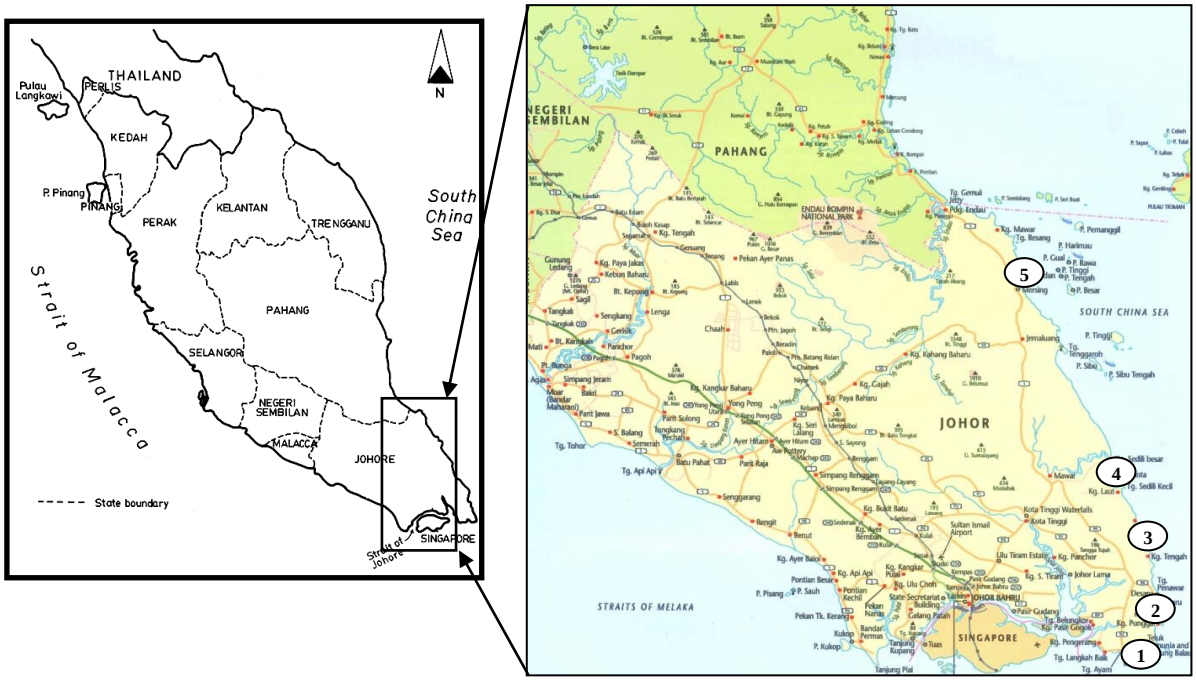

Figure 1. Map showing sampling locations at east Johor coastal waters. Sites are specified in Table 1

The quality of method used was confirmed in a separate comparative study using a standard reference material, Lobster Hepatopancreas TORT-2. Recoveries were as follows: 113.57 % (Pb), 97.31 % (Cd), 85.56 % (Cu), 86.54 % (Zn), 81.80 % (Mn), 96.53 % (Co), 88.59 % (Se) and 82.60% (Sr). One-way ANOVA was employed among assessment of variation between content of analyzed metals concentration in different sites. All comparisons were made at least at the 95% ($p< 0.05$) and 99% ($p< 0.01$) level of significance

Results and Discussion

The different studied species within the same location and the same species from different locations showed variations in their ability to concentrate trace elements. A comparison among species indicates that even closely

related species from the same location might have significantly different accumulated element concentrations as well as interspatial variability. The fact that sampled organisms inhabits common localities but different feeding behavior indirectly shows a function of the preferences for a certain size and nature of food particles and the detoxifying mechanism that each species has. The differences in accumulation of the metals may arise from species-specific feeding habits as uptake of metals via food plays an important role.

According to Table 2, there are significant differences in concentrations of Pb, Cd, Cu, Zn, Mn, Co and Se among sampling locations ($p< 0.05$) but no significant differences were found for Sr ($p> 0.05$) in *S. cucullata.* While for *T. clavigera*, there are significant differences ($p< 0.05$) in Pb, Zn and Co concentrations among locations in the soft tissue and Zn, Se and Sr in the shell. However, no significant differences were found for all studied metals among locations in the operculum. The interspatial distribution on metals shows no similar pattern among body parts.

Table 2. Concentrations of Pb, Cd, Cu, Zn, Mn, Co, Se and Sr (µg g^{-1} dry weight) in soft tissue, operculum and shell of *S. cucullata, T. clavigera* and *N. chameleon* (mean and standard deviation) from East Johore coastal waters

In *N. chameleon,* significant differences ($p< 0.05$) among concentrations of all studied metals between locations were found in the soft tissue of *N. chameleon*, except Cd. There were significant differences ($p< 0.05$) between Pb, Cd, Mn, Co, Se and Sr concentrations in operculum of *N. chameleon* among sampling locations. No correlation was found for Cu and Zn. Significant differences ($p< 0.05$) were found only for Zn, Mn and Co concentrations in shell of *N. chameleon* between sampling locations.

Interspecies

A point to be made on the significance of accumulated trace metal concentrations among species is the potential for metals to be transferred along food chains. The elevated concentration of metals found in *T. clavigera* may be the result of biomagnification transfer from the rock oysters on which they feed while for *N. chameleon*, it might be derived from their herbivorous feeding behaviour on algae on rocks which they graze. Predatory gastropod, *T. clavigera* and prey *S. cucullata* have been acknowledged to have food chain relationships by several studies [8, 9]. Therefore, the levels of heavy metals in this predatory organism could be derived as a result of transfer from the rock oysters [10, 11]. It may obtain significant amounts of metals from the dietary source if the prey has high metals content. Also, field evidence suggests that dietary exposure is the dominant route for *Thais* to accumulate metals [12]. In this case, it is concluded that food (*S. cucullata)* probably is the most important source for metals in *T. clavigera*.

The metal accumulation pattern of Zn and Cu within studied organisms presented a decreasing pattern of *S. cucullata* > *T. clavigera* > *N. chameleon* (Table 2). Zn and Cu concentrations in the studied bivalve are much higher than gastropods by about 6 – 27 times. Zn and Cu are emphasized as they evidently proved to being essential in living organisms in the functioning of metabolic processes and associated with many enzymatic proteins functions [13-14]. Filter feeders are acknowledged to have high proportion of permeable surfaces and thus have been proven to take up metals at high rates [15].

T. clavigera in this study evidently accumulates the highest concentration of Cd and Se with the sequence of *T. clavigera* > *S. cucullata* > *N. chameleon*. The high concentration of Cd within *T. clavigera* is well documented by several studies. This neogastropod is able to accumulate Cd very efficiently from the food without any noxious effect [16], and even in unpolluted waters, neogastropod accumulate Cd at high concentration. Se metal is one of interest because it is classified as both an essential elements for organisms [17] and toxic at elevated levels [18]. It is suggested that this metal has a high potential of biomagnifications during transfer to top predator. Studies by Underwood [19] had shown that there were differences in the type of feeding between grazing species and type of food ingested by these species as well as differences in digestion and feeding mechanisms.

The result highlighted that Sr, which is considered as a non-essential element, is distributed differently in soft tissue of *N. chameleon* compared with the other elements (Table 2). Distribution of Sr within soft tissue in other literature was sparse as they commonly focused on the incorporation of Sr and Mg together with other trace metals as well within the shell [20, 21]. Despite a few differences, the pattern of metal occurrences is in agreement with studies by Ruelaz-Inzunza & Paez-Osuna [22] and Amin et al. [23] that indicate approximately the same pattern of essential metals enrichment.

Inter tissue

Referring to Table 2, metal accumulations in soft tissue, operculum and shell of *T. clavigera* vary in magnitude but generally showed similar patterns of accumulation for certain metals. The Zn and Cu accumulation pattern was in the sequence of soft tissue > operculum > shell; Cd soft tissue > shell > operculum; Se, Mn and Pb operculum > soft tissue > shell; and Co and Sr shell > soft tissue > operculum. While in *N. chameleon*, Pb, Cd, Zn and Mn concentrations was found in the sequence of soft tissue > operculum > shell; for Cu and Se, soft tissue > shell > operculum; Co shell > operculum > soft tissue; and Sr operculum > shell > soft tissue. The results indicated that most metals were accumulated in soft tissue compared to operculum and shell.

In order to evaluate the relationship between the operculum, shell and soft tissue with the concentrations of the metals studied, the ratio in body parts of *T. clavigera* and *N. chameleon* was computed (Table 3). Values of operculum to tissue ratio (OTR) and shell to tissue (STR) higher than unity in *T. clavigera* indicate that operculum had higher affinities for Pb, Mn and Se while shell had higher affinities for Co and Sr. Meanwhile, values of OTR and STR higher than unity in *N. chameleon* display that operculum and shell had similar higher affinities for Co and Sr, with addition of Cd for shells. The high concentration of these metals in operculum and shell could probably be due to the fact that the crystalline structures of the operculum and shell matrix had a higher capacity for incorporation in the soft tissue.

Table 3. Mean ratios and standard deviation of operculum metals to soft tissue metals (OTR) and shell metals to soft tissue metals (STR) in *T. clavigera* and *N. chameleon*

Permissible limits

To safeguard public health, maximum acceptable concentrations of toxic contaminants have been established in various countries, including Malaysia. Most of safety levels established was expressed on a wet weight basis. Therefore, metal concentrations for each species in this study have been calculated into wet weight basis using conversion factor for comparison with permissible limits set by Malaysia and other different countries (Table 4).

Table 4. Maximum permissible limits on heavy metals (in µg g^{-1}) for food safety set by different countries based on wet weight basis of soft tissue

[24] European Community (CE, 2006), [25] Hong Kong Environmental Protection Department (HKEPD, 1997), [26] Food standards Australia New Zealand Authority (FSANZ, 1996), [27] Australian Government, 2006, [28] Food and Drug Administration of the United States (USFDA, 1990), [29] Malaysian Food Regulation Fourteen Schedule (1985), *Values that exceed the permissible limits set by Malaysian Food Regulation Fourteen Schedule

The results of this study indicate that Zn concentrations in rock oyster *S. cucullata* are higher than the food security limits. Thus, *S. cucullata* is considered unsafe for consumption in conjunction with high Zn concentration, as concentrations are approximately three times higher than safety limits. The high levels of Zn may pose a serious problem as *S. cucullata* is one of important food source that consumed in Malaysia [30].

Conclusion

The present work has provided a synoptic survey of metals distribution in selected species in rocky shore areas along the east Johor coastal waters. The bivalve mollusc, *S. cucullata* and the two gastropod molluscs *T. clavigera* and *N. chameleon* possessed high potential as cosmopolitan bioindicators for trace metal. These species have the necessary prerequisites of bioindicators: they are easy to identify and to sample, are available throughout the year, and are widely abundant in almost all rocky shore areas.

Interspecies variation among studied species indicated that certain species are proven to be good bioindicators of certain metals. Inter-tissue variation of metal concentrations lead to the conclusion that essential metals like Zn, Cu, Se and Mn are highly accumulated in soft tissue compare with operculum and shell as a result of having an important role in metabolism. Ratio calculation on body parts indicates high affinities of certain metals in operculum and shell of *T. clavigera* and *N. chameleon*, indicating that these body parts are also able to serve as bioindicator tissue as an alternative to the commonly used soft tissue. Particular significant metal pair correlation indicates that metal accumulation in specific body part might be affected by the other metal in the pairing. Consistent enrichment of essential metals over non-essential metals is also observed.

From the present status, it may be concluded that *S. cucullata* is unsafe for human consumption in conjunction with high Zn concentration, which was approximately three times higher than the safety limits set by Malaysian Food Regulations 1985 Fourteen Schedule and also with the limits set by other countries. Due to the importance of oyster as seafood and its ability to accumulate pollutants, sustained and continued monitoring of metals in *S. cucullata* may be important in avoiding future health risk issues related to their consumption.

Abstract

This study was conducted to evaluate the nitrogen use efficiency of rice mutant lines of MR219, viz. MR219-4 and MR219-9, developed under rice radiation mutagenesis programme for adaptability to aerobic conditions, grown under conditions of varying water potentials and nitrogen levels in a shade house. Direct ^{15}N isotopic tracer method was used in this study, whereby the ^{15}N labeled urea fertilizer was utilized as a tracer for nitrogen nutrient uptake by the test crops. ^{15}N isotope presence in the samples was determined by using emission spectrometer analysis and percentage of total nitrogen was determined by using Kjeldahl method. ^{15}N atom access values of the samples were to determine the efficiency of N use by the mutant varieties. In this work, the data of yield components, viz. grain yield, plant biomass, plant height and 1000 grain weight, and nitrogen components viz, total N, % nitrogen derived from labeled fertilizer (% Ndff), % nitrogen derived from soil (% Ndfs), nitrogen uptake, fertilizer nitrogen use and nitrogen use efficiency were obtained. Results from this study showed a significant difference to the nitrogen component and yield when there is a change in the rate of fertilizer and water potential. However, varietal factor does not show any significant differences.

Keywords: mutant lines of rice, aerobic condition, water potentials, ^{15}N isotopic tracer, nitrogen use efficiency

Abstrak

Kajian ini telah dijalankan untuk menilai keberkesanan penggunaan nitrogen padi garisan mutan dari MR219, iaitu MR219-4 dan MR219-9, yang dibangunkan di bawah program mutagenesis untuk penyesuaian ke keadaan aerob dan ditanam dalam keadaan potensi air dan aras nitrogen yang berbeza di dalam rumah teduhan. Kaedah isotop penyurih ^{15}N secara terus telah digunakan dalam kajian ini, di mana baja urea berlabel isotop ^{15}N digunakan sebagai penyurih untuk pengambilan nutrien nitrogen oleh tanaman ujian. Kehadiran isotop ^{15}N dalam sampel ditentukan dengan analisis spektrometer pelepasan dan peratusan jumlah nitrogen di dalam sampel ditentukan dengan menggunakan kaedah Kjeldahl. Nilai akses Atom ^{15}N yang terkandung dalam sampel akan digunakan dalam penentuan keberkesanan penggunaan nitrogen dalam baja melalui formula pengiraan tertentu. Melalui kajian ini, data daripada komponen hasil (hasil bijirin, berat biojisim, ketinggian tumbuhan dan 1000 berat bijirin) dan komponen nitrogen (jumlah nitrogen, % Ndff, % Ndfs, pengambilan nitrogen, penggunaan baja nitrogen dan kecekapan penggunaan nitrogen) telah diperolehi. Hasil daripada kajian ini telah menunjukkan terdapat perbezaan yang ketara terhadap komponen nitrogen dan hasil tanaman apabila terdapat perubahan faktor kadar baja dan potensi air. Walaubagaimanapun, faktor varieti tidak menunjukkan apa – apa perbezaan yang ketara.

Kata kunci: titisan mutan padi, keadaan aerob, potensi air, isotop penyurih ^{15}N, kecekapan penggunaan nitrogen

Introduction

Malaysia's rice production is presently focused in the major irrigated rice areas in Peninsular Malaysia, contributing to 85 % of the national rice production. The main method of rice cultivation in Malaysia is through flooding. This type of cultivation consumes a very high amount of water, where about 3000 litre of water are used to produce 1 kg of rice [1]. Over 80 % of the freshwater resources in Asia are used for irrigation and about half the amount is consumed for rice [2]. In Malaysia, rice is grown in two seasons where the first season is between August to February, meanwhile the second season is between March to July. Water demands during the first season are less worrying because the rainy season is likely to occur, however during the second season, low rainfall and drought are likely to occur thus the high demand of water is crucial. Rice field will experience drought due to a short supply of water by declining rainfall and dam water level. Globally climate change due to global warming is said to contribute to the water shortage in rice production. Increase in freshwater scarcity has threatened the sustainability of irrigated rice ecosystems [3].

For strategic water management and utilization purposes, the traditional submerged rice cultivation system is gradually moving toward a system where rice is grown in low water input and aerobic conditions while maintaining high productivity. Aerobic cultivation is a planting system where rice is grown in well-drained, non-puddle, and non-saturated soils. In aerobic rice systems, fields remain unsaturated throughout the season. Crop yields are on average only 1000 to 2000 kg/ha) because of adverse environmental conditions (poor soils, little rainfall, weeds), low use of external inputs, and low yield potential of upland rice cultivars [4]. Evidence from studies showed that aerobic rice used only 50 % of the water compared with the lowland rice [5]. The aerobic cultivation can reduce the total water usage by 27 – 51 % and increase water productivity by 32 – 88% [6]. Most countries that suffer from water shortages have been using aerobic cultivation method in their rice farming system. Therefore, steps have been taken including the production of various types of new cultivars is suitable for planting in their aerobic condition. Through a radiation-induced mutation breeding project (IRPA 01-01-03-000/PR0068/0504) using the high yielding and good quality rice MR 219, Malaysian Nuclear Agency (Nuclear Malaysia), in collaboration with Malaysian Agricultural Research and Development Institute (MARDI) and Universiti Putra Malaysia (UPM), discovered an advanced mutant line MR 219-4 and MR 219-9 varieties.

Nitrogen is one of the essential macronutrients for rice growth and becomes the main factors to be considered for developing high-yielding rice cultivar [7]. Nitrogen (N) requirements of the rice plant are supplied from soil and fertilizer. Due to the acute shortage of nitrogen in the soil mostly, nitrogenous fertilizer must be used to meet the needs of the plant. In flooded rice ecosystems, some reports said that nitrogen fertilizer used for rice crops have been lost partly through different mechanisms including ammonia volatilization, denitrification, leaching and run by water [8, 9]. Nitrogen losses can cause environmental problems such as pollution of the atmosphere, aquatic systems and ground water in a bowl. Nitrogen use efficiency is generally low with normally less than 30 – 40 % of the applied N took up by flooded rice [10 – 12]. This situation challenges the researchers to develop the strategies to increase nitrogen use efficiency in rice production. Increasing of nitrogen use efficiency offers the greatest economic benefits to farmers and countries. Nitrogen use efficiency may be defined as yield per unit input. In agriculture, this is usually related to the input of nitrogen fertilizer, whereas in scientific literature the nitrogen use efficiency is often expressed as fresh weight or product yield per content of nitrogen. Thus, nitrogen use efficiency can be defined as nitrogen absorbed by a plant to growth and gave yield [13]. Nitrogen use efficiency of crops can be improved by adopting adequate management practices. The usage of N fertilizers with an adequate amount, form, and methods of application are important management strategies of this element [14].

Although Malaysia has produced aerobic rice varieties and rice adaptable to low water inputs, including MR219-4 and MR219-9, information on nitrogen use efficiency (NUE) of these new lines is negligible. In Malaysia, aerobic rice cultivation is a recent development and there are only a handful of agencies who conducted tests on this rice. In addition to using minimal water, aerobic rice research purposes in Malaysia also aims to improve the effectiveness use of nitrogen in the aerobic rice ecosystem. The previous report stated that changes in water management of flood

conditions to aerobic conditions affecting the availability and forms of nitrogen present in the soil [15]. Change in water management can have a significant impact on the availability of nutrient intake by plants and lost in the environment [16]. There are few reports that have indicated the use of nitrogen fertilizer on dry land is more efficient [17] and nitrogen application improved rice plant growth under continuous aerobic rice cropping, but for phosphorus (P) and potassium (K) and other micronutrients had a little or no effect [18]. Improvement of nitrogen use efficiency is an essential pre-requisite for expansion of crop production into marginal lands with low nutrient availability. Nitrogen use efficiency depends on the ability to efficiently take up the nutrient from the soil, but also on transport, storage, mobilization, usage within the plant, and even on the environment.

The only direct means of measuring nitrogen use efficiency from the applied fertilizer is through the use of isotopes. In nitrogen efficiency study, a labelled fertilizer ^{15}N is added to the soil and the amount of nitrogen that a plant has taken up is determined. In this way, different nitrogen fertilizer practices (placement, timing, sources, etc.) were studied [19]. Isotopic studies using ^{15}N labelled plant materials have been useful in estimating crop N uptake [20 – 22].

The objective of this study is to examine the effects of nitrogen levels and water potentials on yield components and to evaluate the nitrogen use efficiency on MR 219-4 and MR 219-9 mutant lines under different water potential and different nitrogen availability. This data can be used as a reference to farmers or any party who wish to develop and implement aerobic rice industry in this country. Through this study, the added value will be assigned to MR 219-4 and MR 219-9 rice mutant lines.

Materials and Methods

Study location

Aerobic rice cultivation exercise was carried out in a paddy shield house in Malaysian Nuclear Agency. The shade house provided some control on environmental factors, including rain shelter facilities.

Rice varieties

Two types of mutant lines rice varieties namely MR219-4 and MR219-9 were used in this experiment. Both varieties are produced by mutation induction using gamma irradiation on MR219 variety (parent). Mutation induction was carried out by exposure of plant organs such as seeds or biological entity to ionizing radiation that can penetrate the tissue cells so that the heritage elements of the chromosome and the process causes the physical changes to the plants [23].

Soil types

The soil used in this experiment is sandy loam texture with a bulk density of 1.45 g/cm^3. Water retention curve analysis of this soil has been done using pressure plate method. The curve shown in Figure 1 indicated that available water capacity calculated between 10 to 1500 kPa for this soil is about 18 % (w/w).

Experimental design and crop management

Rice mutants MR219-4 and MR219-9 were planted on loam soil through measuring plot 3 m^2 (3m x 1m). Aerobic rice seeds are sown manually at 2 cm depth and covered with soil. Three watering regimes and three nitrogen levels in a completely randomized block design with three replicates treatment were carried out. Aerobic rice were grown for 110 days under three water potentials, (i) Field capacity from 0 to 40 DAS and saturated from 41 to 110 DAS [ST], (ii) Field capacity from 0 to 110 DAS [FC], and (iii) Field capacity from 0 to 40 DAS and 70% of field capacity from 41 to 110 DAS [SS]. DAS is standing for days after sowing. Nitrogen in the form of ^{15}N-labeled urea (5.20 % atom excess) was applied in three rates; none (0 kg N ha^{-1}), moderate (60 kg N ha^{-1}) and high (120 kg N ha^{-1}) in three splits at 7 days after emergence, 35 days after emergence and 60 days after emergence, respectively. Basal fertilizers of phosphorus from triple superphosphate (TSP) at 60 kg P_2O_5 ha^{-1} and potassium from muriate of potash (MOP) at 60 kg K_2O ha^{-1} were applied at 15 days and 65 days after emergence. A tensiometer, an instrument that directly measured soil moisture continuously was installed. Soil moisture was measured and observed daily.

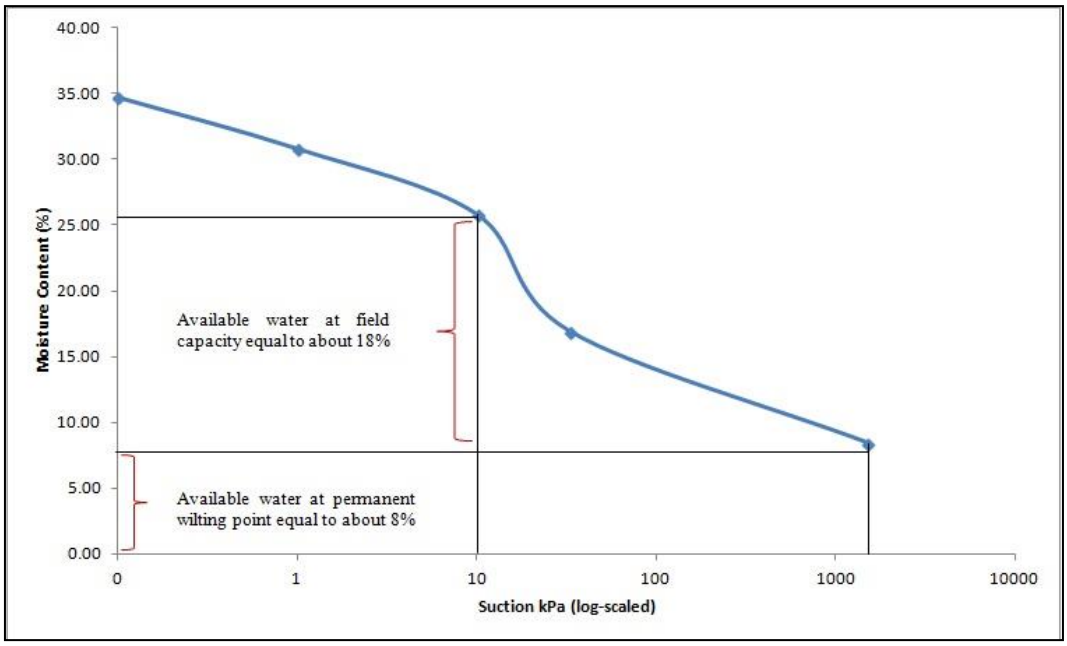

Figure 1. Soil water retention curve for soil moisture content

Plant sampling and analysis

Paddy plants were sampled after 110 days when the aerobic rice has matured and ripened. Harvesting and sampling were done on a 1 m x 0.5 m area (0.5 m^2). Total plant biomass was weighed to obtain the overall fresh weight. Plant parts such as straw, leaf and grain were separated and measured the fresh weight. Straw, leaf, and grain samples were oven dried at 70 to 80 ^oC for three days after which they were weighed and finely milled for further analysis.

Total nitrogen content in straw, leaf and grain was extracted by Kjeldahl digestion followed by steam distillation and subsequently ^{15}N content was analyzed using emission spectrometer [24]. Percentage of ^{15}N abundance was transformed into atom percentage ^{15}N excess by subtracting the natural abundance (0.3663 atom % N) from the percentage of N abundance of the sample.

Kjeldahl digestion method

The Kjeldahl digestion is a method for determination of nitrogen content in rice samples. The Kjeldahl method consist of three main steps; (i) Digestion, where the decomposition of nitrogen in plants samples utilizing a concentrated acid solution. This part was accomplished by boiling a homogeneous sample in concentrated sulphuric acid. The end result is an ammonium sulphate solution. (ii) Distillation, where adding an excess base to the acid digestion mixture to convert NH_4^+ to NH_3, followed by boiling and condensation of the NH_3 gas in a receiving solution and (iii) Titration to quantify the amount of ammonia in the receiving solution.

Emission spectrometer analysis

Emission spectrometer is an analytical instrument that be used to determine ^{15}N isotope tracer in rice samples. Samples were concentrated in liquid forms. An approximately 25 µL of samples were put in a glass capsule and placed in an emission spectrometer syringe. Emission spectrometer is equipped with a data acquisition unit which stores the data and automatically converts the measured to the actual value.

Nitrogen components calculation

After the data were obtained from analysis of samples, the following calculations as expressed in equation 1 – 6 were utilised [19].

$$\% Ndff = \frac{atom\ \%\ 15\text{N}\ excess\ \text{plant}}{atom\ \%\ 15\text{N}\ excess\ \text{fertilizer}}\ x\ 100 \quad (1)$$

where *Ndff* is nitrogen derived from fertilizer.

$$\% Ndfs = 100 - \% Ndff \quad (2)$$

where *Ndfs* is define as nitrogen derived from soil and *Ndff* is define as nitrogen derived from fertilizer.

$$\text{Dry Matter Yield (kg/ha)} = \text{FW (kg)} \times \frac{10000\ (\text{m}^2/\text{ha})}{\text{area harvested}\ (\text{m}^2)} \times \frac{\text{SDW (kg)}}{\text{SFW (kg)}} \quad (3)$$

where FW is fresh weight per area harvested. Meanwhile SDW and SFW are subsample dry and fresh weight, respectively.

$$\text{Nitrogen Yield (kg/ha)} = \text{Dry Matter Yield (kg/ha)} \times \frac{\%\ \text{Total N}}{100} \quad (4)$$

$$\text{Fertilizer Nitrogen Yield (kg/ha)} = \text{Nitrogen Yield (kg/ha)} \times \frac{\%\ \text{Ndff}}{100} \quad (5)$$

$$\%\ \text{NUE} = \frac{\text{Fertilizer Nitrogen yield}}{\text{Rate of Nitrogen application}} \times 100 \quad (6)$$

where NUE is nitrogen use efficiency. Nitrogen use efficiency is a quantitative measure of the actual uptake of fertilizer nutrient by the plant in relation to the amount of nutrient added to the soil as fertilizer. A common form of expression of fertilizer use efficiency is plant recovery of the added fertilizer.

Statistical analysis

Analysis of variance (ANOVA) for variables that was used for testing treatment differences (water and nitrogen treatments and independent T-Test to compare mean between two varieties) was carried out. Correlation analysis was used to evaluate the relationship between nitrogen rates and grain yield. General linear model was used to test the interaction between treatments.

Results and Discussion

Total Nitrogen

Total Nitrogen (Total N) is the sum of nitrate (NO^3), nitrite (NO^2), organic nitrogen and ammonia (all expressed as N). It can be measured in the laboratory using Kjeldahl method. Figure 2 shows the differences in total N contained in plant parts of aerobic rice variety under different nitrogen fertilizer application levels and water potentials. It shows there is no significant different in MR219-4 and MR219-9 rice lines in terms of total N on three plant parts (straw, leaf and grain) with different nitrogen levels and water potentials ($p > 0.05$). It means total N in all parts of aerobic rice are not affected by a varietal factor. However, an analysis of ANOVA test shows nitrogen application levels give a clear significant difference or effect on the total N content in plant parts ($p < 0.05$) but water potentials remain do not have a significant effect on total N in paddy plants. Referring to Figure 2, it also shows that most cases a total N in the straw is higher than leaf and grain. Pirmoradian et al. [25] reported similar finding in this study were increasing of nitrogen levels has significantly affected the total N content in the rice straw and leaf.

Yield components

The experimental results for analysis of variance for yield components such as grain yield, biomass, plant height and weight of 1000 grains are summarized in Table 1. Water potentials and nitrogen levels gave significance effects to the yield components except for 1000 grain weight, where there was apparently no effect by nitrogen treatments. The varietal factor does not show any significant effect of the yield components. It means, there are no

significant different between MR219-4 and MR219-9 in terms of yield components. The significant interactions occurred for total biomass weight and 1000 grain weight with the main treatments factors such as water and nitrogen was included. However, the other interaction effects do not have a significant different to all yield components. From this table, we can conclude that water and nitrogen factors have very importance roles to the yield components in aerobic rice ecosystem.

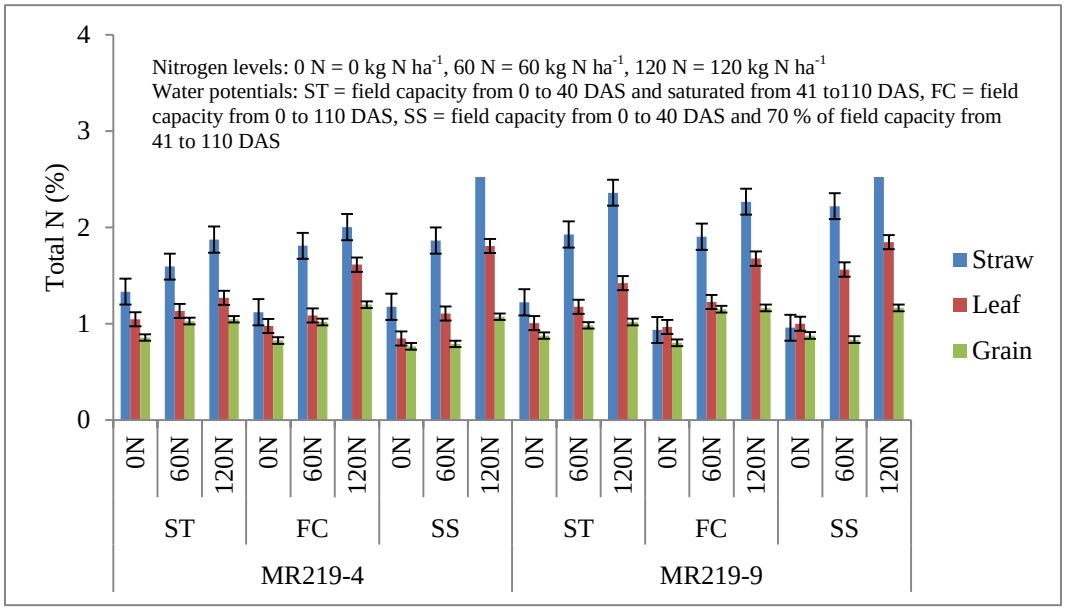

Figure 2. The differences in total N in plant parts of MR219-4 and MR219-9 mutant lines under different nitrogen levels and water potentials. Error bars denote standard errors.

Table 1. Analysis of variance effect of the treatments on the yield components

Source of Variations[a]	Levels of Significance[b]			
	Grain Yield (kg ha^{-1})	Total Biomass Weight (kg ha^{-1})	Plant Height (cm)	1000-grain Weight (g)
W	**	**	**	**
N	**	**	**	NS
V	NS	NS	NS	NS
W x N	NS	**	NS	**
W x V	NS	NS	NS	NS
N x V	NS	NS	NS	NS
W x N x V	NS	NS	NS	NS

[a] W = Water potential, N = Nitrogen rates and V = Variety, [b] Levels of significance indicated: NS = Not significant, ** = Significance at $p \leq 0.05$

The importance of nitrogen to the aerobic rice yield under different water potentials was illustrated in Figure 3 and 4 respectively. Finding study showed that nitrogen level factors have a very strong and significance relationship with the grain yield of both varieties despite the differences in soil water potentials.

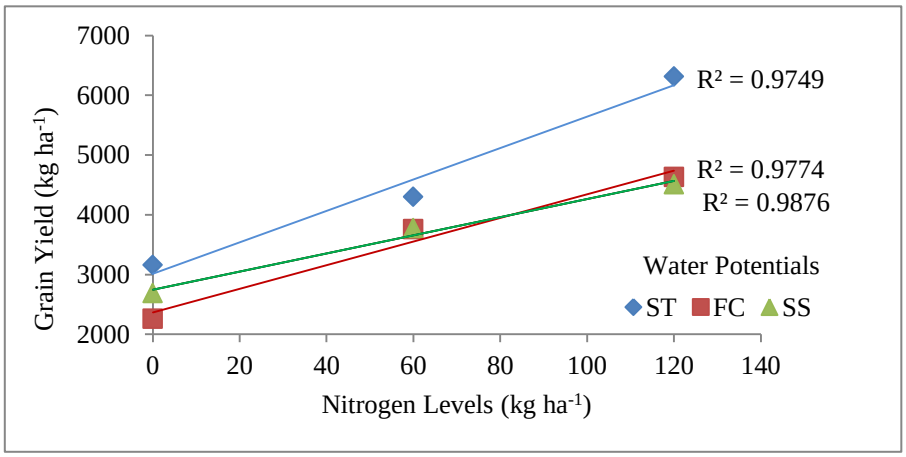

Figure 3. The relationship between nitrogen fertilizer levels on MR219-4 mutant line under different water potentials

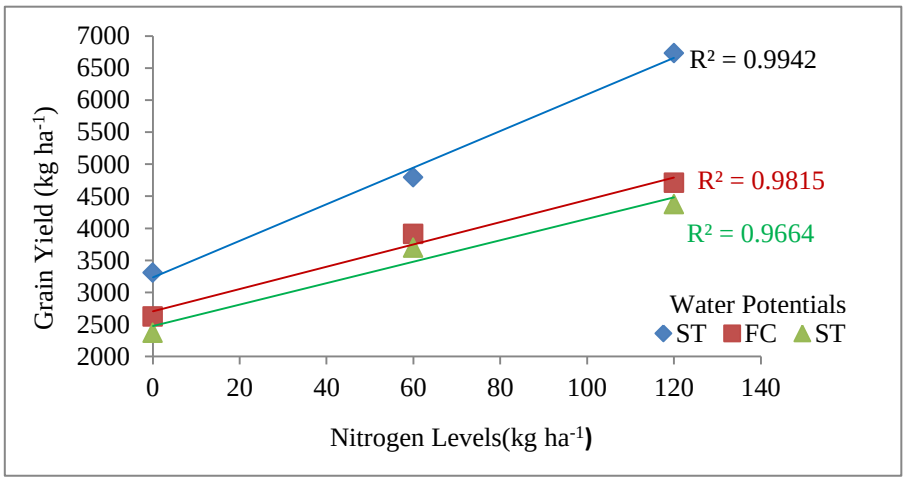

Figure 4. The relationship between nitrogen fertilizer levels on MR219-9 mutant line under different water potentials

Nitrogen components

The experimental results for analysis of variance for nitrogen components such as nitrogen derived from fertilizer (*Ndff*), nitrogen derived from soil (*Ndfs*), nitrogen uptake (NU), fertilizer nitrogen yield (FNY), and nitrogen use efficiency (NUE) were summarized in Table 2. The result clearly showed that only nitrogen level treatments give the significant effect to the percentage of *Ndff* and *Ndfs* but not on the water potential treatments. However, both nitrogen level and water potential treatments are displayed a significant effect to the NU, FNY and NUE. Nayak et al. [26] also found a similar result related to nitrogen levels effect on NU and FNY where increasing the rates of

nitrogen fertilizer application cause a significant effect to NU and FNY. Mannan et al. [27] found NU and FNY on rice crop is lower under water stressed compared to none stressed condition, similar to this study where NU and FNY on both rice varieties is lower under inadequate water supply condition. This study also showed that there are significant interactions between water and nitrogen that influence only the NU and NUE but not FNY. However, the other interaction effects do not have a significant different at all nitrogen components. Both varieties MR219-4 and MR219-9 also found not have significant different with each other at all nitrogen components.

Table 2. Analysis of variance effect of the treatments on the nitrogen components

Source of Variations [a]	Levels of Significance[b]				
	% Ndff	% Ndfs	NU	FNY	NUE
W	NS	NS	**	**	**
N	**	**	**	**	**
V	NS	NS	NS	NS	NS
W x N	NS	NS	**	NS	**
W x V	NS	NS	NS	NS	NS
N x V	NS	NS	NS	NS	NS
W x N x V	NS	NS	NS	NS	NS

[a] W = Water potential, N = Nitrogen rates and V = Variety, [b] Levels of significance indicated: NS = Not significant, ** = Significance at $p \leq 0.05$

Nitrogen use efficiency (NUE)

Nitrogen use efficiency (NUE) for MR219-4 and MR219-9 rice mutant lines, shown in Figure 5 depict the influence of nitrogen application rates on both rice varieties under different water potentials. The result clearly indicated a significant difference of NUE between different water potentials and nitrogen levels. Water treatment at field capacity from 0 to 110 days [FC] showed higher NUE than other water potentials for both varieties. This study also showed that at FC water regime with nitrogen level 60 kg N ha^{-1}, N was utilized more than 50% to produce yield. These results indicated that the use of absorbed nitrogen from soil at the level of 60 kg N ha^{-1} at FC level is more efficient than others. It also proved that changes in water level in the soil can influence the intake of nitrogen by plants. At field capacity 0 to 40 days and saturated from 40 to 110 days [ST] water potential the NUE is slightly lower than FC. Stagnant water conditions at ST level may have caused some nitrogen fertilizer loss through leaching and water runoff.

In this study, nitrogen dynamics data on varieties MR219-4 and MR219-9 rice mutant lines was obtained. Initial data for this crop is very important as aerobic rice cultivation for these varieties is still in the initial stage in Malaysia. However, this study was only made in the shade house where environmental factors were controlled. In future work, studies on the nitrogen dynamics for this crop using isotope techniques can be extended up to the farm level.

The nitrogen use efficiency is affected by several factors, but in most cases for a given irrigation management and water regime, the nitrogen fertilizer rate is the main source of variation, especially with regard to the nitrogen uptake issue. Avoiding over fertilization is the utmost means to match a high use efficiency and economic return of nitrogen fertilizer with limited environmental risks from nitrogen losses. This study has shown that use of high nitrogen rates does not mean that the efficiency of nitrogen use by plants is also high. Farmers in Malaysia should wisely control the use of nitrogen fertilizer on their crops. Excessive use of fertilizers will certainly increase the cost of farming besides doesn't necessarily increase rice production. Apart from the increase in expenditure high nitrogen application is also detrimental to the environmental health issue.

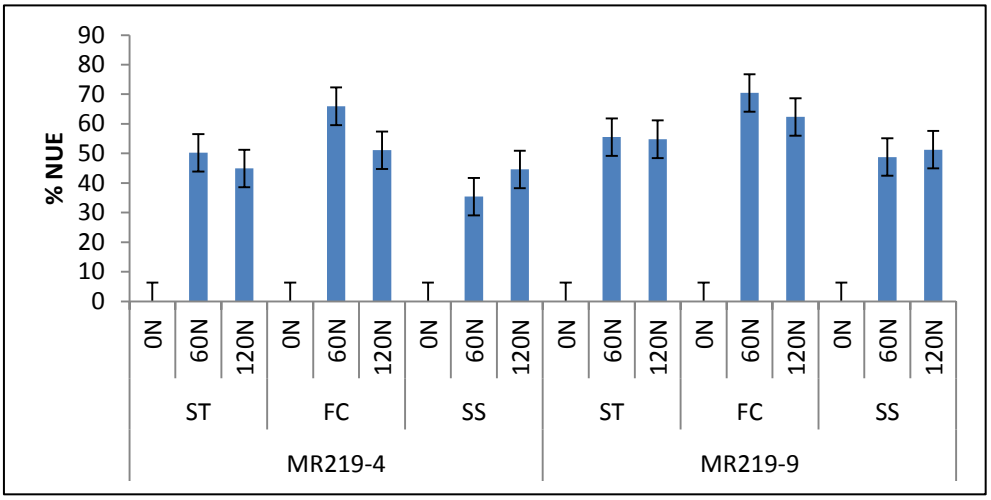

Figure 5. The influence of nitrogen level on nitrogen use efficiency (NUE) on MR219-4 and MR219-9 mutant lines under different water potentials. Error bars denote standard errors.

Conclusion

The present study highlighted the nitrogen use efficiency at a different range of nitrogen levels under different water potentials. In this work, we can conclude that nitrogen and water are affecting yield and nitrogen components on aerobic rice MR219-9 and MR219-4 ecosystem. It clearly shows that nitrogen and water level of application are very important inputs in the aerobic rice industry. Increasing nitrogen rates application may increase the yield but in some water condition, nitrogen use efficiency is low despite high fertilizer rates. Nitrogen use efficiency is optimum at field capacity for 60 Kg N ha^{-1} treatment. Change in soil water potential from flood to aerobic condition is proven to give a good improvement in the efficiency of nitrogen fertilizer uptake. Both aerobic rice MR219-4 and MR219-9 mutant lines exhibit no significant differences in terms of yield and nitrogen components.

Acknowledgement

The first author would like to acknowledge the Government of Malaysia for the scholarship granted to pursue his M.Sc. study at the Faculty of Science and Technology, The National University of Malaysia, Bangi. The present research is funded by MOSTI ScienceFund Grant: 06-03-01-SF0203. The work presented in this paper has been carried out at the Malaysian Nuclear Agency, Bangi, Kajang, Selangor. The capable technical assistance by Latiffah Norddin, Abdul Razak Ruslan and Hazlina Abdullah is deeply appreciated.

Abstract

This study reported on the preparation of newly low pressure active reverse osmosis (LPARO) membrane by phase inversion technique. The effect of cetyl trimethylammonium bromide (CTAB) and sodium dodecyl sulphate (SDS) as surfactants on performance and morphological structure were examined. Using brackish water as a sample, the membrane performance was evaluated in terms of pure water permeation (PWP), flux and salt rejection. Experimental data revealed that at 2.0 wt. % of SDS, the LPARO membrane achieved the optimum performance and produced the finest membrane.

Keywords: low pressure reverse osmosis, surfactant, morphology, performance, brackish water

Abstrak

Kajian ini melaporkan mengenai penyediaan membran osmosis songsang aktif bertekanan rendah (LPARO) dengan teknik fasa penyongsangan. Kesan setil trimetilammonium bromida (CTAB) dan natrium dodekil sulfat (SDS) sebagai surfaktan terhadap prestasi dan struktur morfologi telah diselidik. Dengan menggunakan air payau sebagai contoh, prestasi membran telah dinilai dari segi penyerapan air tulen (PWP), penyingkiran fluks dan garam. Data eksperimen menunjukkan bahawa pada 2.0 wt . % SDS, membran LPARO berjaya mencapai prestasi yang optimum dan menghasilkan membran yang terbaik.

Kata kunci: osmosis songsang bertekanan rendah, surfaktan, morfologi, prestasi, air payau

Introduction

Asymmetric membranes are prepared by phase inversion via immersion precipitation [1]. In this process, it involves the conversion of a homogeneous polymer solution consisting of two or more components to a two-phase system, the solid polymer rich phase and the liquid polymer poor phase. The solid phase forms the membrane structure while the liquid phase forms the membrane pores [2]. The successive solidification of the phase separated solution leads to a porous, asymmetric structure. The morphology and performance of membranes depend strongly on the thermodynamics as well as kinetics of the phase inversion process [3].

One option for controlling the membrane formation process is introducing an additive in the casting solution. PVP is a well-known additive that can increase the viscosity of the polymer solution. Several studies were done on the

effect of PVP as additive on the morphology and performance of membranes. Han and Nam [4] studied the variation of thermodynamic and rheological properties in PSF casting solution by adding PVP. Jung et. al [5] investigated the effect of molecular weight of polymeric additives on formation, permeation properties and hypochlorite treatment of asymmetric polyacrylonitrile (PAN) membranes. The results indicated that the top layer of the membrane and suppression of macrovoid formation strongly depends upon the molecular weight of PVP. Besides that, Fontananova et. al [6] and Curcio et. al [7] reported that PVP was an effective permeation flux promoter, and the thermodynamic effect played a dominant role during the flat-sheet membrane formations of both polyvinylidine fluoride (PVDF) homopolymer and PVDF-HFP copolymer. Also, the preparation, morphology and performance of cellulose acetate (CA)/polyvinylpyrrolidone (PVP) blend asymmetric membranes has been studied by Saljoughi and Mohammadi [8]. It was found out that initial addition of PVP to the cast film solution (from 0 to 3 wt. %) results in increasing macrovoids formation, meanwhile further addition of PVP (from 3 to 6 wt. %) results in suppression of macrovoids.

Addition of surfactant as one of the materials necessary for membrane making formulation can be one of the effective strategies to produce high performance membrane with high selectivity. The effects of surfactants as additive in the process of membrane fabrication were reported in other studies [9-13]. Sodium dodecyl sulphate (SDS) was added as additive into polysulfone (PSF) casting solution for gas separation and as gelatin media on the formation of polyethersulfone (PES) membranes by Yamasaki et. al [9] and Alsari et. al [10], respectively. The effects of temperature and concentration of cationic surfactant, which is cetyl trimethylammonium bromide (CTAB) in the formation of asymmetric nanofiltration membrane is reported by Mulijani et. al [11]. The result indicated that the formation of membrane pore increases as the addition of CTAB increases. Saedi et. al [12] investigated the effect of three types of surfactant including SDS, CTAB and Triton X-100 on the structure and performance of PES membrane for carbon dioxide separation from methane. The result demonstrated that the addition of surfactants in the casting solution increases the formation of macrovoids and large finger-like pores in the sub-layer of PES membranes. The effect of CTAB and Triton X-100 on the surface morphology and nitrophenols separation using CA nanofiltration membrane was investigated by Ghaemi et. al [13]. Addition of surfactants as additive resulted in membranes with superior pure water flux, permeation and rejection in comparison to CA membrane.

Materials and Methods

Chemicals and raw materials

Polysulfone (PSF (Udel-P1700) (Solvay) was used as polymer, while N-methyl-2-pyrrolidone (NMP) (Merck) was used as non-solvent for membrane preparation. Polyvinylpyrrolidone, (PVP, K29-32) (Acros Organics) was used as additive. Cetyl trimethylammonium bromide (CTAB) (EMD Chemicals) and Sodium Dodecyl Sulphate (SDS) (Fisher Scientific UK) were used as cationic and anionic surfactant for addition in the casting solution. Ethanol and n-hexane (Merck) were used as the coagulation bath. Sodium chloride, NaCl (Merck) was used for the salt rejection test.

Membrane preparation

Homogeneous dope solution of the PSF dissolved in NMP was prepared using PVP as additive, and different surfactants which are CTAB as cationic surfactant and SDS as anionic surfactant by stirring for 8 hours at room temperature. The stirring process was fixed at 300 rpm. The solution was poured and cast on glass plate using casting knife with thickness of 150 µm. Then, the membrane was moved into water for immersion precipitation. The immersion precipitation was carried out at room temperature. In order to ensure complete phase separation, the membrane was immersed in water for 24 hours. Then, the membrane was immersed in ethanol for 24 hours and n-hexane for 3 hours to ensure all the solvents is completely removed. As the final stage, membrane was dried for 24 hours.

Membranes morphological characteristics

The cross-section of the prepared low pressure reverse osmosis (LPARO) membranes was investigated using scanning electron microscopy. Samples of the membranes were fractured cryogenically in liquid nitrogen and mounted on the sample stubs with double-surface tape. After the samples were sputtered with gold by an automatic gold coater (JFC 1600), they were scanned by employing a JEOL JSM 6360LA Scanning Electron Microscopy (Tokyo, Japan) under magnification of 500x to 5000x with potentials 15kV.

Reverse osmosis performance evaluation

Reverse osmosis performance in terms of pure water permeation (PWP) and salt rejection for the LPARO membranes were tested using lab-scale cross flow filtration apparatus with circular filtration cell having an effective area of 1.38×10^{-3} m^2. To begin with, the circular membrane coupons loaded in the filtration cells were pressured at 5 bar with deionized water for at least 30 minutes for compaction. Desalination tests were then carried out at operating pressure of 5 bar with aqueous solution containing 2000 ppm of NaCl represent brackish water. The PWP was determined by measuring the permeate volume collected over a certain period in terms of liter per square meter per hour (L/m^2h) and calculated through the following equation 1:

$$J_w = \frac{Q}{A \times \Delta t} \quad (1)$$

where J_w is the volumetric PWP, A is the effective area of the membrane for permeation, and Q is the volume of permeation over a time interval (Δ t). The salt rejection was evaluated using the following equation 2:

$$R = \left(1 - \frac{C_p}{C_f}\right) x100 \quad (2)$$

in which C_p and C_f are the salt concentrations in permeate and feed, respectively. The salt concentration was determined by measuring the electrical conductivity of the salt solution using a conductivity meter (CON 700, Eutech Instruments).

Results and Discussion

Effect of CTAB as cationic surfactant on the performance of PSF membrane

Figure 1 shows that the presence of CTAB in the casting solution increases the PWP values with the maximum value of 1 wt. % CTAB. Increasing CTAB concentration more than 1 wt. % resulted in decreasing the PWP. This might due to the high viscosity of casting solution that prevents the penetration of non-solvent and weaken the macrovoids formation, hence lead to low permeability of membrane.

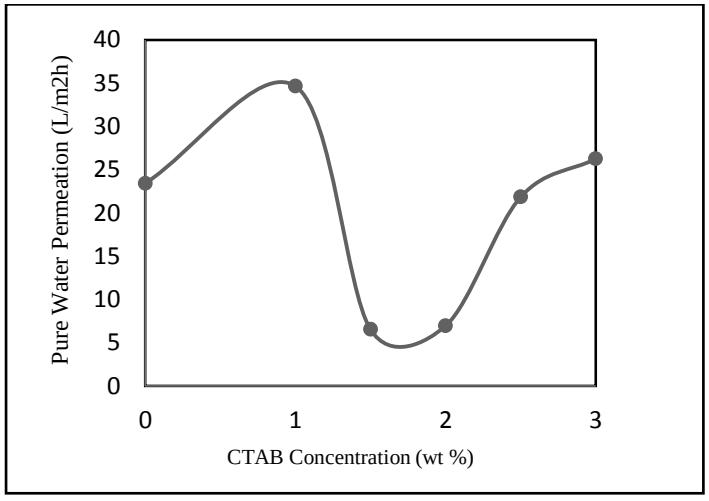

Figure 1. Effect of CTAB concentration on pure water permeation

The effect of CTAB concentration on brackish water flux and salt rejection of membrane prepared from PSF/NMP/PVP/CTAB system is shown in Figure 2. The brackish water flux increases as CTAB surfactant introduced in the casting solution, reaches the maximum at 1 wt. % concentration of CTAB which is 32.48 L/m^2h. The salt rejection improves from 77.8 % (without CTAB) to 81.1 % in the presence of 2 wt. % of CTAB in the

casting solution. As the CTAB concentration increased more than 2 wt. %, the salt rejection gradually decreased. The cross-sectional morphology of the prepared membrane with CTAB (Figure 5b) justify the high PWP and brackish water permeation in the presence of CTAB due to the formation of large finger-like pore in the sub-layer of membranes.

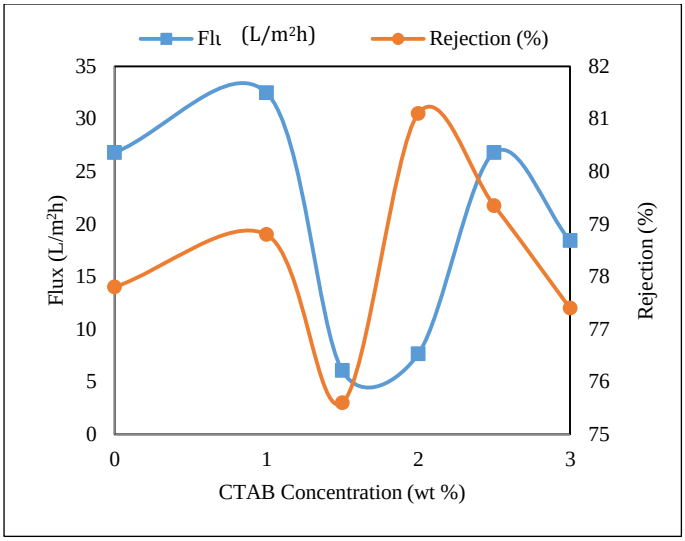

Figure 2. Effect of CTAB on brackish water flux and salt rejection

Effect of SDS as anionic surfactant on the performance of PSF membrane

To investigate the effect of anionic surfactant as additive in the casting solution, sodium dodecyl sulphate (SDS) was selected as strong anionic surfactant. Figure 3 show the effect of SDS concentration on PWP for the prepared membrane. The PWP increases gradually by increasing the SDS concentration in the casting solution, and reaches the maximum value for the concentration of 2.5 wt. % SDS, then decreases afterwards. This corresponds with the finding of Rahimpour et al. [3].

The effect of SDS on brackish water flux and salt rejection are shown in Figure 4. The obtained results demonstrated that the addition of SDS in the casting solution enhance the brackish water flux and salt rejection. On the other hand, as the concentration of SDS increases more than 2.5 wt. %, the brackish water flux and salt rejection decreases.

Most surfactants have a long hydrophobic alkali and a hydrophilic ionic group (polar group) in their structure. Rahimpour et al. [3] reported when the surfactant enters in aqueous media the ionic head tends to water while the non-polar tail tends to absorb on solid surface, air or organic phase. The alkali chain can join to polymer matrix when it comes near to hydro-carbonic structure of polymer but the hydrophilic but the hydrophilic and polar portion leave freely. The accumulation of polar groups in polymer structure results in repulsion between polymer chains and consequently increases the porosity of membrane by forming an open structure. When concentration of the surfactant increase, the non-polar tail of surfactant molecules settle beside one another and form micelles with polar groups in outer surface and non-polar groups inside the micelles in addition to the polymer surfactant complex. These free micelles deteriorate the membrane structure and decrease the membrane performance [11].

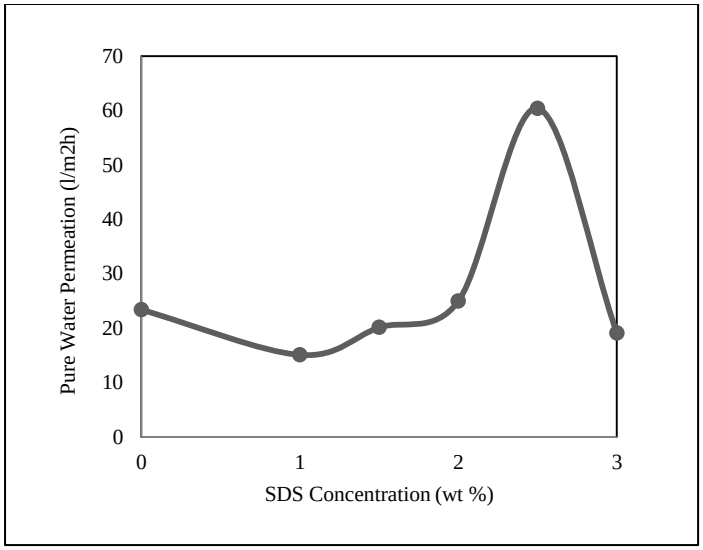

Figure 3. Effect of SDS concentration on pure water permeation

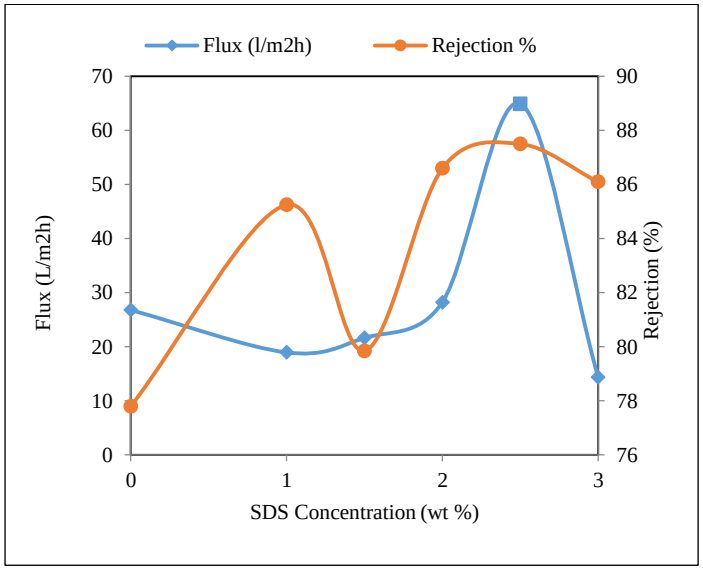

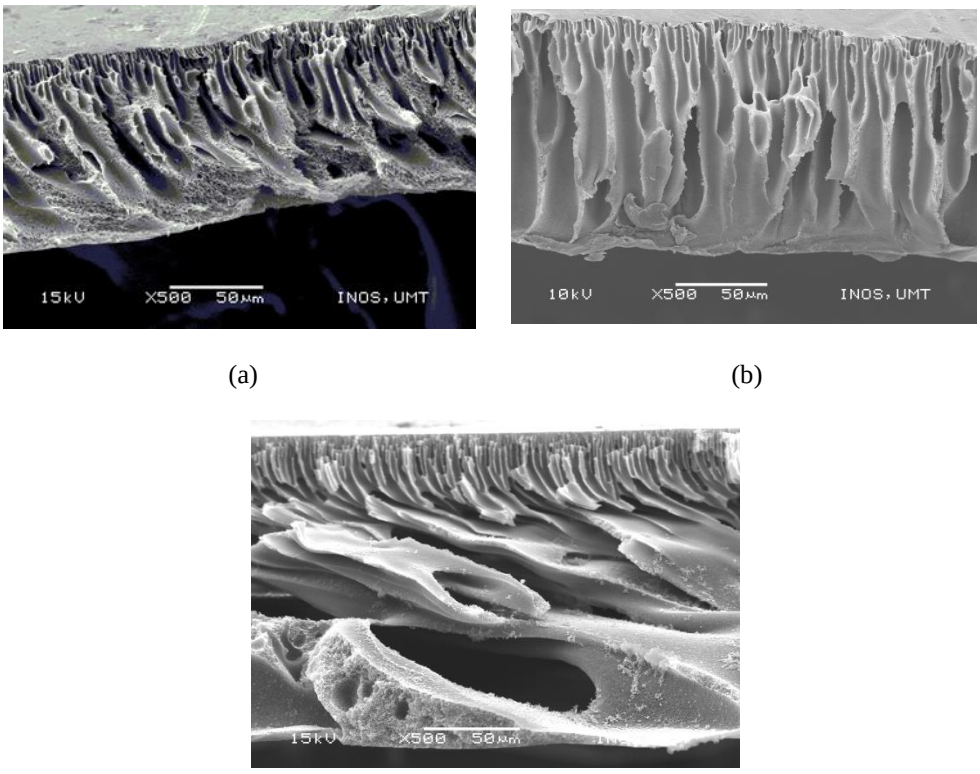

Figure 4. Effect of SDS on brackish water flux and salt rejection

Effect of surfactants on the morphology of the PSF membrane

The scanning electron microscopy (SEM) images were taken to determine the effect of CTAB and SDS as surfactants on the surface morphology of the LPARO membranes. SEM photograph of cross section of membranes, prepared from PSF membrane without surfactant, with CTAB and SDS as shown in Figure 5(a), 5(b) and 5(c), respectively. Asymmetric structure of the membranes consists of a dense top layer, a porous sub-layer that is occupied by closed cell within polymer matrix, and finger-like pores. The SEM images indicate that the addition of CTAB in the casting solution lead to formation of large finger-like pores in sub-layer of membranes. There is evident correlation between the miscibility of surfactant in the coagulant and the formation process of various pores.

Addition of an appropriate surfactants leads to induction or suppression of the macrovoids and finger-like pores in the sub-layer [3]. Although there is low miscibility between CTAB and NMP, CTAB is classified as hydrophilic surfactant that has high miscibility in water. If the added surfactant to the casting solution has high miscibility with the coagulant, it resulting in formation of finger-like pores and macrovoids via decreasing the surface tension and subsequently decrease in the demixing time [12].

(a) (b)

(c)

Figure 5. SEM cross-sectional images of prepared PSF membranes (a) without surfactant, (b) with CTAB and (c) with SDS

Meanwhile, SDS as hydrophilic surfactant can affect membrane morphology and porosity of sub layer in three manners which are (i) enhancement in macrovoid formation and increasing the membrane porosity by increasing solvent–nonsolvent mixing affinity and increasing demixing rate via distribution of SDS molecules as free molecules in NMP and formation of free micelles, (ii) enhancement in membrane free volume and membrane porosity and macrovoid formation via formation of polymer–surfactant complexes, (iii) decreasing sub layer porosity by decreasing demixing rate via increasing casting solution viscosity [12]. The SEM images indicated that the addition of small amount of SDS in the casting solution enhanced macrovoids formation. The high porosity of sub-layer of membranes prepared with SDS can be responsible for high performance of membranes.

Conclusion

This study has demonstrated that the addition of surfactants in the casting solution increases the formation of macrovoids and large finger-like pores in the sub-layer of LPARO membranes. This enhance the pure water permeation, brackish water flux with slight decrease in salt rejection. Surfactant concentration plays an important

role in the membrane morphology and performance. The obtained result revealed that at 2.0 wt. % of SDS, the LPARO membrane achieved the optimum performance and produced the finest membrane.

Abstract

In the present study, the concentration of Cr, Cd, Cu, Zn, Pb, and As in various tissues of *Hemibagrus* sp. from two different habitat were determined with microwave assisted digestion-inductively coupled plasma-mass spectrometry. The objective of this research was to determine the differences between wild and cultivated in terms of heavy metal accumulation in muscle, liver and gills tissues. The metals accumulation pattern relating types of tissue and elements as well as fish habitats were revealed by principal component analysis. The results revealed that variation in metal accumulation pattern is strongly dependent on the type of tissues. The results suggested that Cu, Zn, and Pb are highly associated with liver tissue while Cr and As with muscle and gills. The differences in heavy metal accumulation observed between wild and cultivated *Hemibagrus* sp. were probably due to the differences in their environmental conditions.

Keywords: principal component analysis, pattern recognition, heavy metal, fish, farmed

Abstrak

Kepekatan Cr, Cd, Cu, Zn, Pb, dan As dalam pelbagai tisu *Hemibagrus* sp. dari dua habitat yang berlainan adalah ditentukan dengan pencernaan bantuan gelombang mikro-plasma gadingan teraruh-jirim spektrometri. Objektif kajian ini adalah untuk menentukan perbezaan antara ikan dari habitat semulajadi dan kolam ternakan dari segi pengumpulan logam berat dalam tisu, hati, dan insang. Corak pengumpulan logam berkaitan jenis tisu dan elemen kajian serta habitat ikan ditunjukkan oleh analisis komponen utama. Keputusan menunjukkan bahawa perubahan dalam corak pengumpulan logam adalah bergantung kepada jenis tisu. Keputusan kajian mencadangkan bahawa elemen Cu, Zn, dan Pb adalah berkaitan dengan organ hati manakala elemen Cr dan As adalah berkaitan dengan tisu dan insang. Perbezaan dalam pengumpulan logam berat di antara *Hemibagrus* sp. dari habitat liar dan kolam ternakan adalah mungkin disebabkan oleh perbezaan dalam keadaan persekitaran mereka.

Kata kunci: Analisis komponen utama, corak taburan, logam berat, ikan, kolam ternakan

Introduction

The rapid development of agriculture and industrialization has resulted in increasing of metal pollution in the aquatic ecosystems, which are significantly hazardous for fish and human [1]. Significant quantities of contaminant elements are discharged into river, which can be strongly accumulated and biomagnified along water, sediment and aquatic food chain, thus resulting in sublethal effects or death in fish populations [2-4]. Fish are commonly situated at top of the aquatic food chain and normal metabolism of fish may accumulate large amounts of certain metals from food, water and sediment [5]. Commonly, fish is known to be nutritious with essential proteins, polyunsaturated fatty acids and liposoluble vitamins [6]. Nevertheless, levels of metals in fish are of particular interest due to their high potential to enter and accumulate in food chains [7, 8]. Even low concentrations of these elements have damaging effects to humans and animals because there is no good mechanism for their elimination from the body [9]. On the other hand, fish can be regarded as a good bioindicator because it is easily sampled and found in abundant population, with the potential to accumulate metals and has a long life span with an optimum size for analysis [10]. In this study, heavy metal (Cr, Cd, Cu, Zn, Pb) of *Hemibagrus* sp. in certain tissues (gill, liver, muscle) from wild and cultivated habitat are compared. Accumulation pattern relating tissue and elements and the underlying structure related to their origins and tissues were evaluated with principal component analysis (PCA). The aim of PCA is finding the similarities and differences between *Hemibagrus* sp. of different habitats based on ICP-MS measurement so as to create classification and identification of key discriminants that distinguish between samples.

Materials and Methods

The slaughtered *Hemibagrus* sp. was donated in June 2012 by a local fisherman and local fish farmer. The samples originated from the Selangor River and the cultivated pond located at Taman Agroteknologi Pertanian Bistari Jaya, Kuala Selangor, Selangor (Figure 1). The samples were stored in 20˚C freezer and the length and weight were recorded before dissection. The tissues of muscle, gills, and liver samples were freezing dried (CHRiST, Germany) and the homogenized with a mortar and pestle. Dried samples were kept in amber jars in a desiccator before microwave digestion.

Laboratory procedure

Ultra-Pure Water (UPW) with resistivity more than 18 MΩ was obtained from the PURELAB® UHQII system (ELGA®, UK). 65 % nitric acid and 30 % hydrochloric acid solution were of Suprapur ® quality (Merck, Germany). The dogfish liver (DOLT-4) (NRCC, Canada) certified reference material (CRM) for trace metals were used to evaluate the analytical performance of the methods. The tissue samples were analysed according to the method described by Low et al. [11] in which microwave-assisted digestion (MAD) were carried out in a CEM Mar Xpress Microwave Accelerated Reaction System (CEM, Corporation, Matthews, NC, USA). Dried samples (0.25g) was weighted directly in each 55mL self-regulating pressure control PFA® vessel and digested with a reagent consists of 2.50 mL of 65 % HNO_3, 0.50 mL of 30 % HCI and 7 mL UPW. Under microwave power of 800W, the microwave temperature was ramped to 185˚C in 10.5 min and held for 14.5 min. After digestion, the sample was cooled before being transferred to a 50 mL polypropylene volumetric flask and the volume was made up to the mark with UPW. Diluted sample solutions were stored in polyethylene vials below 8˚C and analysed by ICP-MS [12].

Statistical analysis

Principal component analysis (PCA) was conducted to transform the original data matrix (composed of 120 samples and 5 variables) into a product of two matrices, one which contains information about metal concentrations (loading matrix) and the other about the samples (score matrix). All statistical calculations were performed using the software package JMP version 9.0.

Figure 1. Location of sampling sites, letter S denotes to samples from wild, letter AP denotes cultivated fish.

Results and Discussion

Certified reference materials of dogfish liver (DOLT-4) were used to check the accuracy of MAD-ICP-MS method. The elemental concentrations determined in the standard reference materials were in a good agreement with the certified values (Table 1).

Table 1. Analysis of certified reference materials

		Cr	Cu	Zn	Pb	Cd	As

(mg kg^{-1})	Amount detected	-	32 ± 2	118 ± 7	0.16 ±0.04	28 ± 1.6	9.6 ± 0.3
	Recovery / %	-	102 ± 6	102 ± 5	100 ± 6	116 ± 4	99 ± 3

95 % confidence intervals , n = 7, Note : - not certified

Morphometric data of *Hemibagrus* sp. from wild and cultivated samples are summarized in Table 2. Condition factor (CF) was calculated by the ratio of weight/length which is commonly used as an index of fish health, while hepatosomatic index (HSI) is defined as the ratio of liver weight to body weight that reflects the energy reserve in fishes[13]. Samples obtained from the cultivated pond were generally smaller than those caught from Selangor River. Although there are differences in size variation, there were no substantial differences noted in the effect of metal concentration in studied tissues [14].

Condition factor (CF)	0.8 ± 0.2	0.7 ± 0.0
Hepatosomatic index (HSI)	0.7 ±0.2	0.7 ±0.1

95% confidence intervals, n = 20

Mean concentrations of heavy metals in the muscle, liver, and gills of wild and cultivated *Hemibagrus* sp. are presented in Table 3. Chromium, cadmium, copper, zinc, and lead were selected as the analyte elements. There are significant differences ($p<0.001$) concentrations obtained in different organs. The results have demonstrated that liver tissues generally contained higher concentrations of Cd, Cu, Zn, and Pb for both habitats except for higher Cr concentrations in the gill tissues. This result is also in a good agreement with Fernandes et al [15], where metal concentrations of Cu, Zn, and Pb were higher in liver than other studied tissues. Essential metals such Cu and Zn are needed in fish metabolism, while others such as Pb and Cr have no functional in biological systems. Our study showed that tissue of wild *Hemibagrus* sp. contained significantly higher content ($p < 0.001$) of Pb and As, while tissue of farmed *Hemibagrus* sp. had significantly higher contents ($p < 0.05$)of Cu. However, all metals may cause harmful effects on fish depending on their concentrations [16]. Overall metal concentrations are generally found to be higher in liver compared to other studied tissues regardless of the sample origins.

The accumulation pattern of metals varies greatly depends on the species as well type of tissues. Previous report by Begum et al. [17], showed that the liver appeared to be the main storage of heavy metal, while the muscle tissue with the lowest level. Yet, Mormede and Davies [18], suggested that the liver is the target organ, which functions to detoxify and accumulate [19], while muscles are at most concern to humans because it is the main tissues of human diet [20]. Based on permissible level limits for the muscle meat of fish, all metal studied were below the permissible level recommended by Malaysian Food Regulation and USEPA risk based concentrations. For a better understanding, PCA was conducted to evaluate the distribution of metals in the studied tissues. PCA is usually discussed in terms of loadings and scores since they complement each other. The scree test proposed by Cattell [21] suggest that with only the first two PCs accounted for 74% of the total variability of associated metal concentrations in tissues studies and 3 distinct clusters can be revealed (Figure 2). The model demonstrated that Cluster I is made up of liver tissues, Cluster II composed of scores of gill tissues, while the scores of muscle tissues are grouped in

Cluster III. The variation of these clusters, are totally associated with the type of tissues regardless their habitats. The variation of metal accumulation trends depends on the studied tissues. Combination of the results from Figure 2 and Table 3 suggest that the total metals accumulation is liver > gill > muscle.

Table 3. The concentration of heavy metals in freeze dried *Hemibagrus* sp.

	Tissue (mg kg^{-1})	**Cr**	**Cu**	**Zn**	**Pb**	**Cd**	**As**

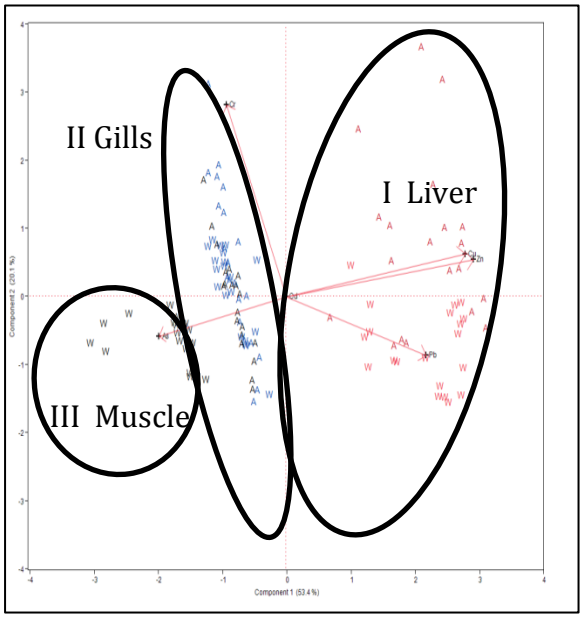

Figure 2. PCA bi-plot for all samples (n = 120). The letter A denotes aquacultured fish, letter W denotes to wild fish.

Based on Figure 2, it is noticed that the scores of liver sample (Cluster I) in PC1 axis was spread in the region with positive loadings of Pb, Cu and Zn. High variation of these metals makes liver samples stand out more from others on the right-hand side of the scores plot. These observations are consistent with the findings reported by [22], that higher metal accumulation in liver tissues are due to the greater binding tendency of the metals with oxygen carboxylate, amino groups, nitrogen, and/or sulphur of the mercapto group in the metallothionein protein.

PCA bi-plot for liver samples demonstrates two clusters (Figure 3) were obtained. The liver samples from cultivated *Hemibagrus* sp. have positive scores on PC1 than wild *Hemibagrus* sp. which explained 52 % of the total variance

and have positive loadings of Cr, Cu, and Zn. The gills (Cluster II) and muscle samples (Cluster III) are discriminated from liver samples with negative score on PC1. Nevertheless, Cluster II and Cluster III overlap with high score of Cr and As. In fact, Cluster III mainly consists of two sub-clusters which can be distinguished by the magnitude of score on PC1 (53% of total variance). Similar trend was observed in gills samples, where the bi-plot also indicates 2 distinct cluster (Figure 4) (which explained 73% of the total variances. These results also demonstrated that cultivated *Hemibagrus* sp. from Selangor River accumulated high metal concentrations than wild *Hemibagrus* sp.

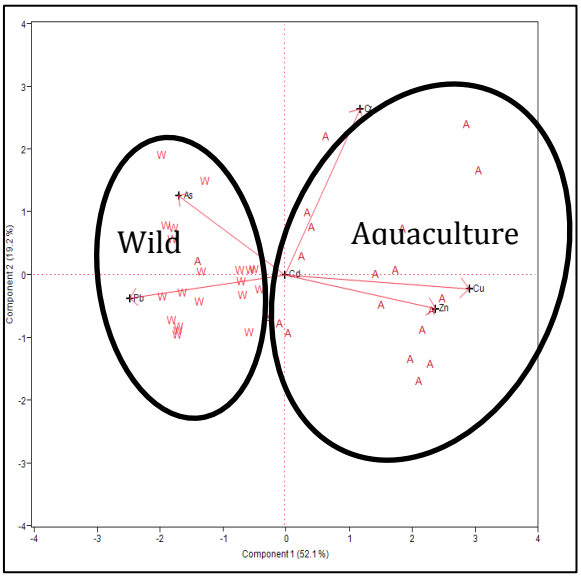

Figure 3. PCA bi-plot for liver samples (n = 40).The letter A denotes aquacultured fish, letter W denotes to wild fish.

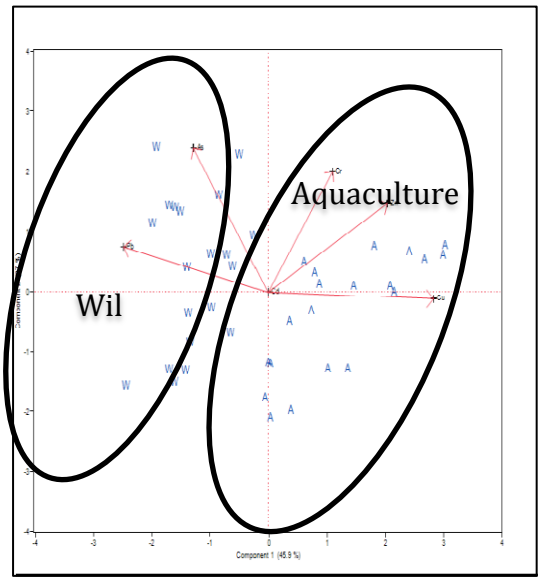

Figure 4. PCA bi-plot for gills samples (n = 40). The letter A denotes aquacultured fish, letter W denotes to wild fish.

Refer to PCA bi-plot for muscle sample (Figure 5), it was demonstrated that two discrete cluster are separated by PC1 (75% of total variance), which high positive loadings of Cu, Zn, and Pb for cultivated fish while negative loading of Cr and As for wild fish. According to the Malaysian Food Act 1983 and Food Regulations 1985 [23], accumulation of heavy metal in muscle samples are below the permissible level.

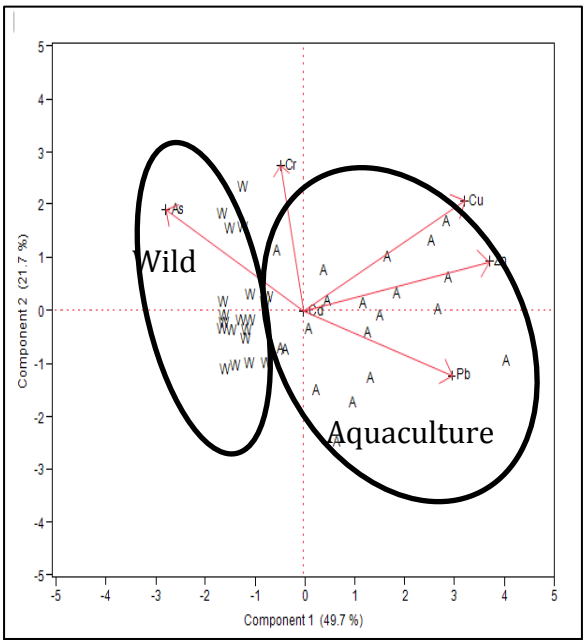

Figure 5. PCA bi-plot for muscle samples (n = 40). The letter A denotes aquacultured fish, letter W denotes to wild fish.

Conclusion

The results of the study show that PCA can identify patterns in our data, where PCA provides a way to visualize the clustering pattern among different organs of *Hemibagrus* sp from two different habitats, and easily identifies which metals contribute most to these variation. It also demonstrates the similar clustering tendencies related to the origin of the samples. The results revealed Cu, Zn, and Pb highly associated with liver tissues while Cr and As with muscle and gills. This suggests that the differences in accumulation of heavy metals between two habitats were probably due to the differences in their environmental conditions.

Abstract

Oil palm fronds containing rich hemicellulose are low cost resources that could be potentially converted into valuable products such as xylooligosaccharides. The main objective of this study was to investigate the production of xylooligosaccharides from OPF hemicelluloses using *Trichoderma longibrachiatum* xylanase. The OPF hemicellulose extracted by alkaline extraction was hydrolysed by xylanase at pH 4.6, temperature 40 °C, hemicellulose substrate concentration 2 % (w/v) and enzyme concentration 2 U/ml for different period of time from 0 to 48 hours to produce xylooligosaccharides. The hydrolysate obtained from enzymatic hydrolysis was further purified through ultrafiltration using 10 kDa molecular weight cut off membranes. The highest total of xylobiose and xylotriose was found to be 21.91 mg/mL and obtained at 8 hours of hydrolysis time. After ultrafiltration step, xylooligosaccharides mixture were obtained in the permeate and retentate. The highest xylobiose (56.64g/100g) and xylotriose (45.80g/100g) were found in retentate and permeate, respectively.

Keywords: xylooligosaccharides, oil palm frond, ultrafiltration, enzymatic hydrolysis, xylanase

Abstrak

Pelepah kelapa sawit yang kaya dengan hemisellulosa adalah sumber kos rendah yang berpotensi untuk ditukarkan kepada produk bernilai seperti xilooligosakarida. Objektif utama kajian ini adalah untuk menyiasat penghasilan xilooligosakarida daripada hemisellulosa pelepah kelapa sawit menggunakan enzim xilanase *Trichoderma longibrachiatum*. Hemisellulosa yang diekstrak daripada pelepah kelapa sawit menggunakan alkali, dihidrolisis menggunakan enzim xilanase pada pH 4.6, suhu 40 °C, kepekatan hemiselulose 2 % (w/v) dan kepekatan enzim 2U/ml umtuk tempoh masa berbeza dari 0 hingga 48 jam untuk menghasilkan xilooligosakarida. Hidrolisat yang diperoleh daripada hidrolisis enzimatik kemudiannya ditulenkan melalui ultrafiltrasi menggunakan membran yang berat molekulnya 10 kDa. Jumlah tertinggi xilobios dan xilotrios adalah 21.91 mg/mL yang diperoleh pada masa hidrolisis 8 jam. Setelah ultrafiltrasi, campuran xilooligosakarida diperoleh dalam 'permeate' dan 'retentate'. Kandungan tertinggi xilobios (56.64g/100g) dan xilotrios (45.80g/100g) ditemui di dalam 'retentate' dan 'permeate'.

Kata kunci: xilooligosakarida, pelepah kelapa sawit, ultrafiltrasi, hidrolisis enzimatik, xilanase

Introduction

Oil palm fronds (OPF) generated the most of waste among the other biomass with 54.17 million tons and 54.24 million tons from oil palm industry in Malaysia for year 2010 and 2011, respectively [1]. The OPF is available daily throughout the year when the palms are pruned during the harvesting of bunches of fresh fruit. It is composed of hemicelluloses, cellulose and lignin. Hemicellulose extracted by alkaline extraction can be used as starting material for xylooligosaccharides (XOs) production. XOs are sugar oligomers made up of xylose unit. XOs can be used as ingredients of functional foods, cosmetics, pharmaceuticals or agricultural products [2]

Enzymatic method is more preferable to produce XOs compared to other methods, because it does not produce undesirable component or high amount of monomers and does not require special equipment [3]. Enzymatic production of xylooligosaccharides performed by xylanase having high endoxylanase and low β-xylosidase activity besides present of others side group enzyme removal include α-arabinofuranosidases, acetylxylan esterase, and α-glucuronidase [4]. Membrane separations, such as ultrafiltration and nanofiltration have been shown to be very promising methods for refining and concentrating several oligosaccharides [3]. Membrane technologies have been applied successfully in conjugation with enzymatic hydrolysis following steam hydrolysis for processing XOs.

Previous study used *Trichoderme viride* xylanase to produce XOs from OPF. However the result showed that the yield of XOs was only 25.64% [5]. Since there is also no purification step was performed in the previous study, thus in the present work, xylanase from *Trichoderma longibrachiatum* was used for enzymatic hydrolysis due to a few reports on their ability to produce high yield of XOs [6-8] following by ultrafiltration step. Therefore, the main objective of this study was to investigate the production of XOs mixture from alkaline extracted oil palm fronds hemicellulose using *Trichoderma longibrachiatum* and ultrafiltration.

Materials and Methods

Raw material

Oil palm frond (OPF) samples used in this study were obtained from local farmers in Perak, Malaysia. The samples were chipped, ground and sieved into fibers with width and length of 0.5 mm and 3 to 8 mm, respectively, and then stored at room temperature prior to use. All chemicals used were of analytical grade unless otherwise stated.

Hemicellulose extraction

Hemicellulose extraction from OPF was conducted according to the method reported by Anis [9] with some modifications. An amount of 50 g sample of oil palm frond chips were soaked in 3 M potassium hydroxide (KOH) with the solid to liquid ratio of 1:10, stirred at 40 °C and 400 rpm with mechanical heat stirrer (HS-30D, WiseStir) for 4 hours. Then, the crude hemicellulose was filtered. The filtrate was acidified with 50 % (v/v) acetic acid to pH 4.8 ± 0.1 and allowed to stand for 24 hours at 4 °C. The extracts were centrifuged (Centrifuged 5702, Eppendorf) at 3500 rpm for 15 min and filtered. The precipitate was washed with 50 mL of 95 % (v/v) ethanol to eliminate acid residue from the sample before dried in an oven (UFB 500, Memmert) at 40 °C for 4 hours. The supernatant was then added with four volumes of 95 % ethanol and was kept for overnight. Hemicellulose in the form of pellet was obtained from precipitate after centrifuged, while the supernatant was discarded. Finally, the pellet was dried in the oven and used as a hemicellulose source.

Enzymatic hydrolysis

A volume of 1 mL of 2 U/mL of xylanase from *T. longibrachiatum* (Sigma, USA) was added to 10 mL of 2 % (w/v) alkaline extracted hemicellulose solution from OPF in 0.05 M citrate buffer at pH 4.6. The mixture was incubated at 40 °C with mild shaking in an incubator shaker (IKA® KS 4000i Control, China). Enzymatic hydrolysis was carried out at pH 4.6, temperature 40 °C, hemicellulose concentration 2 % (w/v) and enzyme concentration 2 U/ml. This hydrolysis was conducted from 0 to 48 hours. Periodically, samples were taken out and the enzymatic reaction was stopped by boiling for 5 min before the samples were subjected to analyses. The hydrolysate obtained at optimal time was further used for purification step using ultrafiltration [10]. XOs contents were determined using HPLC.

Purification of hydrolysate using Ultrafiltration

Purification process was carried out using an Amicon Stirred Ultrafiltration Cell, Model 8400 (Millipore-Amicon, Bedford, MA) pressurized by nitrogen gas. A volume of 50 mL of hydrolysate obtained from hemicellulose

hydrolysis was passed through the ultrafiltration system with 10 kDa molecular weight cut off (MWCO) membrane. The operating condition allowed membrane operating pressure 55 psi at room temperature. The filtration was stopped when approximately 40 mL of permeate was collected. The total sugar in retentate and permeate after ultrafiltration process was determined by phenol/sulfuric acid method. The XOs content was determined by HPLC.

Total sugar analysis

Total sugar content in hydrolysate was measured by using the phenol-sulfuric acid method [11]. An amount of 1 mL of 5 % (w/v) phenol solution and 5 mL of 98 % concentrated sulfuric acid were added to 1 mL of hydrolysate. The mixture was mixed well and kept at room temperature for 10 minutes for color development before being cooled in the water bath (Memmert, Germany) at 25 °C for 20 minutes. The absorbance was measured at wavelength 480 nm by UV spectrophotometer (Perkin Elmer Precise, 35 Lambda, USA). The amount of total sugar was expressed as mg/mL alkaline extracted hemicellulose (pellet).

Monosaccharides determination by HPLC

The content of monosaccharides in the XOs-containing liquor from ultrafiltration process was determined by HPLC (Agilent Technologies 1200 Series, Germany) using Aminex HPX 87P column (300 mm x 7.8 mm). The HPLC was equipped with a refractive index detector (G 1362A, Agilent Technologies 1200 Series, Germany) and column oven (Agilent Technologies 1200 Series, Germany). The sample was filtered through a 0.20 µm nylon syringe filter (Minisart, Sartorius AG, Germany) prior to direct injection into HPLC. The sample was eluted using deionised water as the mobile phase at column temperature of 80 °C and a flow rate of 0.5 mL/min.

Xylooligosaccharides determination by HPLC

XOs were analyzed by HPLC (Agilent Technologies 1200 Series, Germany) equipped with a refractive index detector (G 1362A, Agilent Technologies 1200 Series, Germany), and column oven (Agilent Technologies 1200 Series, Germany). A volume of 2 mL of hydrolysate obtaining from ultrafiltration was filtered through a 0.20 µm nylon syringe filter (Minisart, Sartorius AG, Germany). A 20 µL volume of the filtered sample was injected into HPLC. The sample was eluted using deionised water as the mobile phase. The BioRad-Aminex HPX 42A column (300 mm x 7.8 mm) was used at 80 °C and a flow rate of 0.5 mL/min. Concentration of XOs was measured using an average peak areas compared to the mixture of XOs standards and expressed as mg/mL XOs. Standard calibration curve was plotted based on peak areas against concentration of XOs standards.

Results and Discussion

Monosaccharides Composition of Hemicellulose

The monosaccharide compositions of OPF hemicellulose were xylose, arabinose and glucose. Xylose was the major component with 46.67 % (w/w) found in the OPF hemicellulose indicating the existence of xylan as the main polysaccharides [12], followed by a small amount of arabinose and glucose with 11.01 % (w/w) and 9.01 % (w/w), respectively. Xylose probably originated from the backbone of the hemicellulose [13], while arabinose and glucose came from the side chain [14]. This result is in accordance with the finding reported by Fazilah et al. [15] using similar raw materials.

Enzymatic hydrolysis of OPF

Table 1 shows the enzymatic hydrolysis of OPF for a period of time from 0 to 48 hours using 2 U/mL xylanase concentrations with 2 % (w/v) OPF hemicellulose substrate at pH 4.6 and 40 °C. HPLC analysis indicated that OPF hemicellulose is hydrolysed to xylose and a variety of XOs fractions, which are xylobiose, xylotriose, xylotetraose, xylopentaose and xylohexaose.

During the initial 2 hours, the concentration of xylobiose decreased as much as to 42 % from 7.24 ± 0.44 mg/mL to 4.19 ± 0.06 mg/mL, and the concentration of xylotriose decreased slightly from 8.93 ± 0.16 mg/mL to 8.32 ± 0.47 mg/mL, which corresponds to 7 %. However, the concentration of xylobiose and xylotriose increased rapidly at 8 hours. The highest total of xylobiose and xylotriose was 21.91 mg/mL at hydrolysis time of 8 hours. Further increase in the time from 8 to 24 hours significantly decrease ($p < 0.05$) the xylobiose and xylotriose concentrations.

In the present study, XOs in the range of xylobiose to xylohexaose except xylotetraose were produced by *Trichoderma longibrachiatum* xylanase in all hydrolysis time. This result was in accordance with the study reported by Akpinar et al. [3] for the production of XOs from cotton stalk using *Aspergillus niger* xylanase. The absence of xylotetraose in all hydrolysis time was due to its immediate hydrolysis into smaller oligosaccharides once it was produced. The concentration of xylopentaose increased from 0 to 2 hours, whereas the concentration of xylohexaose increased from 0 to 8 hours. Further increase the hydrolysis time from 8 to 24 hours did not significantly increase the xylopentaose and xylohexaose.

Table 1. Concentration of Xylose and XOs at different time of hydrolysis

Sugars (mg/mL)	**Hydrolysis Time (hour)**				
	0	**2**	**8**	**24**	**48**
Xylose	0.04 ± 0.01^{a}	1.74 ± 0.05^{b}	8.46 ± 0.32^{c}	17.78 ± 0.90^{d}	23.79 ± 0.33^{e}
Xylobiose	7.24 ± 0.44^{c}	4.19 ± 0.06^{b}	9.70 ± 0.04^{d}	3.25 ± 0.59^{a}	3.77 ± 0.42^{b}
Xylotriose	8.93 ± 0.16^{c}	8.32 ± 0.47^{bc}	12.21 ± 0.59^{d}	0.86 ± 0.67^{a}	7.19 ± 1.12^{b}
Xylotetraose	n.d	n.d	n.d	n.d	n.d
Xylopentaose	3.69 ± 0.13^{a}	9.31 ± 0.11^{c}	6.45 ± 0.51^{b}	5.98 ± 0.25^{b}	5.96 ± 0.11^{b}
Xylohexaose	3.85 ± 0.03^{a}	3.02 ± 0.45^{a}	7.05 ± 0.09^{b}	7.18 ± 0.49^{b}	6.90 ± 0.15^{b}
Xylobiose + Xylotriose (Total)	16.17	12.51	21.91	4.11	10.96

Results are presented as means ± standard deviation (n=3), Mean values followed by different superscript letters in a row are significantly different ($p < 0.05$), n.d: not detected.

Table 1 also shows that extending the reaction time to 48 hours did not significantly increase the production of XOs, but instead produced high amount of xylose. The amount of xylose increased drastically after 2 hours. These results were corroborated with the yield of the XOs, which decreased after 8 hours due to a small amount of XOs was hydrolysed into monosaccharides, thus could also inhibit the production of XOs [16]. The concentration of xylose also increased drastically when the reaction time increased. The concentration of Xylose rose up to 23.79 mg/mL when hydrolysis time increased to 48 hours. The result showed that increasing hydrolysis time resulted in higher xylose production.

Purification of OPF XOs by Ultrafiltration

It can be seen that the composition of permeate with molecular weight of 10 kDa MWCO membrane exhibited higher content of xylotriose , followed by xylopentaose, xylohexaose and xylobiose (Table 2) . The xylobiose composition in the initial feed decreased from 27.40 g/100 g to 10.64 g/100 g, whereas xylotriose composition increased from 34.47 g/100 g to 45.80 g/100 g when passing through 10 kDa MWCO membrane. It was found that xylobiose was decreased by 61%, while xylotriose was increased by 33% in the permeate. In addition, xylopentaose and xylohexaose composition in the permeate increased slightly from initial feed with 22 % and 7 %, respectively.

Both xylopentaose and xylohexaose composition decrease in the retentate by 33 % and 38 %, respectively. Other than that, xylobiose composition in the retentate increased significantly ($p < 0.05$) from 27.40 g/100 g to 56.64 g/100 g. This result showed that the composition of xylobiose in the retentate was higher compared to in permeate. However, xylotriose decrease significantly ($p < 0.05$) from 34.47 g/100 g to 18.73 g/100 g in the retentate. The initial feed containing XOs was fractionated with 10 kDa MWCO membrane, clearly showed that the permeate

fraction containing XOs ranging from xylobiose to xylohexaose. In contrast, the retentate fraction containing XOs is ranging from xylobiose to xylohexaose. However, Akpinar et al. [3] found that ultrafiltration with 10 kDa MWCO membrane successfully retained mainly high molecular weight oligosaccharides in the retentate. The presence of low molecular weight oligosaccharides in retentate may be due to fouling mechanism. Fouling mechanism caused by blocking of pore in high cut-off membrane by big molecules, so that transportation of small molecules was hindered. Membrane selection is also very important in order to reduce fouling problem [17].

Table 2. Total sugar concentration and composition of permeate and retentate at 8 hours of hydrolysis.

XOs	**Initial feed amount (Total sugar, mg/ml)**	**Composition of feed (g/100g)**	**Composition of permeate of MWCO 10 kDa membrane (g/100g)**	**Composition of retentate of MWCO 10 kDa membrane (g/100g)**
Total	35.42	100.00	100.00	100.00
Xylobiose	9.70±0.04	27.40^{b}	10.64^{a}	56.64^{c}
Xylotriose	12.21±0.59	34.47^{b}	45.80^{c}	18.73^{a}
Xylotetraose	0.00	0.00	0.00	0.00
Xylopentaose	6.45±0.51	18.22^{b}	22.23^{c}	12.25^{a}
Xylohexaose	7.05±0.09	19.92^{b}	21.33^{c}	12.38^{a}

Mean ± standard deviation of at least duplicate determinations. Mean values followed by different superscript letters in a row are significantly different ($p < 0.05$).

Conclusion

The highest total of xylobiose and xylotriose was found to be 21.91 mg/mL and obtained at 8 hours of hydrolysis time. After ultrafiltration step, mostly xylooligosaccharides mixture were obtained in the permeate and retentate. The highest xylobiose (56.64 g/100 g) and xylotriose (45.80 g/100 g) were found in retentate and permeate respectively.

Abstract

This study was undertaken to investigate the effect of chromium on the reduction behaviour of ferric oxide with carbon monoxide (10 %, v/v) in nitrogen as a reductant. Ferric oxide was impregnated with 3 % chromium to produce chromium-doped ferric oxide (Cr-Fe_2O_3). The reduction behaviour and the kinetic studies of Cr-Fe_2O_3 and Fe_2O_3 have been studied by temperature programmed reduction (TPR) and the phases formed of partially and completely reduced samples were characterized by X-ray diffraction spectroscopy (XRD). Meanwhile, the activation energy values were calculated from the Arrhenius equation using Wimmer's method. TPR results indicate that the reduction of Cr-Fe_2O_3 proceeded in two reduction steps ($Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow Fe$), while, Fe_2O_3 proceeded in three reduction steps ($Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow FeO \rightarrow Fe$) with doped ferric oxide showed a large shifted towards lower temperature. The complete reduction of ferric oxide to metallic Fe occur at 700 °C compared to the undoped ferric oxide (900 °C). The XRD pattern showed that the diffraction peaks of Cr-Fe_2O_3 are more intense compare to Fe_2O_3, indicating that the improvement on the crystallinity of the characteristic peaks of Fe_2O_3 with no additional peak observed meaning that the chromium particles loaded on the ferric oxide were well dispersed. Furthermore, additional of 3 % chromium on ferric oxide gives larger surface area and decrease in the activation energy up to 12.39 % regarding to transition phases of $Fe_2O_3 \rightarrow Fe_3O_4$ during the reduction process may also led to the increase in the rates of ferric oxide reduction.

Keywords: temperature programmed reduction, kinetic, reduction, ferric oxide, chromium, carbon monoxide

Abstrak

Kajian ini dijalankan untuk melihat pengaruh kromium pada kelakuan penurunan ferik oksida di mana karbon monoksida (10%, v/v) di dalam nitrogen digunakan sebagai agen penurunan. Serbuk ferik oksida yang didopkan pada kromium (Cr-Fe_2O_3) disintesis menggunakan kaedah impregnat. Kelakuan penurunan dan kinetik oleh Cr-Fe_2O_3 and Fe_2O_3 dikaji menggunakan teknik suhu penurunan berprogram (TPR) dan fasa - fasa yang terbentuk bagi separa dan penurunan penuh dicirikan menggunakan teknik pembelauan sinar X (XRD) sementara nilai - nilai tenaga pengaktifan dikira daripada persamaan Arrhenius dan kaedah Wimmer. Profil TPR menunjukkan bahawa penurunan ferik oksida yang didopkan kromium melalui dua langkah tindak balas penurunan ($Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow Fe$) manakala ferik oksida yang tidak didopkan melalui tiga langkah tindak balas penurunan ($Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow FeO \rightarrow Fe$). Suhu proses penurunan tamat beranjak kepada suhu yang lebih rendah iaitu 700 °C dan proses penurunan tamat pada suhu (900 °C). Difraktogram XRD terhadap Cr-Fe_2O_3 menunjukkan peningkatan pada kehabluran puncak Fe_2O_3 berbanding ferik oksida yang tidak didopkan dengan tiada puncak tambahan diperhatikan dimana ia

menjelaskan bahawa zarah kromium yang dimuatkan pada ferik oksida telah tersebar dengan baik. Di samping itu, tambahan sebanyak 3 % kromium pada ferik oksida memberikan kawasan permukaan yang lebih besar dan pengurangan tenaga pengaktifan sehingga 12.39 % bagi peralihan fasa $Fe_2O_3 \rightarrow Fe_3O_4$ serta juga membawa kepada peningkatan kepada kadar proses penurunan ferik oksida tersebut.

Kata kunci: penurunan suhu berprogram, kinetik, penurunan, ferik oksida, kromium, karbon monoksida

Introduction

Reduction of ferric oxide was a subject of numerous studies due to the importance of iron and steel in the current and future technologies [1]. The iron and ferric oxide are nontoxic and cheap materials give them as an important chosen material in the catalysis field [2, 3]. As a catalyst, the reduction behaviour and the degree of reduction of the iron species were highly important in such catalysis and previous studies, reaction temperature of ferric oxide reduction was determined using thermodynamics [4, 5] and experimental [1, 6]. The reduction process of Fe_2O_3 involves different mechanism depending on temperature, particle size, concentration reduction gas used and additives to the Fe_2O_3 [7-9]. Reduction by carbon monoxide generally involves two-steps reduction can be described as equation 1 and 2 follows [7-9]:

$$3Fe_2O_3 + CO \rightarrow 2Fe_3O_4 + CO_2 \qquad \Delta H_r = -47.2\ kJmol^{-1} \qquad (1)$$

$$Fe_3O_4 + 4CO \rightarrow Fe + 4CO_2 \qquad \Delta H_r = -13.6\ kJmol^{-1} \qquad (2)$$

Meanwhile three steps reduction is additional of another two subsequent steps from the final process of Fe_3O_4 directly reduce to metallic iron (equation 3 and 4) as describe below:

$$Fe_3O_4 + CO \rightarrow 3FeO + CO_2 \qquad \Delta H = 19.4\ kJmol^{-1} \qquad (3)$$

$$FeO + CO \rightarrow Fe + CO_2 \qquad \Delta H = -11.5\ kJmol^{-1} \qquad (4)$$

Briefly, equations (1) and (2) are responsible for the two-step reduction and whereas a sequence of equations (1), (3) and (4) represents the three-step reduction. Furthermore, the thermodynamic calculations based on the Gibbs free energy change due to reaction and the equilibrium composition of the oxides for the equations above indicate that equation (1), (3) and (4) are spontaneous with ΔG between -102.3 to +9.61 $kJmol^{-1}$ at temperature 300 °C to 900 °C. While, the reduction process for equation (2) is thermodynamically more favourable at rather lower temperatures (below 500 ^{0}C, ΔG<+20 $kJmol^{-1}$). In addition, chromium as an additive to the ferric oxide has been explored widely for their improved catalytic activity due to the unique performance to the role of chromium in stabilizing the ferric oxide against sintering. To enhance the reduction performance of ferric oxide, the addition of other metal additives was considered. In this study we report the reduction behavior of the addition of chromium species into ferric oxides catalyst. The temperature programme reduction was performed to investigate the non-isothermal reduction behaviour of Cr doped ferric oxide by comparing to none doped species. Moreover, the kinetic studies were also carried out to calculate the activation energy of the reduction process using different heating rate.

Materials and Methods

Chemicals and raw materials

Iron (III) oxide (99%) was obtained from Sigma Aldrich Chemical Company and chromium (III) nitrate from R&M Chemicals. Gas mixture CO/N_2 (10% CO) was obtained from Linde.

Catalyst preparation

The Cr doped ferric oxide was prepared by impregnating Fe_2O_3 powder with aqueous solution containing chromium cation additives. The amount of chromium added was adjust to be 3 wt% in Fe_2O_3. The Fe_2O_3 powder was directly impregnated into 50 ml distilled water corresponding metal cation additives in the above proportion and stirred vigorously for 2 hours at room temperature. The impregnated sample was dried at 110 °C overnight and subsequently calcined at 600 °C in the furnace for 3 hours.

Characterization studies

Temperature programmed reduction (TPR) measurements was conducted using a Micromeritic Autochem 2920 Chemisorption Analyzer apparatus; a feed of 10 % CO in N_2 at a flow rate of 20 mL min^{-1} (Standard Temperature and Pressure, STP) was used as reducing gas. An amount 50 mg of samples were heated up to 900 °C, at a rate of 10 °C min^{-1}. For the kinetic study, different heating rate (10, 13, 15 °C min^{-1}) were applied to the samples. The reduction kinetics of doped ferric oxides is an essential point that deserves investigation. There are numerous models in the literature for the estimation of the kinetic parameters and in this study Wimmers's method [11] was chosen and it describes the correlation between shifts in T_{max} with the heating rate. In this method, the activation energy can be calculated from TPR data by using equation (5) below:

$$\ln (\Psi/T_{max}) = -E_a/RT_{max} + \ln (AR/E_a) + C \quad (5)$$

The activation energy is achieved from the shift of rate maximum temperature (T_{max}) against the heating rate (Ψ). If a straight line graph is obtained from the plot of ln (Ψ/T_{max}) versus 1/ (T_{max}), the slop is E_a/R which R is the gas constant. To investigate the role of Cr in the reduction behaviour of Fe_2O_3, the samples were collected and XRD patterns were measured. Samples were collected according to the TPR pattern when the reduction of Cr-Fe_2O_3 is assumed to be finished at 700 °C. Meanwhile, undoped Fe_2O_3 was also collected at 700 °C for the comparison purposes. The carbon monoxide consumption was monitored using a thermal conductivity detector (TCD). Phase characterization was carried out by X-ray diffraction (XRD) Bruker AXS D8 Advance type with X-ray radiation source of Cu Kα (40 kV, 40 mA) to record the 2θ diffraction angle from 10 – 80 degree at wavelength (λ = 0.154 nm). For identification purposes of crystalline phase composition, diffraction patterns obtained were matched with Joint Committee on Powder Diffraction Standards (JCPDS) files. Physical surface analysis (Brunauer–Emmett–Teller, BET) of nitrogen adsorption at 77 K (liquid nitrogen) was conducted using a Micromeritics ASAP 2010 instrument to obtain the adsorption isotherm of each sample. The calcined sample of Cr-Fe_2O_3 and Fe_2O_3 were degassed at 350 °C for 6 h before the BET surface area analyses were done. The Brunauer–Emmett–Teller (BET) surface area were calculated from the isotherms.

Results and Discussion

Isotherm adsorption of N_2

The result indicates that the impregnation of Fe_2O_3 with chromium nitrate (5.90 m^2/g) shows the BET surface area was a little larger than undoped Fe_2O_3 (4.67 m^2/g) manifesting that Cr could also prevent the aggregation of particles. Moreover, Hu et al. [11] mentioned that specific surface area was also an important factor as higher specific surface area usually results in more unsaturated surface coordination sites exposed to the gas which may result in the increasing of the reducibility performance of the ferric oxide in this study.

Crystallinity effect by XRD

Figure 1 shows the XRD patterns of Cr-Fe_2O_3 and undoped Fe_2O_3 before reduction in CO in nitrogen (10%, v/v). The XRD patterns obtained for both sample are identical to the Fe_2O_3 phase (ferric oxide, JCPDS 74-6271). The 2θ Fe_2O_3 main peaks reveal the presence of contribution at about 24.2, 33.2, 35.7, 40.9, 49.5, 53.5, 57.2, 62.4, 64.2, 72.4 and 75.7 °. The diffraction peaks were shifted to higher 2θ positions which is mainly due to the interference of the Cr element changed the lattice constant of the Fe_2O_3. This can be attributed to the small atomic radius of Fe (0.126 nm) compared to those of Cr (0.128 nm) that gave changed to the lattice parameters and lattice spacing. Furthermore, the diffraction peaks of freshly prepared Cr-Fe_2O_3 showed an improvement in the crystallinity of the characteristic peaks of Fe_2O_3 when loaded with Cr. Furthermore, no additional peak observed in the XRD patterns showing that the chromium particles loaded on the ferric oxide were well dispersed.

From the observation in Figure 2, Cr-Fe_2O_3 gives only metallic Fe diffraction peaks (iron, JCPDS 65-4899) at 700 ^{0}C, while undoped Fe_2O_3 still consist of the remaining crystalline phases of Fe_3O_4 (3,1,1), Fe_3O_4 (4,4,0) (magnetite, JCPDS 71-6336) and crystallite phases of FeO (1,1,1) and FeO (2,2,0) (wustite, JCPDS 80-0686). Fe_2O_3 showed a complete reduction to metallic Fe when the reduction temperature reached 900 ^{0}C. To further investigate the mechanism involved in the reduction process of Cr-Fe_2O_3 and undoped Fe_2O_3, samples were collected at various temperatures (400, 500, 600 and 700 ^{0}C) and detailed characterization using XRD were shown in Figure 3 and Figure 4, respectively. At temperature 400 ^{0}C and 500 ^{0}C the XRD patterns show strong diffraction peaks of

magnetite and a growth of metallic iron phases. By increasing the reduction temperature to 600 ^{0}C, undoped Fe_2O_3 started to display a formation of metastable FeO with crystallite phases of FeO (1,1,1), (2,0,0), (2,2,0), (3,1,1) and (2,2,2) (wustite, JCPDS 80-0686). The reduction of Fe_3O_4 to FeO proceeded at higher temperature >570 ^{0}C while FeO was also reduced to Fe, simultaneously (Fig.4). For Cr-Fe_2O_3, FeO was not detected in the XRD patterns for the whole reduction process as the addition of chromium inhibits FeO phases to occur. This indicated that the formation of metastable FeO phase was not only affected by the reduction temperature but also depended on the nature of the sample itself, which in this case the involvement of chromium element in the structure of ferric oxide enhance it reducibility.

Chemical properties by TPR analysis

The TPR patterns for non-isothermal reduction of Cr-Fe_2O_3 and undoped Fe_2O_3 by CO in nitrogen (10 %, v/v) is shown in Figure 5. The TPR profiles of undoped Fe_2O_3 represented 3 reduction events (denoted I, II and III) which event I represent to peak displayed at lower temperature exhibited the reduction of $Fe_2O_3 \rightarrow Fe_3O_4$. Meanwhile, the second peak (event II) was related to the reduction of $Fe_3O_4 \rightarrow$ FeO and the last peak (event III) was attributed to the reduction of FeO to metallic Fe. Three reduction events of Fe_2O_3 reflected by 3 peaks around 361 °C (I), 509 °C (II) and 807 °C (III) as display in Figure 5., showing three-steps reduction route of Fe_2O_3 to Fe through Fe_3O_4 and FeO as an intermediate and for Cr-Fe_2O_3, the temperature for the peak obtained for event I is 353 °C and for higher temperature, the peaks were observed overlaping to each other with a shoulder at 507 °C and a peak at 591 °C. The higher temperature shoulder of Cr-Fe_2O_3 may refer to the Fe_3O_4 to complete the reduction process by forming a better crystallite of Fe_3O_4 as indicated in the XRD results and another peak may refer to further reduction of Fe_3O_4 to metallic Fe. The absence of FeO throughout the reduction process of Cr-Fe_2O_3 attributed to two-steps of

reduction ($Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow$ metallic Fe). Furthermore, the addition of Cr to ferric oxide enhance the reducibility of the ferric oxide to metallic Fe by shifted the peaks to lower temperature and completed at 700 ^{0}C which was lower than undoped Fe_2O_3 (900 °C) as also confirmed by XRD analysis.

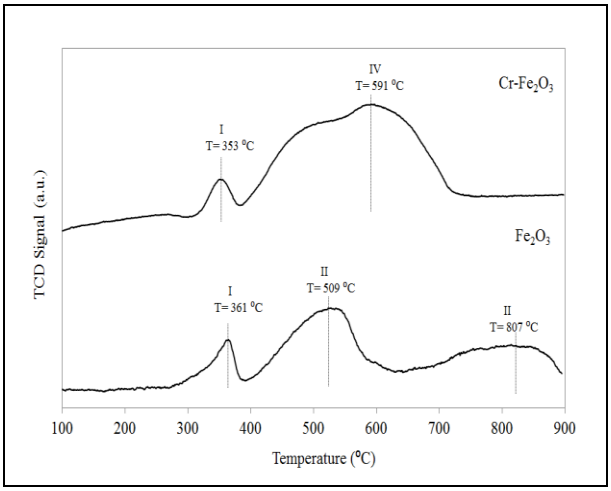

Figure 5. TPR profile of Fe_2O_3 and Cr-Fe_2O_3

Activation energy (Ea) effect

To evaluate the activation energy of Cr-Fe_2O_3 and undoped Fe_2O_3 a TPR measurement with various heating rates (10, 13 and 15 ^{0}C/min) were carried out. The results showed that by increasing the heating rate, the peaks showing a maximal temperature were shifted to higher temperature as shown in Figure 6.

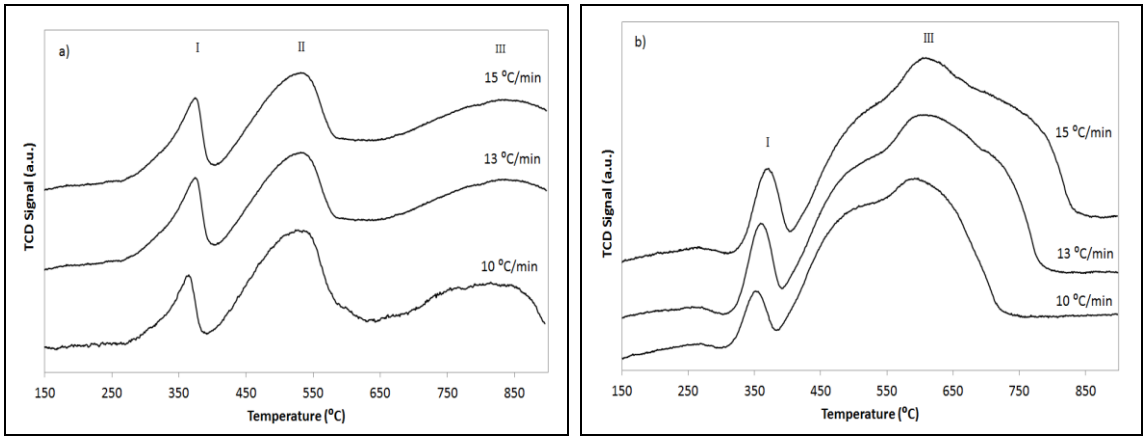

Figure 6. TPR profiles of (a) Fe_2O_3 and (b) Cr-Fe_2O_3 reduction by carbon monoxide with heating ramp of 10 °C/min, 13 °C/min and 15 °C/min

To describe the process, we considered that during the TPR analysis, 3 reduction steps involve for undoped Fe_2O_3 and 2 reduction steps for Cr-Fe_2O_3. The processes were described below with the rate constant of K_I, K_{II}, K_{III} and K_{IV}.

Fe_2O_3: $Fe_2O_3 \xrightarrow{K_I} Fe_3O_4 \xrightarrow{K_{II}} FeO \xrightarrow{K_{III}} Fe$

Cr-Fe_2O_3: $Fe_2O_3 \xrightarrow{K_I} Fe_3O_4 \xrightarrow{K_{IV}} Fe$

The E_a for undoped Fe_2O_3 and Cr-Fe_2O_3 by referring to their transition phase were shown in Table 1. The results suggest that by adding Cr metal into ferric oxide, the Ea value decrease by 12.39 % for the reduction step of $Fe_2O_3 \rightarrow Fe_3O_4$ that lower the reduction temperature. This also in agreement with previous work by Ryu et. al. (2008) [12] with addition of metal additive in their case is Ru metal, played an important role on lowering the reduction temperature which also due to a decrease of activation energy according to $Fe_2O_3 \rightarrow Fe_3O_4$ course in H_2 reducing atmosphere. Nevertheless, Ea value regarding to other transition phases could not be compared since both samples involved a different mechanism in the reduction process. Moreover, Cr-Fe_2O_3 which gives two reduction steps with transition phase of $Fe_2O_3 \rightarrow Fe_3O_4$ display an E_a value of 123.7 kJ mol^{-1} and $Fe_3O_4 \rightarrow$ Fe give a value of 89.0 kJ mol^{-1}. For undoped Fe_2O_3 three values of Ea were calculated, first transition of $Fe_2O_3 \rightarrow Fe_3O_4$ give a value of 141.2 kJ mol^{-1}, second and third transition of $Fe_3O_4 \rightarrow$ FeO and FeO $\rightarrow$ Fe give Ea value of 82.5 kJ mol^{-1} and 100.3 kJ mol^{-1}, respectively.

Table 1. The E_a of Fe_2O_3 and Cr-Fe_2O_3 according to the transition phase

Sample	**E_a^I (kJ mol^{-1})**	**E_a^{II} (kJ mol^{-1})**	**E_a^{III} (kJ mol^{-1})**	**E_a^{IV} (kJ mol^{-1})**
	$Fe_2O_3 \rightarrow Fe_3O_4$	**$Fe_3O_4 \rightarrow FeO$**	**$FeO \rightarrow Fe$**	**$Fe_3O_4 \rightarrow Fe$**
Cr-Fe_2O_3	123.7	n.d.	n.d.	89.0
Fe_2O_3	141.2	82.5	100.3	n.d.

Note: n.d. = not detected.

Referring to Table 1, it has been seen that the activation energy for reduction steps of $Fe_2O_3 \rightarrow Fe_3O_4$ is higher compare to the other transition phases. The values were unpredicted but somehow was similar to the activation energy obtained by Munteanu et al. [13] for reduction of fresh α-Fe_2O_3 by 10% hydrogen in argon with the reduction steps of $Fe_2O_3 \rightarrow Fe_3O_4$ give 139.2 kJ mol^{-1} and $Fe_3O_4 \rightarrow$ FeO and FeO $\rightarrow$ Fe were 77.3 and 85.7 kJ mol^{-1}, respectively [13].

Conclusion

The kinetics and reduction behaviour of chromium doped Fe_2O_3 and undoped Fe_2O_3 were investigated and compared using TPR technique and characterized by XRD and BET. The data obtained from XRD evidenced the presence of well dispersed chromium particles loaded on the ferric oxide and promotes better crystallinity of the Fe_2O_3 leads to the effect on enhancing the reduction process by lowering the reduction temperature of Fe_2O_3 to metallic Fe which has been completed at 700 °C compare to undoped Fe_2O_3 (900 °C). The reducing path of ferric oxide was found to be dependent on the doped element as Cr doped ferric oxide favours complete reduction to metallic iron without formation of intermediate FeO. Thus, addition of chromium element give a two-steps reduction ($Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow$ metallic Fe) and undoped ferric oxide preferentially reduced through wüstite formation with three-steps reduction ($Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow FeO \rightarrow$ metallic Fe). Furthermore, better reducibility of Cr-Fe_2O_3 is also due to the higher in surface area and the decrease of the activation energy regarding to transition phases of $Fe_2O_3 \rightarrow Fe_3O_4$ during the reduction process by carbon monoxide compare to undoped one.

Abstract

Silica was extracted from power plant bottom ash by alkali fusion method and used to synthesize MCM-41 and SBA-15. As comparison, MCM-41 and SBA-15 were synthesized by using tetraethylorthosilicate (TEOS) as pure silica source. All synthesized MCM-41 and SBA-15 were characterized using X-ray Diffraction (XRD) and nitrogen adsorption to determine the formation of hexagonal pores, Field Emission Scanning Electron Micrograph (FESEM) was used to observe their morphology while Fourier Transform Infrared Spectroscopy (FTIR) was used to obtain the functional group and removal of surfactant after calcinations. XRD results confirmed bottom ash MCM-41 (BA MCM-41), pure SBA-15 (PSBA-15) and bottom ash SBA-15 (BA SBA-15) have well-ordered mesostructures. N_2 adsorption of pure MCM-41 (PMCM-41), PSBA-15 and BA SBA-15 indicated type IV isotherm while BA MCM-41 exhibit type III isotherm. According to FESEM analyses, the particle morphology of bottom ash mesoporous silica was different from those prepared using pure chemical. Morphology of PMCM-41 and PSBA-15 showed rod like particle while BA MCM-41 and BA SBA-15 exhibited agglomerated particle. PMCM-41, PSBA-15 and BA SBA-15 shows ordered hexagonal, high surface area and narrow pore distribution.

Keywords: mesoporous silica, MCM-41, SBA-15

Abstrak

Silika telah diekstrak daripada abu bawah loji janakuasa melalui kaedah gabungan alkali dan digunakan untuk sintesis MCM-41 dan SBA-15. Sebagai perbandingan, MCM-41 dan SBA-15 telah disintesis dengan menggunakan tetraetilortosilika (TEOS) sebagai sumber silika tulen. Semua MCM-41 dan SBA-15 yang telah disintesis dicirikan menggunakan kaedah pembelauan Sinar X (XRD) dan penjerapan nitrogen untuk menentukan pembentukan liang heksagon, mikroskopi elektron pengimbasan pancaran medan (FESEM) digunakan untuk memerhati morfologi manakala Spektroskopi Inframerah Tranformasi Fourier (FTIR) digunakan untuk mengenalpasti kumpulan berfungsi dan penyingkiran surfaktan selepas pengkalsinan. Keputusan XRD membuktikan debu MCM-41 (BA MCM-41), SBA-15 tulen (PSBA-15) dan debu SBA-15 (BA SBA-15) mempunyai mesostruktur yang teratur. Penjerapan N_2 oleh MCM-41 (PMCM-41), PSBA-15 dan BA SBA-15 menunjukkan isoterma jenis IV manakala isoterma jenis III bagi BA MCM-41. Berdasarkan analisis FESEM, morfologi zarah silika mesoporos daripada debu bawah loji janakuasa adalah berlainan berbanding yang disediakan menggunakan bahan kimia tulen. Morfologi PMCM-41 dan PSBA-15 menunjukkan zarah jenis rod manakala BA MCM-41 dan BA SBA-15 wujud sebagai zarah bercampur. PMCM-41, PSBA-15 dan BA SBA-15 mempunyai struktur heksagon yang seragam, luas permukaan yang tinggi dan taburan liang yang kecil.

Introduction

In year 1990s, the researchers of Mobil Corporation discovered MCM-41 molecular sieves can be synthesized by using an inorganic silicate species and organic template [1]. Tetraethylorthosilicate (TEOS) and sodium silicate (Na_2SiO_3) were the sources of silicon used by researchers to synthesize mesoporous silica [2]. The features of MCM-41 are high pore volume with large uniform pore size (14-100Å), high specific surface area which give advanced advantages over zeolites and have many applications in material sciences, chemistry and biology [3, 4]. MCM-41 exhibit hexagonal packed rod-shaped micelle structure, cubic shape for MCM-48 and MCM-50 in lamellar form [4]. The pore size of MCM-41 and MCM-48 can be controlled and widely used as an adsorbent, support and catalyst [5]. Santa Barbara Amorphous-15 (SBA-15) has same features as MCM-41 but their specific surface area and pore volume smaller than M41S materials with thicker pore walls [6]. Fly ash has a high recycling rate and can be use in various parts of recycling systems while 79 % of bottom ash thrown and only 21 % was used in asphalt or in construction. Researchers had considerable interest in conversion of coal bottom ash and fly ash into zeolites or mesoporous silica materials as MCM-41, MCM-48 and SBA-15 [7]. Recently preparation of mesoporous materials from natural waste such as coal fly ash have been reported [8 -11]. Limited reports have addressed in converting coal bottom ash into mesoporous silica [7, 12]. Chandrasekar et al. [12] synthesized mesoporous MCM-41, SBA-15 and SBA-16 from supernatant derived from coal bottom ash. They used additional sodium metasilicate in synthesis of SBA-15 and SBA-16.

In this country, there have been no reports thus far in synthesis of mesoporous silica using natural waste like coal bottom ash as silica source. This research aims to extract silica from lower grade bottom ash and mesoporous materials which are MCM-41 and SBA-15 were synthesized using extracted silica. Instead of using expensive reagent, a cheaper silica source can be used to minimize the high production cost of porous silica materials. Then the mesoporous materials were characterized by X-ray Diffraction (XRD), N_2 adsorption desorption, Field Emission Scanning Electron Micrograph (FESEM) and Fourier Transform Infrared Spectroscopy (FTIR) analyses

Materials and Methods

Chemicals and raw materials

All the chemicals used were commercial reagent grade and purchased from Merck and Sigma-Aldrich. Coal bottom ash was obtained from Tanjung Bin Power Plant in Pontian, Johor, Malaysia.

Alkali fusion and silicate extraction

Bottom ash was ground to powder with a mesh size of less than 200 μm by using a commercial mixing grinder. The finely ground ash was mix with NaOH powder at 1:1.2 weight ratio with the sample. The mixture of ash and NaOH was fused in a furnace at 550 $^{\circ}$C for one hour. The obtained fused mass was cooled to room temperature and ground again to obtain a fine powder with mesh size less than 100 μm. The fine powder of fused mixture was mixed with distilled water at 1:4 ratios and stirred for 24 hours. The solution was centrifuged and filtered. The supernatant will be used for the synthesis of mesoporous silica [12].

Synthesis of MCM-41

An amount 1.2 g of cetyltrimethylammonium bromide (CTABr) was dissolved in 15 g of water and 1.0 g of ammonium hydroxide (NH_4OH). The solution was stirred for 30 minutes. Next, 40 mL of bottom ash supernatant was slowly added to the homogeneous solution under stirring and stirring maintained for 2 hour. The synthesis pH was adjusted to 10 using dilute acetic acid. Then the stirring was continued for another 30 minutes. The gel product was heated in an oven at 100 $^{\circ}$C for 48 hours. The solid product was filtered, washed and dried at 100 $^{\circ}$C. The product was calcined at 550 $^{\circ}$C for 8 hours. For comparison, pure MCM-41 was synthesized by using TEOS as silica source same as previous procedure [12].

Synthesis of SBA-15

Template for synthesis of SBA-15 is amphiphilic triblock polymer of Pluronic P123 ($EO_{20}PO_{70}EO_{20}$). An amount 4.0 g of P123 was dissolved in 30 mL of deionised water and 120 mL of 2 M HCl and was stirred at 35 ^{0}C for 20 hours. Then, an amount 8.5 g of bottom ash supernatant was slowly added under vigorous stirring for 15 minutes. The mixture was kept under static conditions at the same temperature (35 $^{\circ}$C) for 20 hours. The milky mixture was

transferred to an oven at 90 °C for 24 hours. For comparison, a pure SBA-15 was synthesized by using TEOS as silica sources same as previous procedure. The solid products were filtered, washed and dried at 45 °C for 72 hours. The products were calcined at 500 °C for 6 hours [13].

Characterization studies

X-Ray Diffraction (XRD) patterns of the synthesized samples were determined by using Rigaku D/max-2500 powder diffractometer with Cu-Kα source (λ = 1.5418 Å, 40 kV, 40 mA). N_2 adsorption isotherm and BET surface area were obtained at 77K on a Micromeritics ASAP 2010 Volumetric Adsorption Analyzer. Carlzeiss Supra 40 VP Field Emission Scanning Electron Microscopy (FESEM) was used to characterize the particle size and morphology of mesoporous silica synthesized. Functional groups and removal of surfactant in samples were analyzed from FTIR spectra obtained by using Perkin-Elmer Spectrum One FTIR spectrometer.

Results and Discussion

X-Ray Diffraction (XRD*)*

The XRD pattern of bottom ash MCM-41 (BA MCM-41) (Figure 1a) exhibits an intense (100) signal and three higher order reflections of (110), (200) and (210) planes which confirm the sample is well-defined hexagonal MCM-41[14]. Pure SBA-15 (PSBA-15) in (b) shows three well resolved diffraction peaks which are corresponding to the (100), (110) and (200), indicating hexagonal symmetry with the *p6mm* space group. As a comparison, the XRD pattern of BA SBA-15 in (c) indexed an intense (100) peak while the other two peaks (110) and (200) were not resolved as well as those in pure SBA-15 [12, 15].

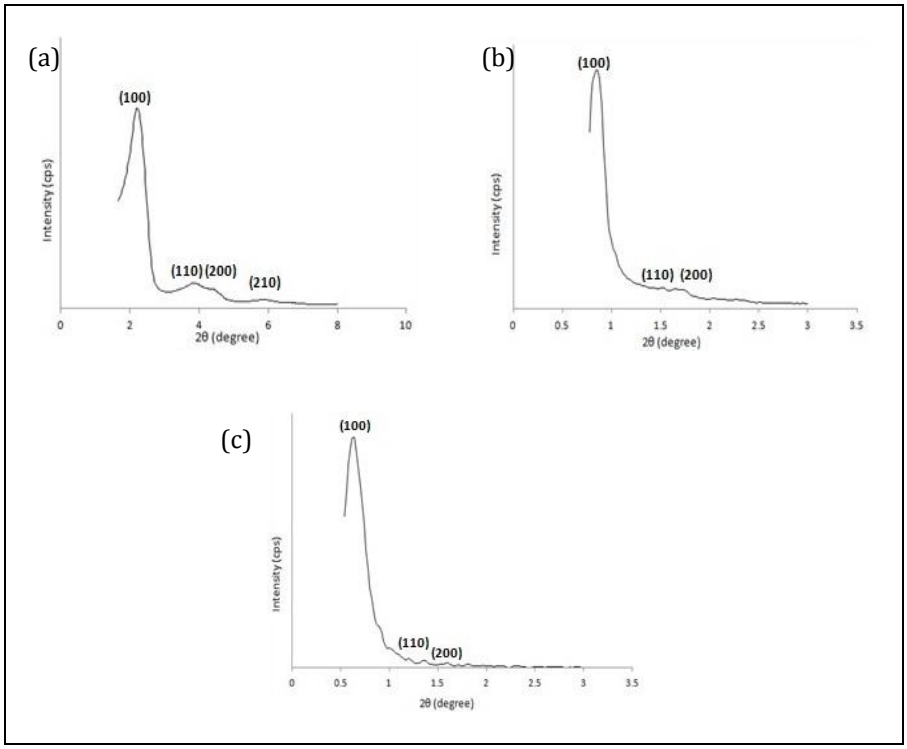

Figure 1. XRD patterns of (a) BA MCM-41, (b) PSBA-15 and (c) BA SBA-15

Nitrogen adsorption desorption

Figure 2 shows the nitrogen adsorption isotherms of calcined MCM-41 and SBA-15 synthesized from bottom ash and TEOS. PMCM-41 in (a) featured hysteresis loops with the sharp adsorption and desorption branches, which

exhibit type IV isotherm [16]. The adsorption branches of PMCM-41 located at P/P_0 from 0.4 to 0.5. Figure 2a inset shows the pore size distributions (PSDs) for PMCM-41 sample, indicate maxima of 47.75 Å. BA MCM-41 (Figure 2b) shows type III isotherm which attributed to the adsorption on macroporous materials [13]. Nitrogen isotherms for PSBA-15 (Figure 2c) and BA SBA-15 (Figure 2d) shows hysteresis loop at P/P_0 from 0.44 to 0.98 and 0.74 to 0.98 respectively. The both isotherms were similar to those reported in the literatures which are type IV. The sharpness of adsorption branches indicate the narrow pore size distribution[17]. Table 1 presents a summary of physicochemical of calcined mesoporous silica synthesized from bottom ash and pure chemical. The specific surface area (S_{BET}) of PMCM-41 was 561.39 m^2/g with a pore volume of 0.406 cm^3/g whereas the corresponding values of BA MCM-41 were 5.25 m^2/g and 0.00477 cm^3/g, respectively. PSBA-15 has 509.41 m^2/g surface area and 0.497 cm^3/g pore volume. The surface area and pore volume of BA SBA-15 decrease to 71.40 m^2/g and 0.204 cm^3/g respectively.

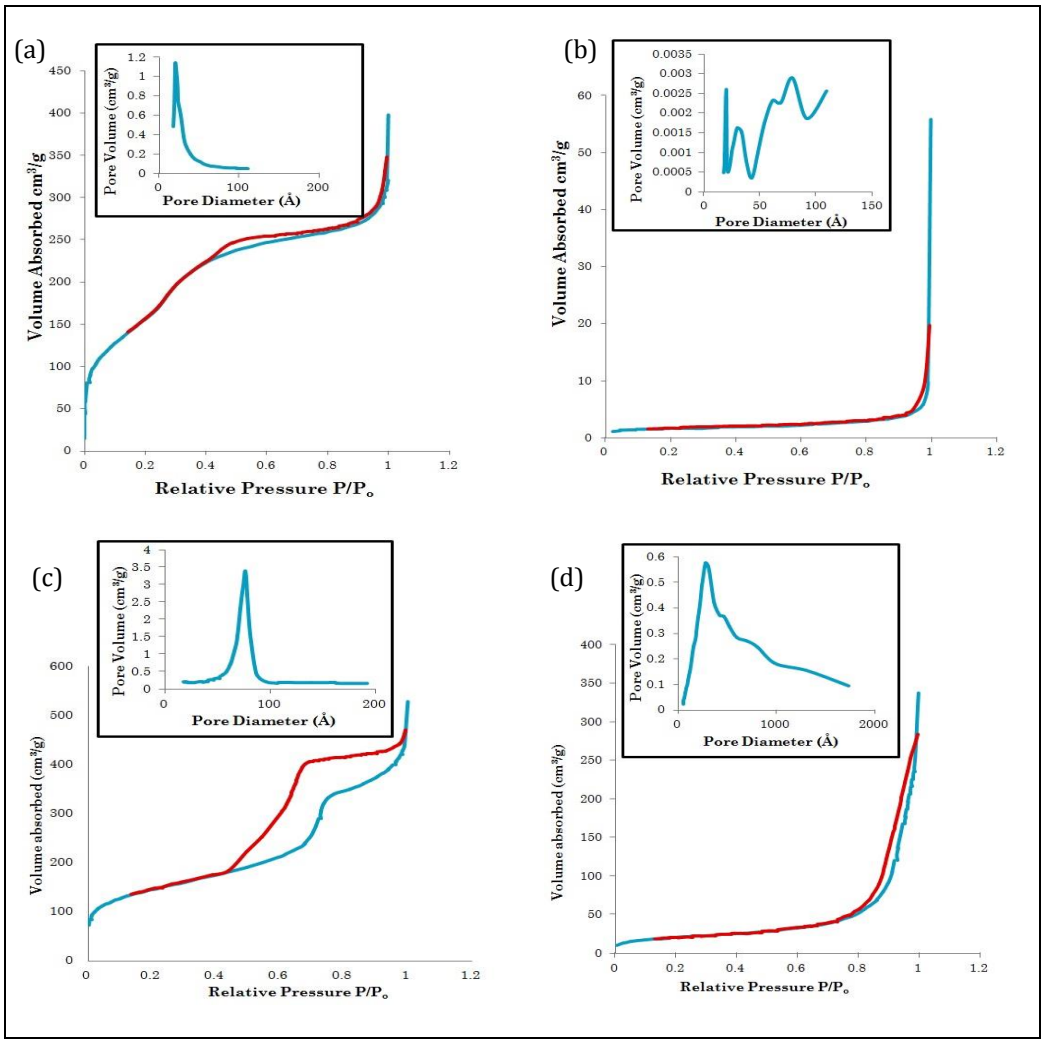

Figure 2. Nitrogen adsorption isotherms and pore size distributions (inset): (a) PMCM-41, (b) BA MCM-41, (c) PSBA-15 and (d) BA SBA-15

Table 1. Physicochemical of calcined mesoporous silica synthesized from bottom ash and pure chemical

Types of mesoporous silica	S_{BET} (m^2/g)	V_p (cm^3/g)	D_{pore} (Å)
PMCM-41	561.39	0.406	47.75
BA MCM-41	5.25	0.00477	1009.32
PSBA-15	509.41	0.497	84.71
BA SBA-15	71.40	0.204	315.65

Field Emission Scanning Electron Micrograph (FESEM)

Figure 3 displays the FESEM micrograph of all synthesized mesoporous silica materials. PMCM-41 (a) and PSBA-15 (c) shows rod like. Particle morphology of BA MCM-41 and BA SBA-15 exhibit agglomerated particles of 1 to 3 μm in diameter [16].

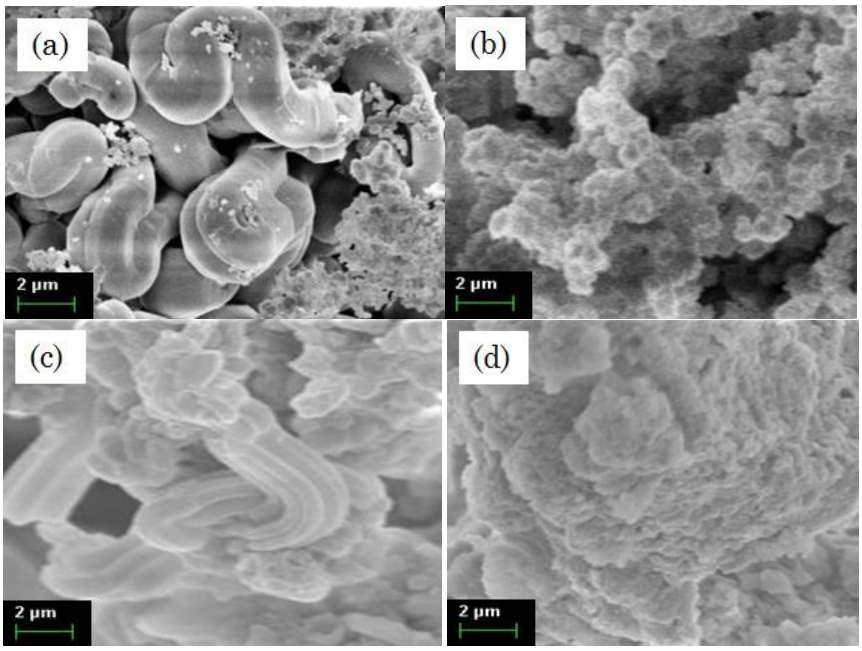

Figure 3. Morphology of: (a) PMCM-41, (b) BA MCM-41, (c) PSBA-15 and (d) BA SBA-15

Fourier Transform Infrared (FTIR)

The infrared spectrum of synthesized materials in the region of 4000 – 400 cm^{-1} recorded at ambient condition with KBr technique shown in Figure 4 (a) and (b), respectively. For calcined MCM-41 (Figure 4a: (ii), (iv)) and calcined SBA-15 (Figure 4b: (ii), (iv)), the bands around 2920 cm^{-1} and 2850 cm^{-1} assigned for the long chain of alkyl group of surfactant molecules were disappeared after calcinations due to the removal of surfactants. The FTIR spectra of MCM-41 and SBA-15 shows the intense bands at 1097.43 - 1067.25 cm^{-1} attributes for asymmetric stretching Si-O-Si bonds while 806.63 – 792.92 cm^{-1} bands indicates the symmetric stretching Si-O-Si bonds. The bands at 965.75 – 941.68 cm^{-1} and 474.69 – 466.46 cm^{-1} accounts for the stretching and bending vibrations of surface $Si\text{-}O^-$ groups [18].

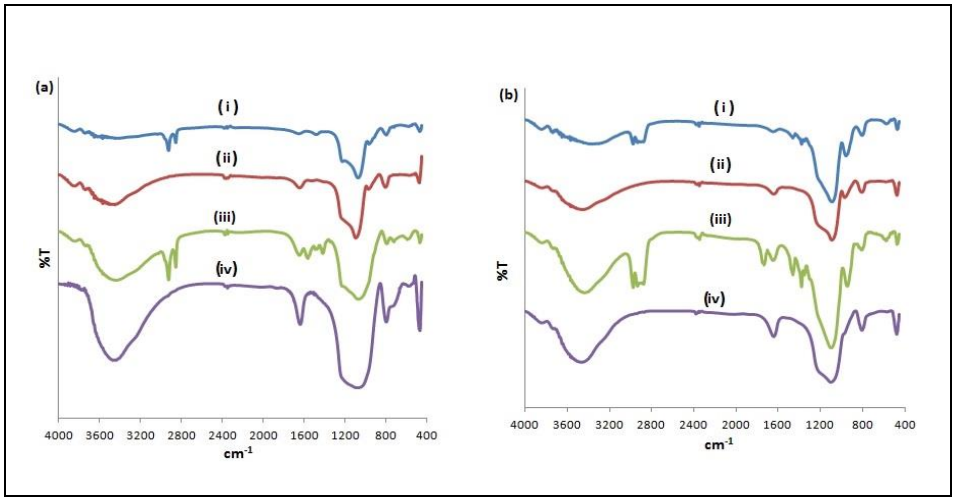

Figure 4. (a) IR spectra of MCM-41: (i) Uncalcined PMCM-41, (ii) Calcined PMCM-41, (iii) Uncalcined BA MCM-41 and (iv) Calcined BA MCM-41; and (b) IR spectra of SBA-15: (i) Uncalcined PSBA-15, (ii) Calcined PSBA-15, (iii) Uncalcined BA SBA-15 and (iv) Calcined BA SBA-15.

Conclusion

Characterization results indicated PMCM-41, PSBA-15 and BA SBA-15 were successfully synthesized. They exhibited ordered hexagonal, high surface area and narrow pore distributions. According to N_2 adsorption desorption analyses, the porous structure of BA MCM-41 was destroyed after calcinations. The synthesis of SBA-15 by using silica source from bottom ash supernatant was better than MCM-41. MCM-41 and SBA-15 synthesized from pure chemical was superior compared to those syntheses from bottom ash supernatant.

Acknowledgement

The authors would like to thank the Ministry of Higher Education (MOHE) for financing the project under the Fundamental Research Grant Scheme no: 600-RMI/FRGS 5/3 (59/2013). Special thanks to Tanjung Bin Power Plant Pontian Johor for the supplied coal bottom ash and highly appreciation to Faculty of Applied Sciences and Faculty of Pharmacy Universiti Teknologi MARA (UiTM) for facilities in completing this research.

Abstract

The stem barks of *Mallotus leucodermis* Hook F. (Euphorbiaceae) was studied for its chemical constituents. The air dried and pulverized of stem bark of *M. leucodermis* (1.3 kg) was extracted successively with acetone for three days at room temperature yielding 66.0 g of crude extract. The crude extract was fractionated using vacuum liquid chromatography (VLC) to afford six fractions. Fraction 6 was further washed and recrystallized to afford bergenin (1). Fraction 3 was subjected to multiple purification using radial chromatography ($CHCl_3$: acetone) with different ratio 9:1, 8:2, 6:4 and 5:5 to yield a flavonoid compound, epicatechin (2). These compounds were elucidated based on spectroscopic analysis (Ultra Violate, Infra-Red, Mass Spectrometry and Nuclear Magnetic Resonance) as well as comparison with literatures.

Keywords: Euphorbiaceae, *Mallotus*, bergenin, epicatechin

Abstrak

Kulit ranting *Mallotus leucodermis* Hook F. (Euphorbicaeae) telah dikaji untuk sebatian kimianya. Kulit ranting *M. leucodermis* (1.3 kg) yang telah dikeringkan dan dikisar, direndamkan dalam aseton selama tiga hari pada suhu bilik bagi memperolehi 66.0 g bahan ekstrak. Fraksinasi telah dilakukan ke atas ekstrak tersebut dgn menggunakan hampagas kromatografi cecair dan menghasilkan enam fraksi. Fraksi 6 telah dicuci beberapa kali dan dihablurkan semula untuk menghasilkan bergenin (1). Manakala fraksi 3 ditulenkan beberapa kali menggunakan radial kromatografi untuk mendapatkan sebatian flavonoid, epicatechin (2). Dua sebatian tulen ini dikenal pasti berdasarkan analisis spektroskopi (Ultralembayung, Inframerah, Spektrometri Jisim and Resonans Magnet Nukleus) dan juga perbandingan data.

Kata kunci: Euphorbiaceae, *Mallotus*, bergenin, epicatechin

Introduction

Mallotus leucodermis Hook F., is a species under genus of *Mallotus* from Euphorbiaceae family. Euphorbiaceae is also commonly known as spurge family. The family of Euphorbiaceae consists of 283 genera and 7300 species which have been distributed in tropical region around the world. The main genus of Eurphobiaceae family consist of *Euphorbia*, *Phyllantus*, *Mallotus*, *Macaranga* and many more [1]. *Mallotus* is a genus of shrubs, trees and climbers with approximately 150 species were distributed in tropical and sub-tropical regions of Asia [2]. The genus of *Mallotus* belongs to the Malphighiales order, the Euphorbiaceae family, Acalyphoideae subfamily, Acalypeae pro parte and Rotterinae subtribe [3]. Research on *Mallotus* species revealed that this genus were very rich with active

compounds such as flavonoids, phenolic compounds, terpenoids and phloroglucinol derivatives [5]. Moreover, the pharmaceutical research has found that some of chemical constituents of *Mallotus* have the capability to possess several biological activities such as antioxidant, anti-inflammatory, antimicrobial, antiviral, cytotoxic and antitumor activities [3]. Therefore, the outcomes from this study will improve and enhance the application of natural product in the development of drug discovery.

Some species of the genus of *Mallotus* in Malaysia are used as traditional medicines. The roots of *M. paniculatus* are boiled and drunk after child birth, the leaves of *M. macrostachyus* are used as an antidote against snake poison whereas the roots and fruits of *M. barbatus* are used against muscle stiffness [2]. *Mallotus leucodermis* Hook f., is also commonly known as "balik angin bopeng" in Malaysia, is used to treat skin complaints [4]. In this study, two compounds namely bergenin (1) and epicatechin (2) have been isolated from the stem bark of *Mallotus leucodermis*. The structure elucidation of these two compounds will be discussed according to NMR (1D and 2D) analysis and also by the comparison with the literature data.

Materials and Methods

Chemicals and plant materials

The industrial grade solvent was used for extraction of sample while the analytical grade solvents such as acetone, chloroform ($CHCl_3$), ethyl acetate (Ea), hexane (Hex), and methanol (MeOH), were used in the isolation and purification of compounds. The stem bark of *M. leucodermis* Hook f., was collected from Kuala Keniam, Pahang National Park.

Extraction procedure

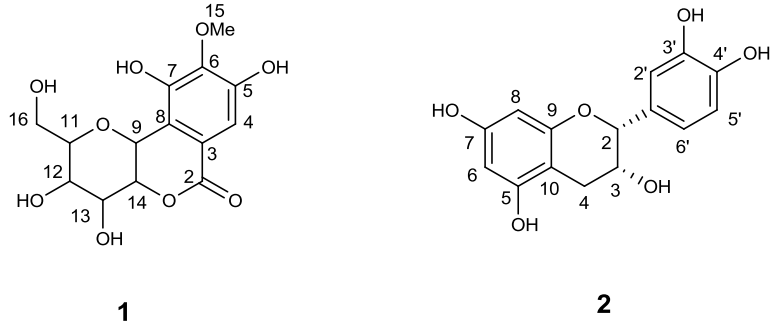
Air dried and pulverized stem bark of *M. leucodermis* (1.3 kg) was successively extracted with 95 % acetone for 72 hours at room temperature. The extract was then filtered and evaporated to dryness under reduced pressure using rotary evaporator. The maceration was repeated three times to obtain optimum yield of crude extract. The crude extract (124.6 g) was subjected to removal of tannin by using diethyl ether yielded less tannin crude extract 67.8 g.

Fractionation and isolation

The crude extract was subjected to vacuum liquid chromatography (VLC) over silica gel eluted with hexane: ethyl acetate (3:7 – 1:9) and $CHCl_3$: acetone (7:3 – 3:7) to yield several fractions. All fractions were spotted on thin layer chromatography (TLC) plate and the similar patterns of separation were combined together into six fractions (F1 – F6). The last fraction from VLC was further purified by repeated washing using acetone and methanol to give white crystal ML1 (0.66 g). Fraction 3 (800 mg) was then subjected to radial chromatography on silica coated plate with $CHCl_3$: acetone (9:1 – 5:5) to give seven subfractions. Subfraction 7 (F3.7) was further purified by radial chromatography (RC) using $CHCl_3$: acetone (8:2, 6:4, 5:5) and washing method to give ML2 (17 mg).

Structure elucidation

The pure compounds were identified by using NMR spectroscopy on a Bruker AC 300 instrument, UV-Vis spectrophotometer, Infra-red, FTIR and gas chromatography – mass spectrometry, GC-MS. The spectra were measured on the spectrometers. Structures identified after analysis of the data obtained from spectra.



Results and Discussion

Structural elucidation of isolated compounds

The isolated compounds were characterized and identified via 1D and 2D NMR spectroscopy and by comparison with literature data. The structures of these pure compounds were shown in Figure 1.

The pure compound ML1 is a white crystals, isolated from VLC and recrystallized in methanol. Compound ML1 gave a $[M]^+$ at m/z 328 in the EI-mass spectrum, which corresponds to the molecular formula $C_{14}H_{16}O_9$. The melting point for this compound is consistent with the reported melting point of bergenin which is 236 – 238 °C [6]. The ^{1}H NMR spectrum showed a signal for an aromatic proton at δ_H 6.99 (1H, s) and a signal for methoxy protons at δ_H 3.77 (3H, s). The ^{13}C APT spectrum showed the total of 14 resonances representing 14 carbons. The carbonyl group signal appeared at downfield region, δ 163.8 (C-2) whereas the signal for methoxy carbon appeared at δ 60.3 (C-15). The methylene carbon (C-16) showed a signal at δ_C 61.5 while the five peaks of methine carbons in glucose

ring appeared at δ_C 71.3 (C-12), 72.5 (C-9), 74.1 (C-13), 80.2 (C-14) and 82.2 (C-11). Table 1 summarised the ^1H and ^{13}C NMR data for ML1 in comparison with the literature data. Based on the spectral data and comparison with literature [7] and [8], ML1 was determined to be a bergenin.

1 **2**

Figure 1. Structure of isolated compounds (1) bergenin and (2) epicatechin

Bergenin is a colourless crystalline polyphenol, which contains five hydroxyl groups that played an important role in its pharmacological activity [5]. This compound is reported in literature to exhibit various biological activities such as antifungal, antiulcer, burn wound healing effects and also immunomodulatory [6]. Bergenin was previously isolated from *Mallotus philippinensis*, *Mallotus japonicus*, and *Bergenial crassifolia* [5].

* ^1H (400 MHz, DMSO-d_6) [7]
**^{13}C (500 MHz, CD_3OD-d_4) [8]

The pure compound ML2 was obtained as yellow powder, after several purification using RC eluted with $CHCl_3$: acetone (9:1 – 5:5). Compound ML2 gave a $[M]^+$ at m/z 313.2 in the EIMS, corresponding to the molecular formula $C_{15}H_{14}O_6$. The melting point obtained 224-226 °C which is acceptable with the literature melting point of epicatechin [9]. The 1H NMR spectrum showed a broad singlet peak at δ_H 4.88 (1H, s, H-2) which indicate a cis-orientation between H-2 and H-3. An ABD system was observed at region by protons at δ_H 6.81 (d_o), 6.83 (d_m) and 7.06 (dd). The spectrum also revealed two doublets at δ_H 6.04 (H-8) and δ_H 5.93 (H-6) which were indicated as proton with meta-subtitution in ring A. The ^{13}C APT spectrum showed the total of 15 resonances representing 15 carbons. The methylene carbon (C-4) showed a signal at very upfield region at δ_C 28.1 whereas the signal at δ_C 78.5 represents C-2. The total of seven signals of quarternary carbons at δ_C 157.0, 157.2, 156.6, 99.6, 131.7, 144.9 and 145.1 representing as C-5, C-7, C-9, C-10, C-1', C-3', and C-4', respectively.

Table 2 summarized the ^1H and ^{13}C NMR data for ML2 in comparison with the literature data. Based on the spectral data and comparison with literature [10], ML2 was confirmed to be an epicatechin. Epicatechin is a flavan-3-ol, a type of natural phenol and antioxidant. It belongs to the family of flavonoids. This major flavanol in food is known to possess antioxidant, antiulcer and anti-inflammatory [7].

Spectroscopic data

Bergenin (**1**): $C_{14}H_{16}O_9$, white crystals (0.66 g), m.p 236-238 °C. ESI-MS (positive mode) m/z 328.0 $[M+Na]^+$. ^1H NMR (DMSO-d_6, 300 MHz) δ: 3.22 (1H, ddd, J=8.1 Hz, 5.1 Hz, H-12), 3.58 (1H, t, J=8.1 Hz, H-11), 3.67 (1H, ddd, J=5.4Hz, 3.3Hz, 5.4Hz, H-13), 3.77 (3H, s, OCH_3), 3.83 (1H, dd, J=10.8Hz, H-16), 4.00 (1H, dd, J=10.2Hz, 9.6Hz, H-14), 4.98 (1H, d, J=10.5Hz, H-9), 6.99 (1H, s, H-4). 13C NMR (DMSO-d_6, 300 MHz) δ: 163.8 (C-2), 151.4 (C-5), 148.5 (C-7), 141.0 (C-6), 118.5 (C-3), 116.4 (C-8), 109.9 (C-4), 82.2 (C-11), 80.2 (C-14), 74.1 (C-13), 72.5 (C-9), 71,1 (C-12), 60.3 (C-15), 61.5 (C-16).

Epicatechin (**2**): $C_{15}H_{14}O_6$, yellowish powder (17 mg), m.p. 224-226 °C. ESI-MS (positive mode) m/z 313.2 $[M+Na]^+$, 291.2 $[M+H]^+$. ^{1}H NMR (Acetone-d_6, 300MHz) δ: 2.72 (1H, dd, J= 16.5 Hz, 3.6 Hz, H-4β), 2.89 (1H, dd, J= 16.5 Hz, 4.5 Hz, H-4α), 4.21 (1H, m, H-3), 4.88 (1H, s, H-2), 5.93 (1H, d, J= 1.2 Hz, H-6), 6.04 (1H, d, J= 1.5 Hz, H-8), 6.83 (2H, m, H-5', H-6'), 7.06 (1H, s, H-2'). ^{13}C NMR (Acetone-d_6, 300MHz) δ: 28.5 (C-4), 66.6 (C-3), 79.1 (C-2), 95.4 (C-8), 96.1 (C-7), 99.6 (C-10), 115.1 (C-2'), 115.5 (C-5'), 119.1 (C-6'), 131.2 (C-1'), 144.9 (C-3'), 145 (C-4'), 156.6 (C-9), 157.0 (C-5), 157.2 (C-7).

Conclusion

The isolation and identification of bergenin (**1**) and epicatechin (**2**) from the stem bark of *Mallotus leucodermis* Hook f., was the first ever to be reported from this plants. These compounds were elucidated based on spectroscopic analysis (UV-Vis, Infra-Red, Mass Spectra and Nuclear Magnetic Resonance) as well as comparison with literatures.

Acknowledgement

The authors would like to thank Professor Dr Mohd Nazip Suratman, the botanist and lecturer from Universiti Teknologi MARA Shah Alam for his contribution in identifying the plant species. The authors are also grateful to Faculty of Applied Sciences (UiTM) for providing lab facility during this study.

FITTING STATISTICAL DISTRIBUTIONS FUNCTIONS ON OZONE CONCENTRATION DATA AT COASTAL AREAS

(Penyesuaian Fungsi Taburan Statistik pada Data Kepekatan Ozon di Kawasan Pesisiran Pantai)

Abstract

Ozone is known as one of the pollutant that contributes to the air pollution problem. Therefore, it is important to carry out the study on ozone. The objective of this study is to find the best statistical distribution for ozone concentration. There are three distributions namely Inverse Gaussian, Weibull and Lognormal were chosen to fit one year hourly average ozone concentration data in 2010 at Port Dickson and Port Klang. Maximum likelihood estimation (MLE) method was used to estimate the parameters to develop the probability density function (PDF) graph and cumulative density function (CDF) graph. Three performance indicators (PI) that are normalized absolute error (NAE), prediction accuracy (PA), and coefficient of determination (R^2) were used to determine the goodness-of-fit criteria of the distribution. Result shows that Weibull distribution is the best distribution with the smallest error measure value (NAE) at Port Klang and Port Dickson is 0.08 and 0.31, respectively. The best score for highest adequacy measure (PA: 0.99) with the value of R^2 is 0.98 (Port Klang) and 0.99 (Port Dickson). These results provide useful information to local authorities for prediction purpose.

Keywords: ozone concentration, coastal area, statistical distributions, goodness-of-fit, performance indicator

Abstrak

Ozon merupakan salah satu pencemar yang banyak menyumbang kepada masalah pencemaran udara. Maka kajian tentang ozon adalah penting untuk dijalankan. Objektif kajian ini adalah mencari taburan statistik yang terbaik untuk mewakili data kepekatan ozon. Tiga fungsi taburan yang digunakan dalam kajian ini adalah Gaussian songsang, Weibull dan Lognormal telah dipilih bagi menentukan taburan statistik yang terbaik untuk mewakili data taburan ozon per jam pada tahun 2010 di Port Dickson dan Port Klang. Kaedah penganggar kebolehjadian maksimum (MLE) telah digunakan untuk mengira parameter yang membentuk graf fungsi taburan kebarangkalian (PDF) dan fungsi taburan kumulatif (CDF). Tiga penunjuk prestasi (PI) iaitu ralat mutlak dinormalkan (NAE), kejituan ramalan (PA) dan pekali penentuan (R^2) telah digunakan untuk menguji prestasi kriteria taburan yang terbaik. Hasil kajian menunjukkan taburan Weibull adalah yang terbaik untuk mewakili data kepekatan ozon dengan nilai ukuran ralat terkecil (NAE) di Port Klang dan Port Dickson masing-masing ialah 0.08 dan 0.031. Skor terbaik juga terhasil untuk pengiraan kejituan tertinggi (PA: 0.99) dengan nilai R^2 di kedua-dua tempat ialah 0.98 (Port Klang) dan 0.99 (Port Dickson). Hasil kajian ini membekalkan maklumat penting kepada penguatkuasa tempatan untuk tujuan ramalan kepekatan pada masa akan datang.

Kata kunci: Kepekatan ozon, pesisir pantai, taburan statistik, penyesuaian terbaik, penunjuk prestasi

Introduction

Ozone is one of air pollutant that exists in the atmosphere. Ozone is known as strong photochemical oxidants and one of the major problems originating from air pollution in urban areas [1]. Ozone formation at ground level was

originated by the ozone precursor which is Nitrogen oxides (NO_x) and Volatile Organic Compounds (VOC_s) has comes mainly from vehicles emission. The ozone concentration trend change when the emissions of its precursor change [2]. The ozone concentration that exists at ground level may be harmful to living organism especially human. Ozone was also known as the major contributing factor on chronic disease and mortality [3].

Ozone was expected to be existing at coastal site by the influence of the geographical structure of the site and others parameters. These secondary pollutants were affected by the continental and maritime wind as well as the sea breeze [4,5]. The diurnal ozone coastal has been investigated by Nair et al. [6], state that the ozone mixing ratio increase during early morning and reach maximum at 1100 hour and start decreasing after 1600 hour. However, the pattern has secondary peak appearing about 1900 hour shows the ozone is closely associate with the circulation pattern from sea-breeze to land breeze. Other studies found that ship emission also give a significant impact to the ozone flocculation. The impact of ships emission to ozone concentration at coastal site up to 15 ppb and about 5 ppb at location 2 km from that coastal site [7]. Hence, this study of ozone concentration is important to predict ozone exceedances to assess and monitor the air quality.

There are many statistical approaches used to study the ozone concentration such as probability distribution, multiple linear regression and artificial intelligence. Among that, probability distribution has been widely used by researcher to predict the air pollutant concentration [8,9]. This study will focus on three distributions namely Lognormal, Weibull and inverse Gaussian distribution for prediction purposes. Those distributions being used for certain parameter to form their own shape and characteristic [10]. These parameters were commonly determined by using few techniques such as maximum likelihood estimator (MLE), method of moment (MOM) and least square error. However, MLE method is preferable in parameter estimation cause its efficiency and good theoretical properties [11].

The two-parameter Weibull distribution (scale (σ) and shape (λ)) is widely used in data analysis because of its flexibility in modeling. There are numerous papers and books dealing with various aspects of Weibull modeling, inference, applications, as well as parameter estimation [12]. The others competitor of Weibull distribution is Lognormal distribution which also good in most cases significant fit in seasonal and meteorological characterizations of daily data [13]. It was known that 2-parameter log-normal distribution (location (μ) and scale (σ)) give the best description of annual mean daily sulphur dioxide concentration for a wide range of ambient level. The others competitor of the Weibull and Log-normal distribution in modelling asymmetric data from various scientific fields is Inverse Gaussian distribution. In reliability and life testing, the inverse Gaussian distribution is particularly useful in situations where early failures dominate [14]. Inverse Gaussian consists of two identical parameters which is location (μ) parameter and scale (σ) parameter. It is a two-parameter family of continuous probability distribution [15].

The first aim of this study is to determine the goodness-of-best fit distribution data representing ozone concentration by using distribution function method. The second aim of this study is to determine the best distribution for ozone concentration level at Port Dickson and Port Klang by using three performance indicators namely normalized absolute error (NAE), prediction accuracy (PA), and coefficient of determination (R^2).

Materials and Methods

Study area

Two sites were selected for this study, Port Dickson and Port Klang as illustrated in Figure 1.

Site 1 (Port Dickson) is located 1 km from sea and it has large contributions to the local economy in oil and gas sector. It has two refineries that have been operating by Shell Refining and Petron Company which expected to contribute with air pollution problem. According to Department of Environment Malaysia (DoE) [16], Port Dickson was recorded 7 days unhealthy during 2012 which means that the air quality in Port Dickson needs to be investigated. Site 2 (Port Klang) has the main business in marine-based activity. A lot of ships docked here for export and import purposes. Highly shipping emission and traffic congestions were observed here due to truck involvement was expected to trigger the ozone formation, thus lead to high ozone concentration. Malaysian

Department of Environment (DOE) [16] stated that Port Klang had 13 unhealthy days on 2012 which represents third highest in Klang Valley based from the annual Environment Quality Report.

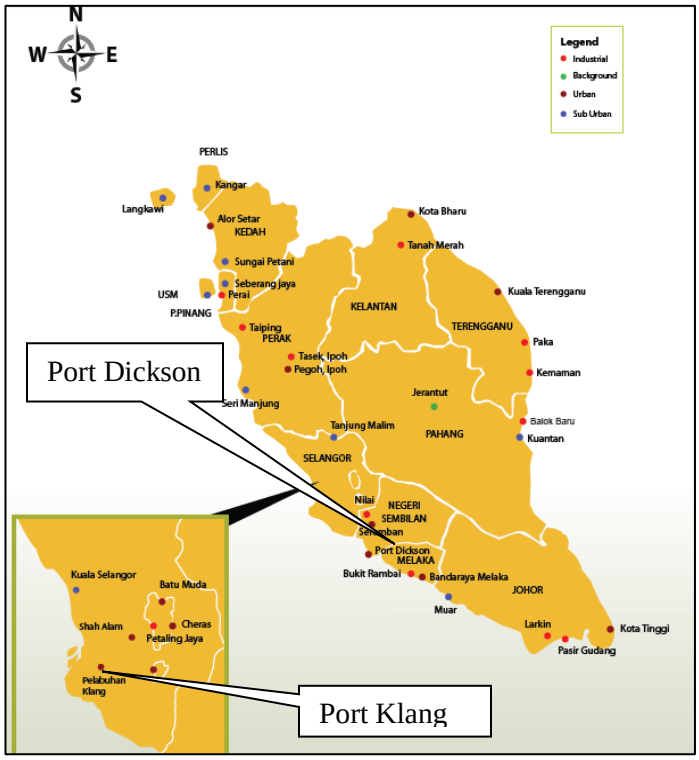

Figure 1. Description of the selected study area (Source: EQR 2012).

Probability distribution

Probability distribution is mathematical form to construct theoretical and idealization of real data set [17]. The probability density function (PDF) and cumulative density function (CDF) were used to estimate the probability of the exceedences of ozone based on Malaysian Ambient Air Quality Guideline (MAAQG). The PDF plot was used to identify the skewness of the distribution and it plot by using the value of parameter estimation [18]. The derivation of PDF was used for prediction of exceedences [19] and the CDF was used to determine the probability of air pollutant concentration [20]. Table 1 shows the PDF and the parameter estimation used [21].

Weibull distribution

The formula used for parameter estimation that was given by Lu [9]:

$$f(x) = \left(\frac{\lambda}{\sigma}\right)\left(\frac{x}{\sigma}\right)^{\lambda-1} \exp\left[-\left(\frac{x}{\sigma}\right)^{\lambda}\right]$$

The cumulative distribution function takes the form as

$$F(x) = 1 - \exp\left[-\left(\frac{x}{\beta}\right)^{\alpha}\right]$$

where $x \geq 0$, α = shape parameter, β = scale parameter.

β was obtain by

$$\frac{\left(\sum_{i=1}^{n}(x_i^{\sigma}\ln x_i)\right)}{\left(\sum_{i=1}^{n}x_i^{\sigma}\right)}-\left(\frac{1}{\sigma}\right)-\left(\frac{1}{n}\right)\left(\sum_{i=1}^{n}\ln x_i\right)=0$$

and α was then calculated using following equation

$$\lambda=\left(\frac{1}{n}\sum_{i=1}^{n}x_i^{\hat{x}}\right)^{\frac{1}{\sigma}}$$

Table 1. Probability density function and its parameter estimates

Distribution	Probability Density Function	Parameter Estimates
Weibull	$f(x)=\left(\frac{\lambda}{\sigma}\right)\left(\frac{x}{\sigma}\right)^{\lambda-1}\exp\left[-\left(\frac{x}{\sigma}\right)^{\lambda}\right]$	$\frac{\left(\sum_{i=1}^{n}(x_i^{\sigma}\ln x_i)\right)}{\left(\sum_{i=1}^{n}x_i^{\sigma}\right)}-\left(\frac{1}{\sigma}\right)-\left(\frac{1}{n}\right)\left(\sum_{i=1}^{n}\ln x_i\right)=0$; $\lambda=\left(\frac{1}{n}\sum_{i=1}^{n}x_i^{\hat{x}}\right)^{\frac{1}{\sigma}}$
gnormal	$f(x)=\frac{1}{x\lambda\sqrt{2\Pi}}\exp\left[-\frac{1}{2}\left(\frac{\ln(x)-\sigma}{\lambda}\right)^2\right]$	$\sigma=\frac{1}{n}\sum_{i=1}^{n}\ln(x_i)$; $\mu=\sqrt{\frac{1}{n}\sum_{i=1}^{n}[\ln(x_i)-\sigma]}$
Inverse gaussian	$\left(\frac{\sigma}{2\pi x^3}\right)^{\frac{1}{2}}\exp(-\frac{\sigma(x-\mu)^2}{2\mu^2 x})$	$\mu=\bar{x}$; $\sigma=\frac{n-1}{\sum_{i=1}^{n}\left(\frac{1}{x_i}-\frac{1}{\bar{x}}\right)}$

*μ is the location parameter, σ is the scale parameter, λ is the shape parameter, n is the total number of data

Lognormal Distribution

Lognormal was used to fit the ozone concentration data. Lognormal distribution with probability density function is given by Lu [9]:

$$f(x)=\frac{1}{x\lambda\sqrt{2\Pi}}\exp\left[-\frac{1}{2}\left(\frac{\ln(x)-\sigma}{\lambda}\right)^2\right]$$

The cumulative density function form for normal distribution is

$$f(x)=\frac{1}{2\Pi}\int_{-\infty}^{\frac{\ln(x)-\sigma}{\alpha}}e^{-\frac{x^2}{2}}\,dt$$

σ is obtain by solution below

$$\sigma=\frac{1}{n}\sum_{i=1}^{n}\ln(x_i)$$

and α by using solution below

$$\lambda = \sqrt{\frac{1}{n}\sum_{i=1}^{n}[\ln(x_i) - \sigma]}$$

Inverse Gaussian distribution
The probability density function (pdf) for Inverse Gaussian distribution given by Tweedie [15] is:

$$\left(\frac{\sigma}{2\pi x^3}\right)^{\frac{1}{2}} \exp\left(-\frac{\sigma(x-\mu)^2}{2\mu^2 x}\right)$$

where λ is scale parameter and μ is location parameter. The parameter estimation used is:

$$\sigma = \frac{n-1}{\sum_{i=1}^{n}\left(\frac{1}{x_i} - \frac{1}{\bar{x}}\right)}$$

for shape parameter, and

$$\mu = \bar{x}$$

for location parameter.

Performance indicator
The performance indicators used for this study were NAE, PA, and R^2 to identify the best distribution. The best distribution were selected by range of value that closest to 1 for adequacy measure (PA and R^2) and the value closest to zero for error measure (NAE). Table 2 shows three equations used for the performance indicator [22].

Table 2. Performance indicator equation

Indicators	**Equation**
Normalize absolute error	$\frac{\sum_{i=1}^{n} Abs(P_i - O_i)}{\sum_{i=1}^{n} O_i}$
Prediction of accuracy	$\frac{\sum_{i=1}^{N}(P_i - \bar{O})^2}{\sum_{i=1}^{N}(O_i - \bar{O})^2}$
Coefficient of determination	$\left(\frac{\sum_{i=1}^{N}(P_i - \bar{P})(O_i - \bar{O})}{NS_{pred}S_{obs}}\right)^2$

* N = Number of observations, P_i = Predicted values, O_i = Observed values, $\bar{P}$ = Mean of the predicted values, $\bar{O}$ = Mean of the observed values, S_{pred} = Standard deviation of the predicted values, S_{obs} = Standard deviation of the observed values

Results and Discussion

Ozone concentration data

The ozone concentration data collected over a year period 2010 from January to December by DOE Malaysia and managed by private company Alam Sekitar Malaysia Sdn Bhd (ASMA). The ozone concentration was measured by ASMA using Teledyne Ozone Analyzer Model 400 A UV Absorption [23]. The data was collected every hour and the unit measurement is part per million (ppm). All descriptive statistic ozone concentration for Port Klang and Port Dickson is run by using IBM SPSS statistic 20 analytical and MATLAB r2014a computational software. Table 3 is the descriptive statistic of ozone concentration result from the software used in this study.

Table 3. Descriptive statistics of ozone concentrations

Descriptive	Port Klang (ppm)	Port Dickson (ppm)
Maximum	0.123	0.140
Mean	0.020	0.026
Median	0.014	0.022
Standard Deviation	0.018	0.019
Skewness	1.321	1.013

From Table 3, the maximum value of ozone concentration recorded in Port Dickson was higher than Port Klang. However, measurements at both sites were exceeding the MAAQG (0.1ppm). The mean value of both sites was greater than median indicated there was high concentration recorded during period of study. The result also shows positively skewed to the right for Port Klang (sk = 1.321) and Port Dickson (sk = 1.013) explicate that the right tails of data is longer and higher concentration has been occurred.

Parameter estimation

Table 4 shows the parameter estimation values for Port Dickson and Port Klang, respectively. From the table, the shape parameter (λ) is higher than scale parameter (σ) for Weibull distributions indicate higher ozone concentration has occurred at both sites. The Lognormal parameter shows higher ozone concentration has occured which indicate by the scale parameter (σ) is higher than location parameter (μ). The inverse Gaussian parameter also show the location or mean parameter (μ) is higher than shape parameter (λ) which indicates high ozone concentration was occurred during this period.

Table 4. Parameter estimation for Port Dickson and Port Klang

Distribution	Site	Parameter	
Weibull	Port Dickson	σ= 0.029	λ= 1.418
	Port Klang	σ= 0.021	λ= 1.098
Lognormal	Port Dickson	μ= -3.963	σ= 0.901
	Port Klang	μ= -4.386	σ= 1.036
Inverse Gaussian	Port Dickson	μ= 0.026	λ= 0.019
	Port Klang	μ= 0.020	λ= 0.012

The location parameter (μ), the scale parameter (σ) is the shape parameter, λ.

Probability distribution graph

From the parameter estimation, the CDF graph can be plotted to estimate goodness-of-fit of data. CDF graph for all distribution used were plotted to determine the best goodness-of-fit and the result were found to be Weibull distribution. Figure 2, shows the Weibull CDF plot of Port Dickson and Port Klang, respectively. The observation line was underestimates at approximately 0.038 ppm before it fitted again with theoretical line between 0.04 ppm and 0.06 ppm for Port Dickson site. Meanwhile, observation line was overestimates at 0.08 until 0.02 ppm then underestimate between 0.02 ppm and 0.06 ppm before it fitted again with theoretical line at 0.07 ppm for Port Klang site. Figure 3 shows the PDF plot of Weibull distribution depicted as it skewed to the right. The result also showed that the mode for Port Dickson site is approximately about 0.012 ppm and Port Klang site is approximately 0.008 ppm.

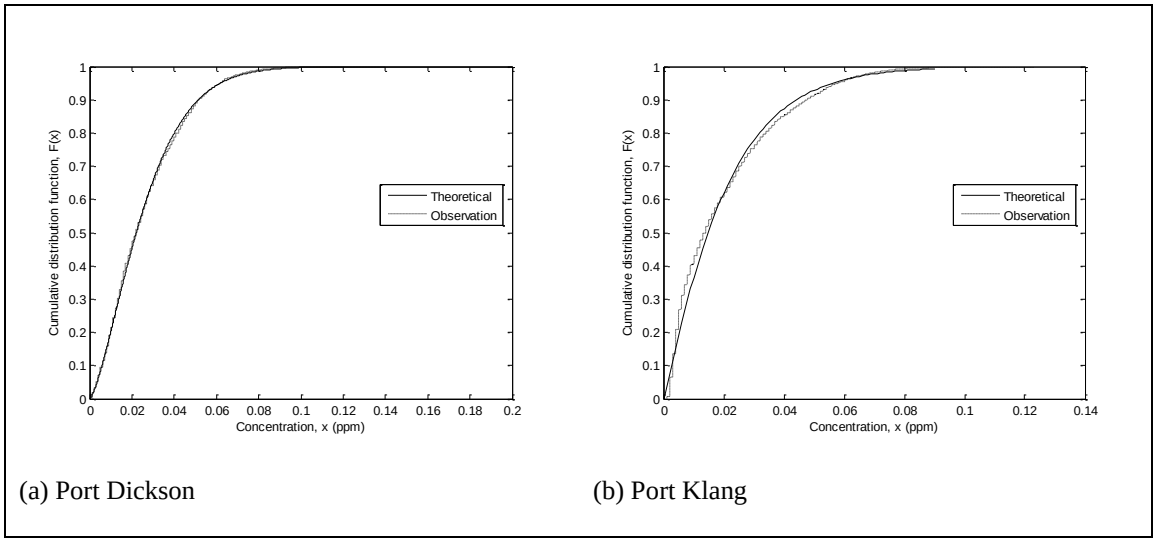

Figure 2. Weibull distribution CDF plot for Port Dickson and Port Klang

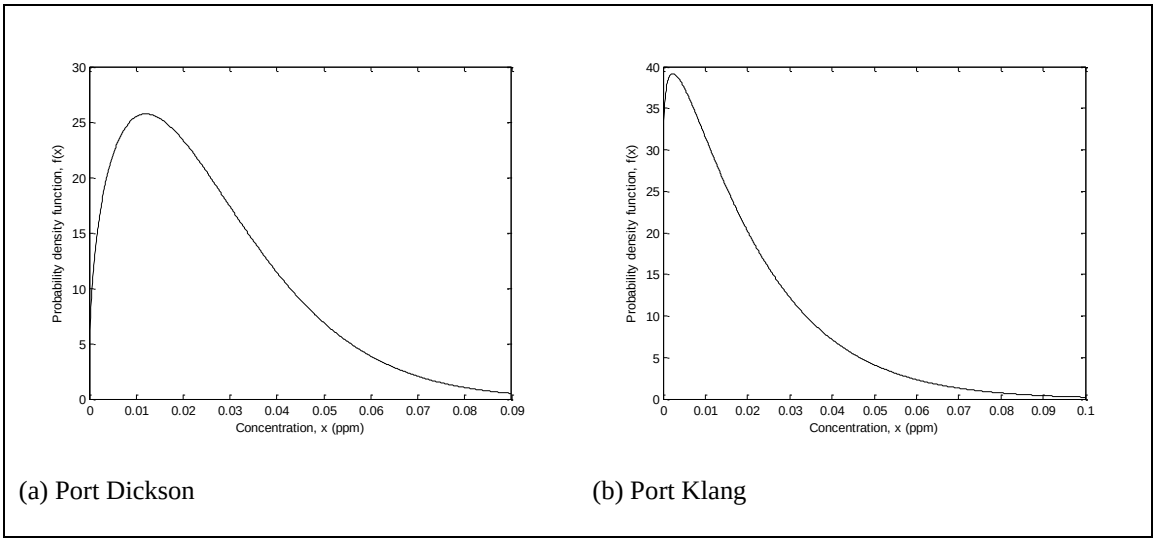

Figure 3. Weibull distribution PDF plot for Port Dickson and Port Klang

Performance indicators

Table 5 shows the best performance for both sites is Weibull distribution that computes by using computational MATLAB software.

The best result for adequacy measure PA and R^2 at Port Dickson is 0.99 and 0.98, respectively. Meanwhile, Weibull distribution scores the best for adequacy measure (PA = 0.99 and R^2 = 0.99) and error measure (NAE = 0.08) at Port Klang site. Thus the Weibull distribution can be used for prediction purposes at both sites.

Table 5. Descriptive of performance indicator

Distribution	Site	NAE	PA	R^2
Weibull	Port Dickson	0.309	0.992*	0.984*
	Port Klang	0.077*	0.993*	0.986*
Lognormal	Port Dickson	0.205*	0.911	0.829
	Port Klang	0.203	0.886	0.786
Inverse Gaussian	Port Dickson	0.264	0.921	0.849
	Port Klang	0.213	0.923	0.852

*best distribution

Conclusion

The descriptive of ozone concentrations in Port Dickson and Port Klang were statistically investigated. This study concluded the best distribution to represent ozone concentration at Port Dickson and Port Klang were found to be Weibull distribution. This distribution performs the best goodness-of-fit data from CDF graph plotted. This distribution also shows best performance indicator with highest score in NAE with smallest error measure (value closest to zero) for Port Klang. It is also scored well in PA and R^2 with highest adequacy measure (value closest to 1) for both sites.

Abstract

The present study is aimed to prepare three different granular adsorbents and applying on fluoride removal in column operations. Commercially available powdered adsorbents activated alumina (PAA) and tri-calcium phosphate (PTCP) is agglomerated to obtain granular polymer agglomerated alumina (GPAA) and granular polymer agglomerated tri-calcium phosphate (GTCP). Agglomeration was carried out using powdered adsorbents with neutral and non-toxic polymer Poly (vinyl acetate) to granular form of 20 – 50 mesh size. Plain Amberlite IRA 400 anion exchange resin (PR) was chemically modified (CMR) through phosphorylation by alum impregnation and investigated for fluoride removal as a third adsorbent. Column studies were carried out using 1.5 cm diameter columns to find out the suitability of the material for large scale applications. Solutions containing 5 mg L^{-1} of fluoride adjusted to pH 7.0 were allowed to percolate through the column at known flow rates. Under optimum conditions of flow rate 10 mL min^{-1} and bed height of 31 cm (25 g) of GPAA, 36 cm (20 g) of GTCP and 42 cm (20 g) of CMR respectively. The amount of fluoride removed were 1.948 mg g^{-1}, 2.1005 mg g^{-1}, and 2.3325 mg g^{-1} of the respective adsorbent. The effects of co-existing anions were also studied in column experiments. Column regeneration studies were also carried out for all the adsorbents with $Al_2(SO_4)_3$ solutions. The cyclic regeneration experiments indicated that all the three adsorbents could be completely regenerated and used for repeated cycle. Ground water sample was collected from a village in Dharmapuri district of South India. The defluoridation capacity of the wet resin (6.80 mg g^{-1}) was found to be three times more than dried resin. CMR potentially can be the best adsorbent for fluoride removal.

Abstrak

Matlamat kajian ini adalah untuk menyediakan tiga penjerap berbutir yang berbeza dan diaplikasikan untuk penyingkiran fluorida dalam operasi turus. Penjerap komersial serbuk teraktif alumina (PPT) dan tri-kalsium fosfat (PTCP) digumpalkan untuk mendapatkan polimer berbutir alumina (GPAA) dan polimer berbutir tri-kalsium fosfat (GTCP). Penggumpalan telah dijalankan dengan menggunakan penjerap serbuk poli polimer (vinil asetat) neutral dan tidak toksik kepada bentuk berbutir dari 20-50 saiz sirat. Amberlit kosong IRA 400 anion resin pertukaran (PR), telah diubahsuai secara kimia (CMR) melalui kaedah pemfosforilan mengunakan impregnasi alum, dan diuji untuk penyingkiran fluorida sebagai penjerap ketiga. Kajian turus telah dilakukan dengan menggunakan 1.5 cm diameter turus bagi mengetahui kesesuaian bahan untuk aplikasi skala besar. Larutan fluorida yang berpekatan 5 mg L^{-1} dan pH 7.0 dibiarkan meresap melalui turus pada kadar aliran yang telah dikenalpasti. Di bawah keadaan

optimum, kadar aliran ialah 10 mL min $^{-1}$ dan ketinggian dasar masing – masing ialah 31 cm (25 g) GPAA, 36 cm (20 g) GTCP dan 42 cm (20 g) CMR. Jumlah fluoride yang disingkirkan ialah 1,948 mg g^{-1}, 2,1005 mg g^{-1}, dan 2,3325 mg g^{-1} mengikut bahan penjerap masing-masing. Kesan anion sedia ada juga dikaji dalam eksperimen turus. Kajian pengunaan semula turus turut dijalankan untuk semua penjerap menggunakan larutan $Al_2(SO_4)_3$. Eksperimen penghasilan semula kitaran menunjukkan bahawa ketiga-tiga penjerap boleh dihasilkan semula sepenuhnya dan digunakan untuk kitaran berulang. Sampel air bawah tanah telah dikumpulkan dari sebuah kampung di daerah Dharmapuri, India Selatan. Kapasiti penyingkiran fluorida oleh resin basah (6.80 mg g^{-1}) telah didapati tiga kali lebih tinggi daripada resin kering. CMR berpotensi menjadi penjerap yang terbaik untuk penyingkiran fluorida.

Kata kunci: penyingkiran fluorida, penggumpalan, poli vinil asetat, penjerap berbutir, kajian turus

Introduction

It is well known that trace elements are essential and beneficial to organism in minute concentrations, as they play a significant role in many metabolic processes. But they would be toxic when their concentrations exceed the permissible levels. Fluoride, a typical trace element is distributed in rock, soil and water. The safe limit of fluoride in drinking water level in between 0.7 mg L^{-1} to 1.5 mg L^{-1} but harmful once it exceeds to 1.5 mg L^{-1} which is the World Health Organization limit being followed in most of the nation's [1]. Fluoride in minute quantity is an essential component for normal mineralization of bones and formation of dental enamel [2]. However its excessive intake may result in slow, progressive crippling scourge known as fluorosis.

Defluoridation is the only practicable option to overcome the problem of excessive fluoride in drinking water, where alternate source is not available. Adsorption technique retains a major place in defluoridation research and practice because of its greater accessibility and lower cost. Several adsorbent materials have been tried in the past to find out an efficient and economical defluoridating agent. Activated carbons, low cost waste materials, alum impregnated materials, mineral based adsorbents, activated alumina, tri-calcium phosphate and ion-exchange resins etc. are different adsorbent materials reported. Activated alumina is regarded as an excellent and widely used adsorbent for defluoridation. Tri-calcium phosphate is another adsorbent that has gel structure and better characteristics than that of activated alumina [3]. Both the adsorbents show increased adsorption capacity in the powder form as the surface area and consequently more number of active sites are exposed.

However, the adsorbents in the powdered form are not suitable for continuous column operations as they produce pressure drop. It was decided to agglomerate the above powdered adsorbents into granular form so that the adsorbents could be profitably used in column operations without loss in their capacity for fluoride removal. A suitable method could be agglomeration using a cheap, readily available and non-toxic polymer. Polyvinyl acetate was found to be a better choice as it is soluble in simple organic solvents but insoluble in aqueous medium. Apart from the preparation of granular adsorbents from powdered activated alumina and tri-calcium phosphate by agglomeration it was also decided to prepare a superior adsorbent for fluoride removal and compare its fluoride removal capacity with other two adsorbents. The better choice would be to chemically modify readily available granular ion exchange polymer resin so that its physical characteristics could be retained, simultaneously improving its capacity, pH tolerance and selectivity towards fluoride in the presence of common anions.

Materials and Methods

Defluoridation materials

Commercially available acidic powdered activated alumina (PAA) and powdered tri-calcium phosphate (PTCP), and solid poly vinyl acetate were used for agglomeration. Granular polymer agglomerated alumina (GPAA) was prepared by thoroughly mixing one part by weight of Poly (vinyl acetate) in minimum quantity of acetone and 2.5 parts by weight of finely powdered activated alumina till a semi-solid mass was obtained. Large volume of water was poured into it in one lot with vigorous stirring. It was found that this approach was effective to cover the aluminium oxide powder by polymer. The agglomerated product was separated and pressed between two glass plates into a sheet of 2 – 3 mm thickness. The sheet was washed with water dried overnight at room temperature and then cut to 20 – 50 mesh size for detailed examination. Polymer agglomerated granular tri-calcium phosphate (GTCP) was also prepared by the same method used for the preparation GPAA. Chemically modified resin (CMR) was prepared by phosphorylation of Amberlite IRA 400 anion exchange resin followed by alum impregnation.

Initially the resin was washed with distilled water and dried at room temperature for few hours. An amount of 50 g of this resin was treated with 100 mL of concentrated phosphoric acid and heated in the hot air oven at a temperature of 160 ± 1ºC for 12 hours. The material removed from the oven was washed with distilled water to remove excess acid. The sample was then soaked in 1% aluminium sulphate solution; the pH was adjusted to 3.0 – 3.5 and left soaked for 12 hours. At the end of this period, the resin was separated, washed to remove excess of Al(III) ions and then dried at 100 ± 5 ºC.

Reagents and standard solutions

Fluoride stock solution was prepared by dissolving 2.21 g pure of anhydrous sodium fluoride (Sd fine-chemicals Ltd) in 1000 mL distilled water in a plastic volumetric flask and all working solutions were prepared by appropriate dilution of stock solution with distilled water. The Total Ionic Strength Adjustment Buffer (TISAB) was prepared according to a recommended procedure [4]. Fluoride ion concentration was estimated by Orion Ion meter (EA 920 model).

Column experiments

Powder activated alumina (PAA) and powder tri-calcium phosphate (PTCP) developed pressure drops in the course of column experiments. To overcome the problem of pressure drop, GPAA, GTCP were used and their fluoride removal behaviors were compared with that of CMR. Column experiments were carried out using 70 cm long and 1.5 cm diameter. Teflon column packed with the materials under study, to a predetermined height. As the fluoride concentration of untreated drinking water usually lies below 5 mg L^{-1} and pH remains in the range of 6.5 to 8.5, solutions containing 5 mg L^{-1} of fluoride adjusted to pH 7.0 were allowed to percolate through the column at known flow rates. Each batch of the effluent (1000 mL) was separately collected and analyzed for fluoride content using Orion ion meter. Percolation of fluoride solution was stopped when the concentration of fluoride in the effluent exceeded the permissible limit of 1.5 mg $L^{-1.}$ In order to find out the optimum flow rate, the fluoride solutions were allowed to flow through the column of constant bed height at separate flow rates from 7, 10, 12 and 15 mL min^{-1}. The effluent was analyzed until breakthrough (1.5 mg L^{-1}) occurred and the capacity of the adsorbents in each instance was established. In order to find out the optimum bed height for maximum removal of fluoride, experiments were conducted using varying amount of each adsorbents to fill up the column to different bed heights, and percolating the fluoride solution at optimum flow rate.

Effects of co-existing anions

The effect of co-existing anions (Cl^-, SO_4^{2-}, HCO_3^- and PO_4^{3-}) on fluoride removal efficiency of the adsorbents were also studied using column experiments with fluoride solution of 5 mg L^{-1} and varying anions concentration from 50 mg L^{-1} to 200 mg L^{-1}. All the experiments were conducted using GPAA, GTCP and CMR with already established optimum flow rates and bed heights. Each batch of the effluents (1000 mL) were separately collected and analyzed for fluoride content.

Column regeneration studies

Regeneration of the column was done by percolating sufficient volume of aluminium sulphate solution of predetermined concentrations through the exhausted bed of adsorbents. In order to find out the efficiency of the adsorbents after regeneration, experiments were performed using columns containing 25 g of GPAA, 20 g each of GTCP and CMR. Fluoride solution containing 5 mg L^{-1} was allowed to percolate through the column at 10 mL min^{-1} till the break point. The volume of aluminium sulphate solution used was measured in terms of number of bed volumes. Since the desorption of fluoride from the adsorbent bed is a slow process, the exhausted column was washed with three bed volumes of aluminium sulphate solution at a flow rate of 5 mL min^{-1} and one bed volume of aluminium sulphate solution was left in contact with the adsorbent for 12 hours.The solution was then drained out and the column was washed thoroughly with water to render it free from aluminium (III). The capacity of the regenerated adsorbents was determined after conducting the defluoridation experiments under optimum conditions. Attrition loss of all the three adsorbents was found out by the usual procedure [5].

Application of CMR for defluoridation of real water sample

In order to find out the suitability of the adsorbent for large scale applications for removal of fluoride from ground water, experiments were conducted using 20 g of wet CMR. The water used for the experimental purposes was

collected from Dharmapuri district of Tamilnadu in South India. Water sample was analyzed for its characteristics as presented in Table 1. The capacity of CMR under wet condition for real water sample was determined as per the procedure discussed in column studies.

Table 1. Characteristics of the real water sample

Characteristics of the water sample	**Concentration (mg L^{-1}) except pH**
pH	7.98
Alkalinity	96 as $CaCo_3$ equivalent
Total hardness	161 as $CaCo_3$ equivalent
Chloride	109
Sulphate	42
Fluoride	3.3

Results and Discussion

Influence of flow rate

The capacities at various flow rates obtained for GPAA, GTCP and CMR are summarized in Table 2. It was found that the fluoride removal is almost constant 1.694 ± 0.03 mg g^{-1} for GPAA, 1.86 ± 0.02 mg $g^{-1}$for GTCP and 2.36 ± 0.03 mg g^{-1} for CMR up to flow rates 12 mL min^{-1}. At a higher flow rate of 15 mL min^{-1} the fluoride removal was found to be drastically reduced to 1.165 mg g^{-1}, 1.506 mg g^{-1} and 1.9175 mg g^{-1} for the respective adsorbents. It may be concluded that at lower flow rates the fluoride ions have sufficient time to reach the reaction sites and get adsorbed. At higher flow rates there is a reduced interaction between the fluoride and the adsorbent and hence there was a rapid fall in the capacity of adsorbents for fluoride. Therefore, in all subsequent experiments, a flow rate of 10 mL/min was employed for all the three adsorbents.

Table 2. The capacities of various flow rates obtained for GPAA, GTCP and CMR

Adsorbents	**Fixed bed heights (cm)**	**Capacities at various flow rate (mg g^{-1})**			
		7 mL (min^{-1})	**10 mL (min^{-1})**	**12 mL (min^{-1})**	**15 mL (min^{-1})**
GPAA	25	1.697	1.694	1.693	1.165
GTCP	27	1.868	1.868	1.846	1.507
CMR	42	2.390	2.333	2.328	1.918

Influence of bed height

The bed height is another important parameter that determines the capacity of any adsorbent. The effect of variation of fluoride removal capacity by unit weight of all the three adsorbents, at the fixed flow rate of 10 mL min^{-1} was summarized in Table 3.

It was found that the minimum bed heights for maximum fluoride removal, in terms of unit weight of adsorbents are 31 cm (25 g) for GPAA 36 cm (20 g) for GTCP and 42 cm (20 g) for CMR. Therefore the fluoride removal capacities by unit weight of all the three adsorbents can be reported as 1.95 mg g^{-1} for GPAA, 2.10 mg g^{-1} for GTCP and 2.33 mg g^{-1} for CMR. The results obtained are summarized in Table 4. Therefore the optimum bed heights maintained for further experiments are 31 cm for GPAA, 36 cm for GTCP and 42 cm for CMR.

Table 3. The capacities of various bed heights obtained for GPAA, GTCP and CMR

Adsorbents	Fed flow rate (mL min^{-1})	Various bed height (cm)	Adsorption capacities (mg g^{-1})
GPAA	10	19 (15 g)	1.309
		25 (20 g)	1.695
		31 (25 g)	1.948
		37 (30 g)	1.950
GTCP	10	18 (10 g)	1.848
		27 (15 g)	1.868
		36 (20 g)	2.099
		45 (25 g)	2.140
CMR	10	21 (10 g)	1.896
		31.5 (15 g)	2.185
		42.0 (20 g)	2.333
		52.5 (25 g)	2.331

Table 4. The results obtained for GPAA, GTCP and CMR

Adsorbents	Flow rate (mL^{-1})	Bed heights (cm)	Capacities of the adsorbents (mg g^{-1})
GPAA	10	31	1.948
GTCP	10	36	2.099
CMR	10	42	2.333

Effect of common anions on the removal of fluoride on GPAA, GTCP and CMR

From the results (Table 5), it was observed that the presence of chloride has no significant effect on the efficiency of the adsorbents up to 200 mg L^{-1}. The presence of sulphate found to affect the efficiency of the adsorbents to a small extent. For GPAA the fluoride removal capacity was found to be reduced to 95.2 %, 87.5 %, 66.5 % and 45.7 % and in case of GTCP it was found to be reduced to 99.6 %, 92.7 %, 78.6 % and 67.3 % for respectively for 50 mg L^{-1},100 mg L^{-1}, 150 mg L^{-1} and 200 mg L^{-1} of SO_4^{2-} ion concentration. Presence of sulphate has no significant effect on fluoride removal capacity of CMR within the tested concentration range of 50 mg L^{-1} to 200 mg L^{-1}. The bicarbonate interference showed significant reduction of fluoride removal due to the change in pH as well as the competing effect of this co-ion for the active sites of the adsorbents [6]. For the presence of bicarbonate concentration 50 mg L^{-1}, 100 mg L^{-1},150 mg L^{-1} and 200 mg L^{-1} the fluoride removal capacity was found to be reduced to 77.7 %, 67.5 %, 48.7 % and 38.6 % respectively for GPAA and 80.2 %, 44.7 %, 32.8 % and 22.4 % respectively for GTCP.

The presence of bicarbonate has no significant effect on the fluoride removal capacity of CMR up to a concentration of 200 mg L^{-1}. The other ion PO_4^{3-} interferes with the sorption of fluoride at the elevated concentrations due to the preferential adsorption of PO_4^{3-} over activated alumina and tri-calcium phosphate. The fluoride removal efficiency of GPAA decreased to 69.9 %, 44.8 %, 26.4 % and 18.4 % for 50 mg L^{-1}, 100 mg L^{-1},150 mg L^{-1} and 200 mg L^{-1} of PO_4^{3-} and for GTCP it was reduced to 79.8 %, 33.2 %, 21.1 % and 10.6 %. It was noted that, the affinity sequence for anion adsorption on these two adsorbents were in the order $PO_4^{3-} > HCO_3^- > SO_4^{2-} > Cl^-$. These results agreed

with the reported defluoridation property of activated alumina [7].The presence of ion PO_4^{3-} found to significantly interfere with the adsorption of fluoride over CMR and the fluoride removal efficiency of the adsorbent decreased to 78.4 %, 60.0 %, 48.7 % and 39.5 % for 50 mg L^{-1}, 100 mg L^{-1}, 150 mg L^{-1} and 200 mg L^{-1} of PO_4^{3-} ion. From the results it was observed that bicarbonate, sulphate and chloride have no significant effect on fluoride removal capacity of CMR. The phosphate alone showed negative effect on CMR that to a lesser extent compared to the other two adsorbents. These characteristics of CMR suggest the fact that the adsorbent is selective for fluoride removal. Similar types of results were reported by Viswanathan and Meenakshi [8].

Table 5. Effect of common anions on the removal of fluoride on GPAA, GTCP and CMR

Adsorbents	Anions	Concentration of solution (%)			
		200 mg L^{-1}	150 mg L^{-1}	100 mg L^{-1}	50 mg L^{-1}
GPAA			Negligible		
GTCP	Cl^-		Negligible		
CMR			Negligible		
GPAA		38.6	48.7	67.5	77.7
GTCP	SO_4^{2-}	22.4	32.8	44.7	80.2
CMR			Negligible		
GPAA		38.6	48.7	67.5	77.7
GTCP	HCO^{3-}	22.4	32.8	44.7	80.2
CMR			Negligible		
GPAA		18.4	26.4	44.8	69.9
GTCP	PO_4^{3-}	10.6	21.1	33.2	79.8
CMR		39.5	48.7	60.0	78.4

Column regeneration

From the column regeneration studies, it was established that 0.25 %, 0.5 % and 1.0 % solutions of $Al_2(SO_4)_3$ was adequate for the complete regeneration of GPAA, GTCP and CMR. The cyclic defluoridation and subsequent regeneration with aluminium sulphate indicated the potential usefulness of the adsorbents for nearly 8 cycles without significant loss of adsorption capacity. The attrition loss was only around 5 %, for GPAA and GTCP, and 4 % for CMR even after 8 cycles. After 8 cycles, the adsorbents were withdrawn from the column, washed, air dried and weighed to find out its loss. It was noticed that there was no significant loss of all the three adsorbents [9].

It was surprising to note that the fluoride removal capacity of CMR was increased three fold after first regeneration and remained nearly the same, cycle after cycle. Hence, it could be established that the regeneration is not only complete but also has introduced new sites for adsorption of fluoride. The reason for this phenomenon may be due to the replacement of γ- AlOOH present on the dried resin by $-Al(H_2O)_3(OH)_3$ during regeneration under wet condition. This was also verified by fluoride column adsorption studies using freshly prepared wet CMR without drying. Hence, the following mechanism was proposed.

$$-Al(H_2O)_3(OH)_3 + 3F^- \longrightarrow Al(H_2O)_3(F_3) + 3OH^-$$

$$-Al(H_2O)_3(OH)_3 \text{ (under wet condition)} \longrightarrow AlOOH \text{ (Dry)} + 4H_2O$$

$$\text{-AlO-OH (under dry condition)} + F^- \xrightarrow{105 \pm 5^oC} \text{- AlO-F} + OH^-$$

Similar phenomenon has been observed for removal of fluoride using alum impregnated coconut shell carbon in wet condition [10].

Application of CMR

The defluoridation capacity of the wet resin for real water sample was calculated to be 6.8 mg g^{-1}. From the results, it is evident that the capacity of the adsorbent remained unaffected when applied to ground water containing fluoride. The attrition loss of CMR was found to be only around 4 %, even after 8 cycles of adsorption and regeneration.

Conclusion

Aluminium sulphate solution was found to be the best regenerent for regeneration of all the three adsorbents after saturation with fluoride. Complete regeneration could be achieved with 0.25 %, 0.5 % and 1.0 % aluminium sulphate solution in the case of GPAA, GTCP and CMR respectively. Column studies have clearly demonstrated that the unit capacity of CMR for adsorption of fluoride was found to be higher than that of other adsorbents GPAA and GTCP. The application of CMR to fluoride bearing waste water showed considerable adsorption capacity. In column regeneration studies, it could be seen that the capacity of GPAA and GTCP for the removal of fluoride remained nearly the same, cycle after cycle showing that the regeneration was complete and the capacity of the adsorbents were retained. The cyclic defluoridation and subsequent regeneration experiments indicated the potential usefulness of the GPAA, GTCP and CMR for nearly 8 cycles without significant loss of sorption capacity. But the fluoride removal capacity of CMR was increased three fold after first regeneration and remained nearly the same, cycle after cycle. It may be pointed out that chemically modified resin (CMR) is superior to other two adsorbents with respect to the removal of fluoride. A ground water sample collected from a village in Dharmapuri district of South India was tested for fluoride removal. The results showed that the defluoridation capacity of the wet resin was 6.80 mg g^{-1}, which leads to the conclusion that CMR could be a better adsorbent for fluoride removal from drinking water.

Abstract

Recently, we reported the isolation of a novel flavonoid named uncariechin along with epicatechin and epiafzelechin from the leaf extract of *Uncaria longiflora* variety *pteropoda* (Miq.) Ridsd. of the family *Rubiaceae*. Continuing our investigation on the *Uncaria* genus, the identification and quantification of its phytoconstituents was carried out. The species of particular interest is the Malaysian *Uncaria gambir*. This species is distributed mainly in Malaysia and Indonesia and has been cultivated for the flavonoid catechin in Indonesia. Hence, the objective of this study is to determine the quantity of catechin in hexane (Hx), dichloromethane (DCM) and methanol (MeOH) extracts in both stem and leaf parts of the plant via HPLC-DAD. Our findings indicate that catechin is present in higher amounts in the MeOH extract [8.64 % (leaves); 5.12 % (stems)] compared to the DCM extract [0.77 % (leaves); 0.92 % (stems)] with no catechin found in the hexane extract. This is the first report of the quantification of catechin from Malaysian *U. gambir* using HPLC-DAD. The method can be used for the quantification of flavonoids from other *Uncaria* and related genus and is useful for targeted isolation of interest flavonoids.

Abstrak

Kami telah melaporkan pengasingan satu flavonoid novel iaitu unkariekin bersama-sama dengan epikatekin dan epiafzelekin daripada ekstrak daun *Uncaria longiflora* var. *pteropoda* (Miq.) Ridsd. yang tergolong dalam famili *Rubiaceae.* Lanjutan terhadap penyelidikan genus ini, pengenalpastian fitokonstituen serta kuantifikasinya telah dijalankan, khususnya terhadap species *Uncaria gambir* dari Malaysia. Spesies ini banyak dijumpai di Malaysia dan Indonesia dan telah ditanam di Indonesia untuk flavonoid katekin. Maka, objektif penyelidikan ini adalah penentuan kuantiti katekin dalam ekstrak heksana (Hx), diklorometana (DCM) dan metanol (MeOH) dari batang dan juga daun *Uncaria gambir* dengan menggunakan KCPT-PSD. Hasil penyelidikan mendapati bahawa katekin banyak dijumpai di dalam ekstrak metanol [8.64 % (daun); 5.12 % (batang)] berbanding di dalam ekstrak diklorometana [0.77 % (daun); 0.92 % (batang)] tetapi tidak dikesan dalam ekstrak heksana. Ini merupakan laporan pertama bagi kuantifikasi katekin daripada *U. gambir* tempatan melalui KCPT-PSD. Kaedah ini boleh digunakan untuk kuantifikasi flavonoid dari spesies *Uncaria* lain dan genus berkaitan, malah berguna untuk pengasingan flavonoid sasaran.

Kata kunci: *Uncaria gambir*, katekin, flavonoid, KPCT-PSD

Introduction

The Uncaria genus comes from family of *Rubiaceae* and has been known for their medicinal and therapeutic properties. This genus represents 34 species which is widely distributed in tropical regions and about 14 species are available in Malaysia [1]. The most popular among local *Uncaria* species is *Uncaria gambir*. Malaysian *Uncaria* species have been reported to have antioxidant properties due to their flavonoids [2]. Catechin is a flavonoid frequently used as a chemical marker in the analysis of flavonoids in *Uncaria*. The choice of catechin as a marker flavonoid is due to its abundance in *Uncaria gambir* [3]. Previous studies on the quantification of flavonoids from crude extracts showed that five flavonoids are present in *Uncaria gambir* which are (-)-epigallocatechin, (-)-gallocatechin, (+)-catechin hydrate, (-)-epicatechin and (-)-epicatechin gallate [4]. Quantification of catechin on *Uncaria gambir* especially Malaysian *Uncaria gambir* has not been reported. There has been some report on the quantification of catechin in the leaves of *Uncaria gambir* collected from West Sumatera but no report has been found on the stems and leaves of Malaysian *Uncaria gambir*.

Thus, the objectives of this study are to obtain HPLC profiles and to quantify the amount of catechin in hexane, dichloromethane and methanol extracts of leaves and stems of *Uncaria gambir*. This study provides beneficial information regarding catechin content in the leaves and stems of Malaysian *Uncaria gambir* and knowledge on quantification of flavonoids by High Performance Liquid Chromatography (HPLC).

Materials and Methods

Chemicals and raw materials

The reference compound catechin was purchased from Sigma-Aldrich (India). The purity of the reference compound was over 95 %. HPLC-grade acetonitrile was purchased from RCL Labscan Limited (Bangkok, Thailand). HPLC-grade methanol and formic acid 98 % pure were purchased from Merck (Darmstadt, Germany). HPLC-grade hexane and HPLC-grade dichloromethane were purchased from Merck (USA) and Fisher Scientific (UK). Ultra-pure water, 18 MΩ-cm resistances, filtered through a 0.2 μm filter by Thermo Scientific (referred to here as deionized water). Trifluoroacetic acid (TFA), 99 % pure was purchased from Merck (Hohenbrunn, Germany).

Uncaria gambir was collected from Bukit Diman, Ajil, Terengganu, Malaysia. Voucher specimens (HTBP 4320) were deposited at the Herbarium Taman Botani, Putrajaya, Malaysia.

Preparation of reference and sample solutions for quantification and identification

Standard catechin was accurately weighed and dissolved in 0.05 % formic acid in 70 % methanol to make a stock solution with a concentration of 1.0 mg/ml. Appropriate volumes of the stock standard was added into the appropriate volume of 0.05 % formic acid in 70 % MeOH to prepare a mix working standard. The mixed standard was stored at 4 ^{o}C in the dark.

For sample preparation, dried leaves and stems of *U. gambir* were ground into fine powder. The finely ground plants materials were accurately weighed and macerated individually with MeOH for 72 hours at room temperature. The solvent was evaporated off under reduced pressure. A 10 g of crude methanolic *Uncaria gambir* extract (stems and leaves) was dissolved in H_2O: MeOH (1:1) and was put in a separatory funnel. The mixture was then subjected to liquid – liquid partitioning using Hx and DCM to yield Hx, DCM and MeOH extracts after solvent evaporation. The weight of the extracts was recorded. The extracts were stored at 4 ^{o}C until they were subjected to HPLC analysis.

For quantification, an amount 1.0 mg of each extracts was accurately weighed and dissolved in 1.0 ml of 0.05 % formic acid in 70 % MeOH. The solutions were then filtered through a 0.2 μm membrane filter before being injected into HPLC for analysis.

HPLC-DAD quantitative analysis

HPLC quantitative analysis was performed on an Agilent series 1200 LC system (Agilent Technologies, USA) equipped with a quaternary solvent delivery system, an on-line degasser, a diode-array detector (DAD) system performing the wavelength scanning from 190 to 400 nm, an injector with 20 μL sample loop and a column

compartment. Separation was carried out using a Zorbax Eclipse XDB-C18 column (250 mm x 4.6 mm, i.d. 5 μm), from Agilent Technologies (USA). Column temperature was maintained at 25 ^{o}C. Elution was conducted using mobile phase A (0.1 % TFA in 5 % acetonitrile) and mobile phase B (0.1 % TFA in acetonitrile) with a gradient elution program at a flow rate of 0.8 mL/min. The following gradient was applied: 0-10 min 88-82 % A, 10-15 min 82 % A, 15-30 min 50 % A. The UV absorbance was monitored at wavelength of 280 nm. The solvents for the mobile phases were filtered through a 0.45 μm membrane filter. 10 μL of each sample and standard was injected manually to the HPLC system. The data were processed with Agilent ChemStation software (Agilent Technologies, USA).

Method validation

Linearity was measured at six concentration levels for each standard. Each solution was tested in triplicates. Calibration curves were constructed by plotting the peak area versus concentration of each standard. Acceptability of linearity data was determined by the correlation coefficient, r^2. Limits of detection (LOD) and quantification (LOQ) for each standard were calculated based on linear regression method. Accuracy was determined by analyzing the percentage recovery for the catechin flavonoid in the *U. gambir* leaf extract by spiking the raw material with reference standards at three levels. Three replicates were performed for each analysis. Variations of all the tests were expressed in terms of relative standard deviation (% RSD).

Results and Discussion

Validation of HPLC method

The HPLC method for quantification was validated and the results are summarized in Tables 1 – 2, respectively. As seen in Table 1, the calibration curve demonstrated good linearity with $r^2 \geq 0.981$. The LODs and the LOQs were found to be 2 mg/L and 6 mg/L, respectively, showing good sensitivity of the method. The recovery test represented in Table 2 which ranged from 80.1-88.1 % showed good accuracy of the method.

Table 1. Figure of merits of catechin

Analyte	Concentration range (mg/L)	Regression equation	Correlation coefficient (r^2)	Limit of detection (mg/L)	Limit of quantification (mg/L)
Catechin	2 – 100	y = 8.7935x + 22.615	0.981	2	6

Table 2. Recovery of catechin

Analyte	Concentration level (mg/L)	Percent recovery (%)
Catechin	25	88.10 ± 1.13
	50	80.10 ± 0.71
	75	82.30 ± 0.71

Quantification of flavonoids

Catechin was successfully determined and quantified from the hexane, dichloromethane and methanol leaf and stem extracts of Malaysian *U. gambir* using the developed HPLC-DAD method. The chromatogram of the leaf and stem extract is shown in Figure 1 and Figure 2, respectively. The identity of the peaks was determined by comparison of the UV-vis spectra and the retention times with the authentic standard. The purity of the peak was ascertained by the singularity of the peak component.

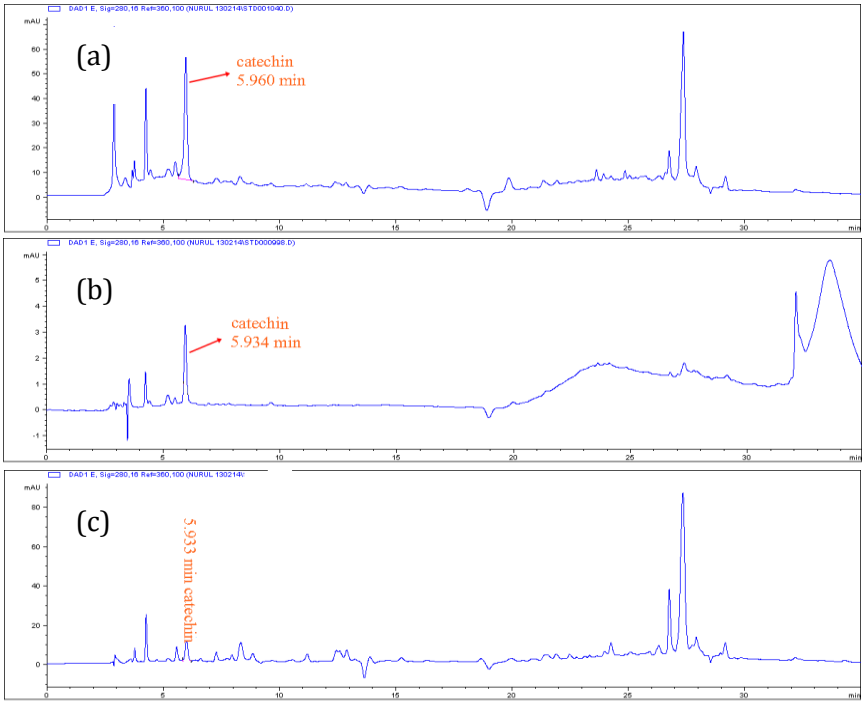

Figure 1. HPLC chromatograms *of U. gambir*: (a) MeOH extract (b) Hx extract and (c) DCM extract of the leaves

Quantification of catechin was performed using the external standard method. The relationship between the amount of standard solution (concentration) and detector responses (peak area) were plotted to construct the calibration curve. The data was fitted by linear least squares to determine response equation.

Recently, a study done by Amir et al. [5] on *U. gambir* collected in Indonesia found that the estimated total flavonoid content of this plant using the aluminium chloride colorimetric method to be 5.82 ± 2.23 mg rutin equivalents (RE)/g dry weight. In addition, the catechin content of four sub-species of Indonesian *U. gambir* known as gambir cubadak, gambir udang, gambir riau mancik and gambir riau gadang had been earlier determined by HPLC [6]. They had found that the catechin content of the respective sub-species was 104.5, 101.2, 99.4 and 108.5, 104.5 µg/ml, respectively. However, the initial concentration of the extract was not specified. Hence, the content of catechin in µg/mg could not be determined for comparison.

As far as our knowledge, the quantification of the catechin in *Uncaria gambir* from the Malaysian population has not yet been determined by HPLC methods. The contents of catechin obtained in each leaf and stem extracts are shown in Table 3 and Table 4, respectively. Catechin was present in higher amounts in the MeOH extract compared to Hx and DCM extracts. It was suggested that polar compounds in plant matrix would be easier to extract with more polar solvent such as MeOH. The amount of catechin present in MeOH leaf extract was 86.35 mg/g while in MeOH stem extract was 51.20 mg/g. The DCM extract showed that reasonable amounts of catechin can be extracted from the leaves and stems with 7.71 mg/g and 9.19 mg/g, respectively. This is because DCM is a moderately polar compound, thus it has the ability of 'like dissolve like' between the polar compounds. The Hx extract indicated that the amount of catechin cannot be quantified since the peak area was below limit of quantification. Furthermore, by comparing stems and leaves of *Uncaria gambir*, the amount of catechin present in leaf extracts are higher than in the stem extracts with an average amount of 94.06 g/kg and 60.39 g/kg plant material correlating to 9.406 % and 6.039 %, respectively.

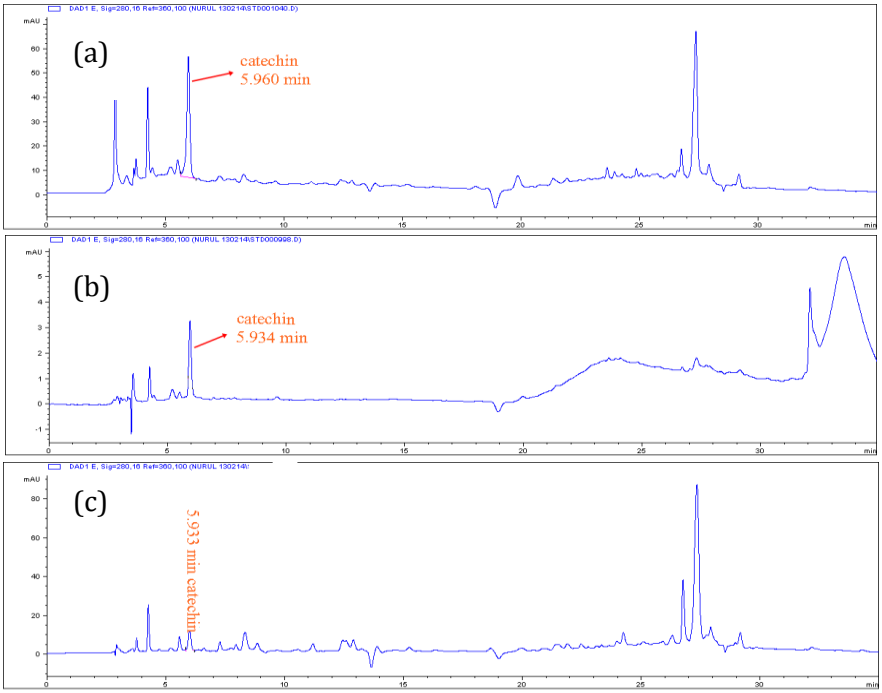

Figure 2. HPLC chromatograms *of U. gambir*: (a) MeOH extract (b) Hx extract and (c) DCM extract (C) of the stems

Table 3. Contents of catechin in leaf extract of *U. gambir* (mg/g)

Sample	Retention times (min)	Area (mAU* s)	Amount of catechin (mg/g)	Percentage of catechin (%)
MeOH extract	6.027 ± 0.020	782.3 ± 3.5	86.35 ± 0.35	8.635
DCM extract	5.942 ± 0.070	90.4 ± 1.4	7.71 ± 0.16	0.771
Hx extract	5.913 ± 0.050	11.0 ± 0.8	N/A	N/A

± is standard deviation value, N/A is non-applicable (below the limit of quantification)

Table 4. Contents of catechin in stem extract of *U. gambir* (mg/g)

Sample	Retention times (min)	Area (mAU* s)	Amount of catechin (mg/g)	Percentage of catechin (%)
MeOH extract	5.901 ± 0.0800	473.05 ± 1.06	51.20 ± 0.14	5.120
DCM extract	5.918 ± 0.110	103.40 ± 1.06	9.19 ± 0.12	0.919
Hx extract	5.920 ± 0.020	22.60 ± 0.49	N/A	N/A

± is standard deviation value, N/A is non-applicable (below the limit of quantification)

Conclusion

A HPLC-DAD method was successfully developed and validated for the analysis of catechin in Malaysian *U. gambir*. The developed LC method is proven to be an efficient, selective and rapid analytical method for the quantification of catechin in the hexane, dichloromethane and methanol leaf and stem extracts of the plant. Catechin can be found in each of the three extracts in different amounts. This is the first report on the quantification of flavonoids from Malaysian *U. gambir*. The method can be used for the quantification of flavonoids from other *Uncaria* and related genus and useful for targeted isolation of interest flavonoids.

Abstract

Pimeleodendron griffithianum, locally known as Perah ikan is available in Thailand, Peninsular Malaysia and Sumatra. The plant can be found in wet forest, secondary forest, pole forest, semi-swamps, and along logging roads or on hill slopes. In Malaysia, the stem of *P. griffithianum* being used as commercial timber. So far, no chemical constituents have been reported from *P. griffithianum*. In this study, a phytochemical study was conducted on the stem bark of *P. griffithianum*. The stem bark was obtained from Sungai Siput, Perak. The cleaned, chopped and dried stem-bark was extracted using acetone for several times. The separation of the components was carried out using vacuum liquid chromatography (VLC) followed by recrystallization method. The structure of the pure compound was elucidated by spectroscopic methods including nuclear magnetic resonance (NMR), ultraviolate – visible (UV-Vis) and comparison with literature. One compound (1) was isolated and identified as acetyl aleuritolic acid. This compound was reported for the first time from this plant.

Keywords: *Pimeleodendron griffithianum*, Euphorbiaceae, acetyl aleuritolic acid

Abstrak

Pimeleodendron griffithianum, yang dikenali sebagai pokok Perah ikan oleh penduduk tempatan didapati di Thailand, Semenanjung Malaysia dan Sumatra. Pokok ini dapat ditemui di dalam hutan lembap, hutan sekunder, semi-paya dan di sepanjang jalan pembalakan atau di cerun bukit. Di Malaysia, batang pokok ini lazimnya digunakan sebagai kayu komersial. Setakat ini tidak ada laporan direkodkan mengenai bahan kimia yang ditemui daripada pokok ini. Dalam penyelidikan ini, satu kajian fitokimia telah dijalankan ke atas kulit batang *P. griffhianum*. Kulit batang pokok *P.griffithianum* diperolehi dari Sungai Siput, Perak. Kulit pokok yang telah dibersihkan, dipotong-potong kecil dan dikeringkan, diekstrak menggunakan aseton untuk beberapa kali. Pengasingan komponen dilakukan menggunakan kaedah kromatografi cecair vakum (VLC) diikuti dengan proses penghabluran semula. Struktur kimia sebatian tulen dijelaskan dengan kaedah spektroskopi termasuk spektroskopi resonans magnet nukleus (NMR), ultralembayung (UV) dan perbandingan dengan data literatur. Satu sebatian (1) yang dipisah dikenal pasti sebagai asid asetil aleuritolik. Sebatian ini dilaporkan buat kali pertama bagi tumbuhan ini.

Kata kunci: *Pimeleodendron griffithianum*, Euphorbiaceae, asid asetil aleuritolik

Introduction

Malaysia is known for its lush tropical rain forest. The natural resources of tropical rainforest in Malaysia bring many benefits to the country. Among them is supplying food resources to local community, timber, rattan and

bamboo. Forests are not only a source of food supply and construction, but also a source of valuable medicinal plants. Forest plants in Malaysia contain many medicinal properties in the production of medicines. The tropical rain forests are chemically and biologically diverse resources as they synthesize various chemicals as defense agents against pests, diseases and predators. Euphorbiaceae is among the largest flowering plant families consisting of a wide variety of vegetative forms some of which are plants of great importance. The family is very diverse in range, comprises of all sorts of plants ranging from large woody trees through climbing habit to simple weed that grows prostrate to the ground. Euphorbiaceae is comprised of five subfamilies, 49 tribes, 317 genera and about 8000 species [1].

Pimeleodendron is a small genus in the Euphorbiaceae. Its distribution ranges from Peninsular Thailand to the Solomon Islands and tropical East Australia, Peninsular Thailand, Malay Peninsula, Sumatra, Borneo, Sulawesi, Lesser Sunda Islands, Moluccas, New Guinea, Solomon Islands, and NE Australia. *Pimeleodendron* comprises five species which are *P. amboinicum*, *P. griffithianum*, *P. macrocarpum*, *P. zoanthogyne* and *P. dispersum* [2]. Some species of this genus are economically important since they provide food, medicine, or varnish for local people. The wood of *P. macrocarpum* is used in house construction. In Sumatra, the fruit of *P. griffithianum* is used for seasoning. In eastern Malay Peninsula *P. amboinicum* furnishes edible seeds, which taste like hazelnuts; its bark being used as a purgative; the juice of the leaves, used in a mixture, cleans the mouths of children, and acts as a gentle purgative (adults can eat the leaves without purging) while the latex serves as a varnish. People in the Solomon Islands drink an infusion of the bark of *P. amboinicum* as a remedy for fever [2].

Pimeleodendron griffithianum (P. griffithianum) is one of the species in the genus *pimeleodendron*. This plant is locally known as Perah ikan. It is a mid-canopy tree up to 30 m tall. The bark is light brown, rugose, glabrous, and the inner bark is light brown about 2 mm thick with pale yellow sap. It is distributed in Thailand, Peninsular Malaysia, Sumatra, Borneo and Philippines. The plant usually found in wet forest, secondary forest, and pole forest, semi-swamps, and along logging roads or on hill slopes [2]. In Malaysia, *P. griffithianum* is found in over hill dipterocarp forest. The plant was used mainly as commercial timber. The timber being used for general light or temporary construction, interior trim, lining, shelving, joinery, furniture, mouldings, tool handle for non-impact purposes and plywood [3]. It also be used as edible fruit [4] while in Sumatra, the fruit of *P. griffithianum* is used for seasoning [2]. There is very limited information available regarding the uses of *P. griffithianum*. Currently, there is no chemical constituents have been reported from *P. griffithianum.*

Materials and Methods

Instrumentation

The NMR spectra were recorded on a Bruker AV300 NMR spectrometer 1D-NMR (^{1}H-NMR, ^{13}C-APT) and 2D-NMR (HMQC, HMBC and COSY) with TMS as internal standard and $CDCI_3$ as solvent. UV spectra were determined using UV-Vis spectrophotometer LAMBDA 35 Perkin Elmer. Silica gel 60 G (Merck 7747) was used for vacuum liquid chromatography. TLC were performed on pre-coated silica gel 60 F_{254} plates (Merck 5554) and visualized under UV light and by spraying with Cerium sulphate reagent followed by heating.

Plant collection

Fresh stem bark was collected from Sungai Siput, Perak. The stem bark was cleaned, chopped and dried under shade at room temperature until completely dry (5.60 kg). Then, it was ground to coarse powder using mechanical grinder (5.05 kg).

Extraction and isolation

The extract of the *P. griffithianum* was obtained by taking 4 kg of the powder, macerated with 5 liter of acetone in a container covered with aluminum foil and left to macerate overnight. The solvent was then filtered and evaporated under reduced pressure to obtain crude extract (207.6 g) [5]. The crude extract was then dissolved in 200 ml methanol and added with 2 L diethyl ether to precipitate tannin constituents. Decantation and evaporation of MeOH-dietyl ether soluble fraction gave crude extract that contain less tannin [6]. Crude extract obtained from this process (187.6 g) was used for further isolation and purification.

The extract which contain less tannin was fractionated by vacuum liquid chromatography (VLC) eluted with hexane: chloroform: ethyl acetate from 10:0:0 to 8:0:2. The fractionation produced 16 fractions. Fraction 10 was observed as green crystal with the mass of 138.0 mg. This fraction was washed several times with hexane. From the recrystallization processes, compound (1) was obtained as white needles (10.1 mg). The compound was detected by TLC profile and confirmed by $CeSO_4$ reagent. The compound (1) was characterized using NMR, UV-Vis and comparison with previous data.

Results and Discussion

Compound (1): Crystallized as white needles; showed maximum absorption of λ($CHCI_3$) 242.22 nm. It indicated that the compound did not contain chromophore. ^{13}C APT NMR spectrum ($CDCI_3$) of compound (1) displayed 32 carbon resonances; they are nine quartenary carbons (C) at δ_C 29.3 (C-20), 37.3 (C-13), 37.6 (C-4), 37.9 (C-10), 39.0 (C-8), 51.5 (C-17), 160.5 (C-14), 184.2 (C-28) and 171.0 (C-1'), five methine groups (CH) at δ_C 41.9 (C-18), 49.2 (C-9), 55.3 (C-5), 81.0 (C-3), 117.0 (C-15), ten methylene groups (CH_2) at δ_C 17.3 (C-11), 18.7 (C-6), 23.4 (C-2), 30.7 (C-22), 31.3 (C-16), 33.6 (C-21), 35.6 (C-8), 37.3 (C-1), and 40.7 (C-7) and eight methyl group (CH_3) at δ_C 16.6 (C-25), 16.6 (C-24), 21.3 (C-2'), 22.5 (C-27), 26.2 (C-26), 27.9 (C-23), 28.6 (C-3) and 31.8 (C-29). ^{1}H NMR (300 MHz, $CDCI_3$) δ_H: 0.84 (H-23, s, 3H), 0.87 (H-24 s, 3H), 0.90 (H-27, H-30, s, 3H), 0.92 (H-29 ,s, 3H), 0.94 (H-25, H-26 ,s, 3H), 2.03 (H-2', s, 3H), 4.45 (H-3, dd, *J* = 6.54, 9.18 Hz, 1H), 5.50 (H-15, dd, *J* = 3.19, 7.77 Hz, 1H). The ^{1}H and ^{13}C NMR assignments are given in Table 1.

The presence of thirty-two resonances showed a pentacyclic triterpene skeleton. The signals at δ_C 184.25 and 171.02 indicate the presence of carboxylic acid and acetoxy carbonyl function. Position of acetoxy group was determined from HMQC spectrum, which revealed that protons were found to be related with C-3 and it can be recognized from HMBC spectrum of quaternary carbon at acetoxy group. Position of carboxylic acid group was determined from HMBC spectrum, which revealed that carbon on carbonyl groups and C-17 were found correlate to protons at C-16 and C-22. The double bond (C=C) showed deshielding condition at δ_C 160.5 and 116.8, which is a typical C14-C15 double bond of taraxerane skeleton. Position of this double bond was clearly determined from the HMBC spectrum, which revealed that H-15 correlate to C-15 and recognized with carbon C-14. ^{1}H NMR spectrum showed a characteristic singlet at δ_H 2.03 assigned to acetoxy protons, a doublet doublet proton at 5.50 (*J* = 7.77 and 3.19 Hz) indicating a proton on the trisubstituted double bond adjacent to methylene function. Another doublet of doublet proton resonated at δ_H 4.45 (*J* = 9.18 and 6.54 Hz) assigned to the ubiquitous 3 α methane proton germinate to the acetoxy function of triterpene skeleton. Seven tertiary methyls appeared as singlets in the region δ_H 0.84 – 0.94. The above data of ^{1}H NMR and ^{13}C APT NMR for the compound (1) was identical with the reported data of that acetyl aleuritolic acid [7 - 10]. The structure of acetyl aleuritolic acid is shown in Figure 1.

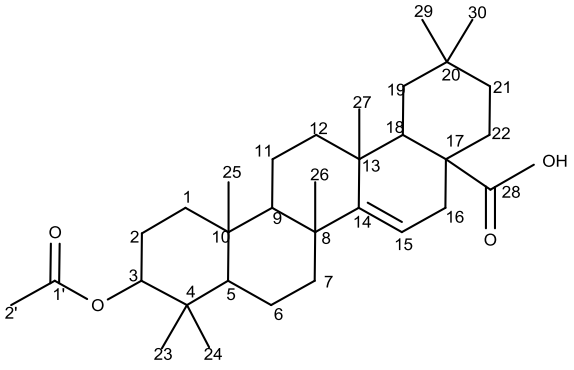

Figure 1. The chemical structure of acetyl aleuritolic acid

Conclusion

Acetyl aleuritolic acid was successfully isolated from the stem bark of *P. griffithianum*. This compound is reported for the first time from this plant. The structure of the pure compound was elucidated by spectroscopic methods including nuclear magnetic resonance (NMR), ultraviolate – visible (UV-Vis) and comparison with literature.

Abstract

Immobilized metal affinity chromatography (IMAC) has been established as a highly specific chromatographic technique for the production of enzymes and proteins including lysozyme. This study aimed to prepare and characterize the IMAC beads for lysozyme separation. Silica gel served as chromatographic matrix which has been coated with chitosan layer and crosslinked with glutaraldehyde (GTA-CTS-SiO_2) since it is very convenient to promote fixation. Various IMAC ligands were immobilized by chelating 1500 mg/l Cu^{2+}, Zn^{2+}, Fe^{2+}, Fe^{3+} and Al^{3+} ions, respectively on GTA-CTS-SiO_2. IMAC which was immobilized with 1200mg/l Cu^{2+} exhibited the maximal immobilization capacity (27.08mg/g) of within 30 minutes incubation time. This fundamental study can be a momentous pathway to develop an efficient chromatographic system for lysozyme separation in the future**.**

Keywords: silica gel, chitosan, glutaraldehyde, metal ions, copper (II) ion

Abstrak

Kromatografi afiniti logam dipegun (IMAC) telah diperlihatkan sebagai satu teknik kromatografi yang sangat spesifik untuk pengeluaran enzim dan protein termasuk lysozim. Kajian ini bertujuan untuk menyediakan dan mencirikan manik IMAC bagi tujuan pemisahan lysozim. Gel silika berperanan sebagai sokongan kepada kromatografi yang telah dilapisi dengan lapisan kitosan dan diaktifkan dengan glutaraldehid (GTA-CTS-SiO_2) kerana kesesuaiannya yang berupaya menggalakkan lekatan. Beberapa ligan IMAC dengan kepekatan 1500mg/l (Cu^{2+}, Zn^{2+}, Fe^{2+}, Fe^{3+} dan Al^{3+} ion) telah dipegunkan pada GTA-CTS-SiO_2. IMAC yang dipegunkan dengan kepekatan 1200mg/l Cu^{2+} menunjukkan penjerapan kapasiti yang maksimum (27.08 mg) dalam tempoh 30 minit masa pengeraman. Kajian asas ini boleh menjadi satu anjakan dalam langkah membangunkan sistem kromatografi yang berkesan untuk pengasingan lysozim pada masa akan datang.

Kata kunci: gel silika, kitosan, glutaraldehid, ion logam, ion kuprum (II)

Introduction

Currently lysozyme has been commercially become as an important enzyme used due to the high specificity, selectivity and efficiency function in the industries. Potent bacteriostatic and bactericidal properties of lysozyme give a huge impact as an antimicrobial agent [1] for the human body and as the food preservative especially in

extension shelf life in food industries. Small amount of lysozyme makes the process of purification becomes challenge and intricate especially for the large scale production. Conventionally, separation of lysozyme has been obtained by several techniques such as ion exchange chromatography, ultrafiltration and affinity chromatography. However rigorous limitations occur including lengthy steps, complicated and expensive for large scale production has hampered the applications. Separation technique for protein by Immobilized Metal Affinity Chromatograph (IMAC) has established [2] due to the ligand stability, high adsorption capacity, mild elution condition, simple regeneration and low cost [3]. Selection of IMAC solid chromatographic matrix to entrap metal ions for the best serve as affinity ligands for various proteins such a critical attention in order to meet the requirement of high efficiency and fast flow operation. Conventional supports for IMAC are based on soft gel that coating with dextran and agarose give the compressible and restricted low flow rate in chromatography operations [4]. Upgrading matrix with porous silica as an ideal IMAC support which has high mechanical resistance, insolubility and available for long shelf life inorganic materials. To achieve the maximum protein adsorption, surface of silica beads are modified by coating with a hydrophilic and functional natural polymer. According to Wu et al, silica beads cross-linked with chitosan indicate convenient matches for metal ion adsorption [5].

Chitosan (CTS) is widely used for the hydrophilic modification due to its biocompatibility, biodegradability, chemical innertness, high mechanical strength and non-toxic material [6]. Besides, amino and hydroxyl groups in chitosan molecules supplied active reaction sites for the various functional ligands, therefore it considered as an excellent matrix for IMAC. However, chitosan required a cross-linker to modify chemical structure and textural properties by linking at the amine or the hydroxyl sites. Glutaraldehyde (GTA) is the best chosen cross-linker for chitosan which has a porous network that could improve adsorption properties and helped to form quaternary structure on the surface of the materials, thus increase the content of protonated amino groups [7] as well as improved the chemical stability of chitosan in acidic solution [8]. Practically, IMAC is depend on the formation of coordinate bonds between immobilized metal ions such as Cu^{2+}, Zn^{2+}, Ni^{2+}, and Fe^{2+} with the functional groups of exposed amino acids on the surface of the target protein [9].

Inspired by previous researches, we have prepared IMAC beads with porous silica based characterized by chitosan-glutaraldehyde modified polymer. ATR-FTIR was analysed to determine the binding of chitosan and crosslinking agent onto the silica beads. Then, modificated silica beads were studied the immobilized various metal ions sorption and the evaluation of optimum metal ion in different concentration by ICP-OES.

Materials and Methods

Chemicals and materials

Silica gels (70-230 mesh size) were obtained by Merck Millipore. Chitosan as a modified polymer and glutaraldehyde were purchased by Sigma Aldrich. Glacial acetic acid, sodium hydroxide, hydrochloric acid, dimethylsulphoxide (DMSO), copper (II) sulfate, calcium sulfate, iron (II) sulfate, iron (III) sulfate and zinc sulfate were analytical grade reagents commercially available and used without further purification.

Preparation of chitosan coated silica beads

Preparation of Chitosan-coated silica beads (CTS-SiO_2) was according to Shi et al. [8] with some modification. Chitosan powder (5 g) was added into 250 ml of 1M acetic acid and dissolved by magnetic stirring for several minutes at room temperature and finally, the prepared chitosan solution was stored in a Schott bottle at room temperature. Initiate with treated 50 g of silica beads with 20 % of hydrochloric acid for 8 hours in incubator shaker at room temperature to obtain high adsorptive property of porous silica beads. The beads were rinsed with distilled water to remove the residual of hydrochloride inside silica beads and dried at 40 ^{o}C in oven. Prior to the surface coating, treated silica beads were immersed again into distilled water for 2 hours in order to wet the pore surface. An amount 10 g of silica beads were immersed into the chitosan solution and the flask containing the mixture was placed in the incubator shaker for the process of surface coating reaction at room temperature with 100 rpm for 72 hours. Subsequently, immersed chitosan coated silica beads with dimethylsulphoxide (DMSO) for one hour to enhance polarity of the surface. Coated beads were then added into sodium hydroxide (NaOH) solution (pH 8) for 2 hours to ensure solidify and fix the coating layer in the incubator shaker at 25 ^{o}C.

Beads activation and ligand immobilization

CTS-SiO_2 beads were cross-linking with glutaraldehyde which can be form a Schiff's base for chitosan. CTS-SiO_2 beads were incubated in incubator shaker for 30 minutes in reacting solution containing 50 v/v % (25 % glutaraldehyde in 0.1M NaCl and 0.1M sodium acetate-acetic acid buffer pH 7.4) at room temperature. After adjusting pH to 6.0 by adding acetic acid, the flask was sealed and reaction was allowed to continue for 16 hours in the incubator at 25 ^{o}C. When the reaction achieved, the excess GTA was removed by washing the beads with distilled water.

Activated silica beads (GTA-CTS-SiO_2) were reacted with 0.1M of five metal ions; $CuSO_4$, $FeSO_4$, $Al_2(SO_4)^3$, $Fe(SO_4)^3$ and $ZnSO_4$ respectively for 20 hours in incubator shaker (100 rpm) at room temperature. The adsorbent were then rinsed with distilled water before storage or usage for the lysozyme adsorption. Prepared beads hereafter are called immobilized metal affinity chromatography (IMAC) beads. IMAC is operated based on the affinity adsorption between the metal-binding amino acids in the side chains of the proteins such as histidine, lysine, glutamic acid and etc as well as the metal ions including Cu^{2+}, Fe^{3+}, Fe^{2+}, Al^{3+} and Zn^{2+} chelated by chelating ligand immobilized on the solid supports. The optimum metal ion immobilization has been chosen and verified the best concentration of metal ion before further studies with the evaluation performance of lysozyme adsorption.

IMAC characterization

Prepared IMAC beads were characterized in terms of morphology and the structure were observed using Scanning Electron Microscope (SEM), while the presence of elements has been analyzed by inductively coupled plasma optical emission spectrometry (ICP-OES) and the determination of functional groups for modified beads by using Attenuated Total Reflectance Fourier Transform Infra-Red Spectroscopy (ATR-FTIR).

Adsorption studies

After the metals concentration analysis using the ICP-OES, the amount of elements (Cu^{2+},Fe^{3+},Fe^{2+},Al^{3+} and Zn^{2+}) immobilized on the beads, P(mg/g), were approximately calculated using the following equation 1:

$$P\ (mg/g) = V\ (Co - Ce) / W_D \quad (1)$$

where Co (mg/l) is the initial elements concentration; Ce (mg/l) is the final elements concentration after adsorption; V is the volume of the elements solution used; and W_D (g) is the weight of beads.

Results and Discussion

IMAC characterization

IMAC beads were achieved in several stages including treating silica beads with hydrochloric acid, chitosan coating, cross-linking with glutaraldehyde and metal chelating. Chitosan mechanism interaction with silica beads been established [10] and the glutaraldehyde cross-linking could exhibit high operational stability of chitosan beads was coated [11]. Amination of the residue epoxy groups of could recover the loss of primary amino group during cross-linking with glutaraldehyde [12]. Hydrophilic characteristics of activated beads were improved the tendency of matrix for metal ion immobilization in the final stage of IMAC preparation. The surface morphologies of silica bead treated with hydrochloric acid is shown in Figure 1(a). The treated silica beads displayed smooth and channel like surface. The surface morphologies of silica beads modified with chitosan-glutaraldehyde represented in Figure 1(b) covered with a layer of rough surface as well as Figure 1(c) presented the rough and highly porous surface structure which can exhibit surface area and reducing the mass transfer resistance and facilitated the diffusion of protein molecules.

The ATR-FTIR spectra of native and modified silica beads are represented in Figure 2. The large broad stretching band around 3400 cm^{-1} corresponds to the associated O-H stretching vibration of the hydroxyl groups and adsorbed water which means the hydrophilic character of the porous silica shown in Figure 2(a). The peaks at around 800 and 566 cm^{-1} are attributed to the typical symmetric and bending vibration of Si-O-Si in support framework of silica beads, respectively [13].

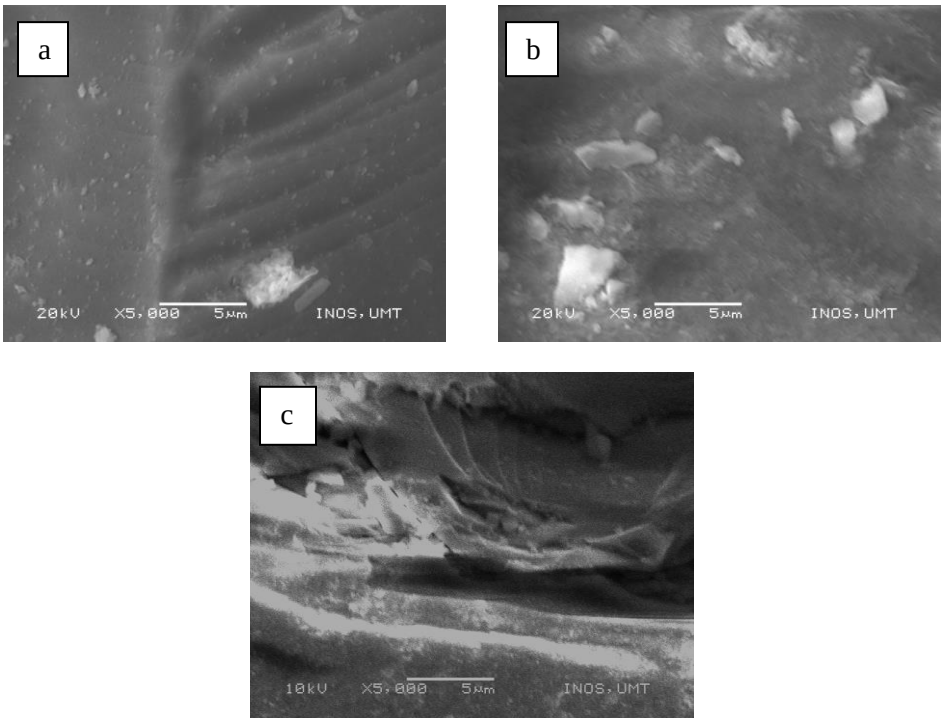

Figure 1. SEM micrograph of (a) silica bead treated with hydrochloric acid (b) modified silica beads with chitosan glutaraldehyde (c) IMAC absorbent

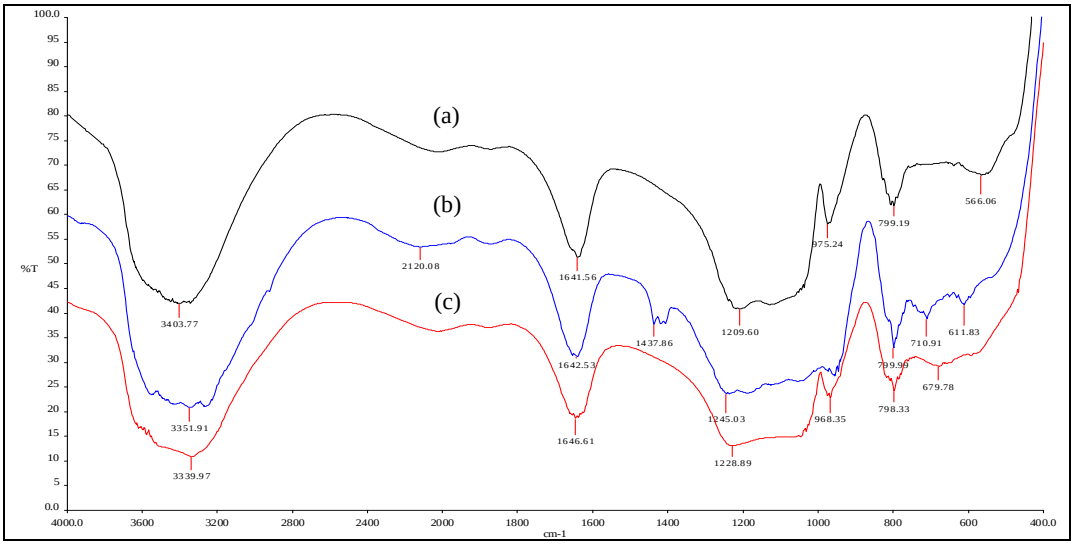

Figure 2. ATR-FTIR spectra (a) silica beads (b) chitosan coated beads (c) GTA-CTS-SiO_2

The band around 975 cm^{-1} from free silanol groups of silica disappeared or weakened after the modification (Figure 2(b)). The stretching vibration around 1640 cm^{-1} represent the C=N in amine reaction between amino groups in

silica and chitosan and aldehyde groups in glutaraldehyde [14]. The chitosan cross-linked with glutaraldehyde (Figure 2(c)) illustrated peaks at 968 and 1200 cm^{-1} assigned to saccharide structure. Hence, all peaks summarized the characterization of chitosan and glutaraldehyde for IMAC support.

Immobilization capacity of metal ion onto IMAC matrix

According to the IMAC separation concept, the use of metal ions that covalently bound chelating compound on a solid chromatographic matrix serves as affinity ligands that were vital to entrap optimum target proteins. Immobilization capacities studies of several kinds of metal ions were investigated in order to choose the most excellent metal ion among them. The chosen of metal ions; Cu^{2+}, Fe^{2+}, Fe^{3+}, Al^{3+} and Zn^{2+} ions rather than Ni^{2+} which is usually used in IMAC technique and has higher binding affinity for protein because of the leaking Ni^{2+} ions could cause human carcinogenic even in trace amount [15]. In this study, the GTA-CTS-SiO_2 beads were used as IMAC supports and immobilization of ligand (metal ion) displayed in Figure 3.

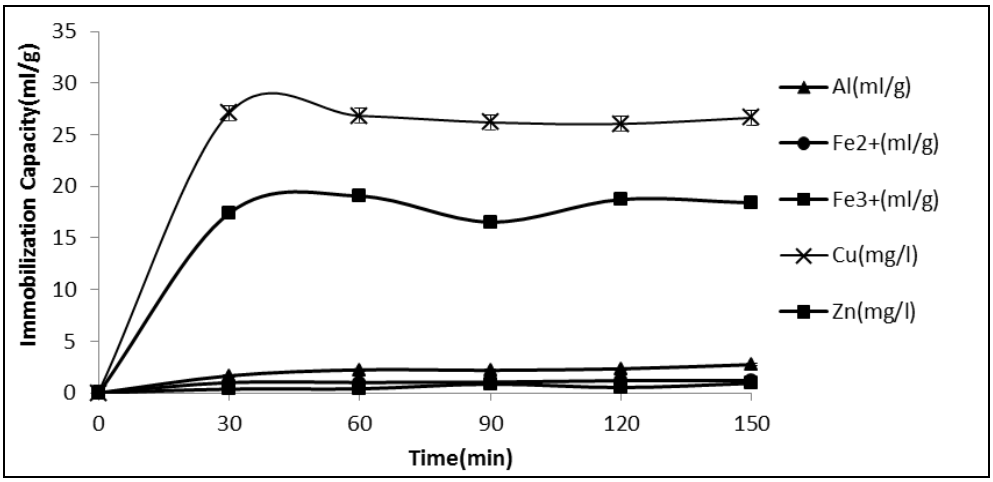

Figure 3. Immobilization capacity of metal ions

The capacity of Fe^{3+}, Fe^{2+} and Al^{3+} ions adsorption is the lower than surfactant modified chitosan beads. Those metal ions might not suitable for the chitosan coated beads adsorption. Fe^{3+} and Al^{3+} have been used for *Ortho*-phosphoserine (OPS) chelating compounds for immobilization in IMAC [16]. The adsorption capacities for Zn^{2+} is lower than Cu^{2+} otherwise still give high adsorbent amount. The maximal adsorption achieved at 30 minutes of incubation time. Obviously, Cu^{2+} is the high immobilized metal ion towards the GTA-CTS-SiO_2 with the maximal capacity 28.07 mg/g within the optimum time incubation, 30 minutes. The apparent affinity of a protein for a metal chelate depends strongly on metal ions involved in coordination. To fulfil the requirement of high protein adsorption onto the IMAC beads, the particular concentration of metal ion need to be obtained.

The principle of IMAC towards the immobilization of protein on IMAC beads were mainly through the coordination between metal ions with electron donating side chain of residues such as histidine and crysteine hence known as important factors in determining the absolute concentration of immobilized metal ion [17].

Based on the calculated values which is analysed by ICP-OES, the optimum concentration amount that ideal to the IMAC beads is 1200 mg/l with maximal adsorption amount 286.11 mg/g (Figure 4). It shown that efficient ligand immobilization could be achieved when 1200 mg/l ligand were utilized. An increased of ligand concentration up to 1500 mg/l tend to the formation of precipitation due to the excess of Cu(II) and also effected the adsorption of further protein. This optimum concentration of ligand provided higher surface area and accessible for lysozyme to bind. The lower concentration of glutaraldehyde was maintained to give the sufficient amount of free amino groups of Cu^{2+} interaction on the chitosan beads as well as yielded better adsorption capacity. The glutaraldehyde method

was served high endurance for the ligand immobilization [18]. Furthermore, Cu^{2+} adsorption was performed excellent at neutral pH to avoid the formation of Cu^{2+} hydroxide which could affect the adsorption capacity for the further protein recovery.

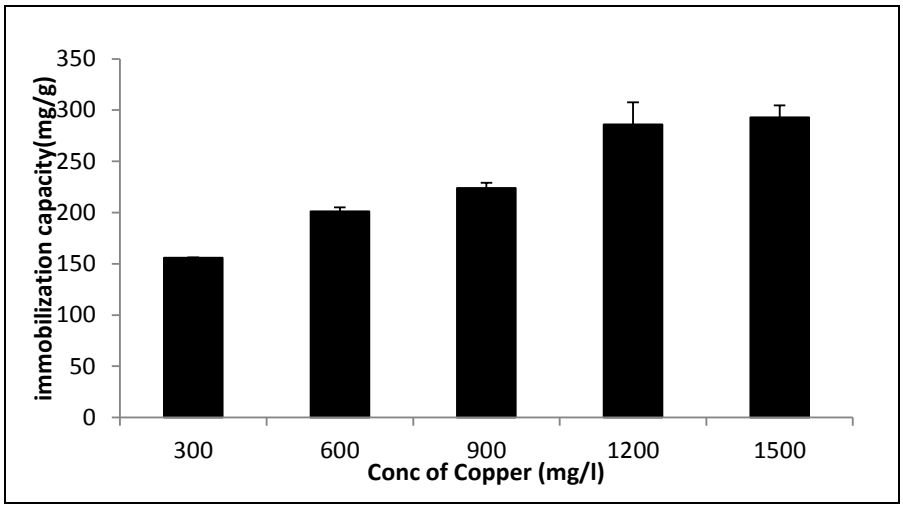

Figure 4. Immobilization capacity on different concentration of copper (II) ion

Conclusion

Preparation and characterization of IMAC beads were successfully performed by modification of silica beads with chitosan and glutaraldehyde as activated cross-linked. The morphology of modified polymer and IMAC absorbent was visualized by SEM and followed with the ATR-FTIR analysis, which was verified the presence of chitosan, glutaraldehyde and Cu^{2+} onto the IMAC surface. Maximum immobilization capacity of metal ion obtained using Cu^{2+} at 1200 mg/l and this finding could be used for further application of lysozyme adsorption.

Abstract

Three different grinding techniques (dry, semi-wet, and wet) were employed in rice flour production. Investigation on the effects of the grinding techniques on starch damage percentage, particle size distribution, pasting profiles, morphological and textural properties of rice flours produced were evaluated. Wet grinding resulted in significantly ($p< 0.05$) has lower percentage of damaged starch (3.24 %) than other grinding methods. Morphological studies (microscopy and particle size analysis) have reflected significant differences among rice flours granule shapes. The granules displaying different shapes of polygonal, round and angular forms, with some as an individual granule while others tend to attached together. Wet grinding technique also yielded flour that exhibit significantly ($p< 0.05$) with higher gel hardness (16.62 g). Pasting profiles showed that pasting temperature for rice flour produce using these three grinding methods varied between 80.15 – 80.42 °C. Results revealed that the three grinding techniques clearly affected the physicochemical properties of rice flour. The results from this study play an important role in the selection criteria of rice flour with desirable pasting and textural properties for manufacturing rice-based product.

Abstrak

Tiga jenis teknik pengisaran (kering, separa basah, dan basah) telah digunakan dalam penghasilan tepung beras. Kajian ke atas kesan teknik pengisaran pada peratusan kerosakan kanji, taburan saiz partikel, profil pempesan, sifat morfologi dan tekstur tepung beras yang dihasilkan telah dianalisa. Pengisaran basah menyebabkan peratusan kanji rosak ($p< 0.05$) lebih rendah secara signifikan (3.24 %) berbanding kaedah – kaedah pengisaran lain. Kajian morfologi (mikroskopi dan analisis saiz zarah) telah menunjukkan perbezaan yang signifikan antara tepung beras dari segi saiz dan bentuk granul yang terhasil. Granul memaparkan bentuk berlainan seperti poligon, bulat dan bentuk bersudut, samada wujud sebagai granul sendirian ataupun berkluster. Teknik pengisaran basah juga menghasilkan perbezaan yang signifikan ($p< 0.05$) berbanding teknik pengisaran lain dari segi kekerasan gel yang lebih tinggi (16.62 g). Profil pempesan menunjukkan suhu pempesan untuk tepung beras yang dihasilkan menggunakan ketiga – tiga kaedah pengisaran berada dalam julat antara 80.15 – 80.42 °C. Hasil kajian dengan jelas menunjukkan bahawa tiga teknik pengisaran memberi kesan kepada ciri – ciri fizikokimia tepung beras. Hasil kajian ini sangat penting dalam menentukan kriteria tepung beras berdasarkan sifat dan sifat tekstur yang dikehendaki untuk pembuatan produk berasaskan beras.

Introduction

Rice (*Oryza sativa* L.) has been consumed by humans for almost 5000 years. Rice is a staple food for Malaysians, with current intake of rice is approximately 2.8 million tons [1]. The rice paddy will be milled in order to obtain white or brown rice grains. Rice flour is widely used to produce many kinds of food; hence it is crucial to produce flour with fine size particle for applications in various types of food products. Rice has been shown to vary widely in its cooking [2] and eating quality [3], depending on variety and type of rice.

Grinding is a unit operation widely used in the food industry. In developing countries, it is the common method for food powder processing [4]. In general, grinding is one part of a larger set of operations involved in the process of size reduction [5]. Dry grinding uses no water, need few manpower, and thus require low cost in production. While semi-wet grinding consume small amount of water for the soaking process and use one particular machine. As compared to dry and semi-wet grinding process, wet grinding involved usage of more than one machine, more manpower and more water thus generate higher cost as compared to others.

Flour characteristics as result from grinding process, such as particle size and damaged starch level; determine its suitability for specific end-products [6, 7]. When starch is heated continuously in excess water with stirring, starch granules swell irreversibly, accompanied by leaching of amylose and possibly solubilisation of amylopectin, resulting in the formation of paste. To a certain extent, the starch pasting behaviour determines rice cooking quality and functionality, since starch is the main component in rice [8].

This study aim to investigate the effect of different grinding practices in rice utilization, and filling the gap by providing specific information on physicochemical properties and pasting profiles of rice flour from Malaysian variety which is still lacking. The information is essential for predicting their functionality and subsequent end-use in foods. In addition, the present study were conducted to compare the performance of the dry grinding, semi-wet grinding, and wet grinding processes in order to improve the eating quality of rice or for selection of specific behavior/characteristic by using the appropriate grinding method.

Materials and Methods

Raw material

Malaysian rice variety of MR220 was obtained from Malaysian Agricultural Research and Development Institute (MARDI) Pulau Pinang, Malaysia. This rice variety was grown from genes seeds obtained from cross breeding of parents MR151 and MR137. Rice paddy was harvested at maturity, cleaned, dehulled and milled to obtain milled rice grains. Only whole rice grain without any physical damage or insect infestation was selected for analysis. The chemicals were obtained from the commercial scientific suppliers. The assay kit of damaged starch content was purchased from Megazyme International Ltd. (Ireland).

Grinding machines

For dry and semi-wet grinding process, a hammer mill (Rotary Type CNS, Taiwan) was used. For wet grinding, hammer mill and stone mill (Wet Grain Grinder, WGG 254, Malaysia) were used.

Rice flour preparation

Sample was prepared using three different grinding techniques. In the dry grinding technique, the rice grains obtained were directly ground into rice flour for two cycles using the hammer mill. In the semi-wet grinding technique, rice grains were soaked in water for 8 hours at rice to water ratio of 1:1 (w/v). The excess water was then drained and the rice grains were allowed to dry at room temperature before grinding with the hammer mill. In the wet grinding technique, rice grains were ground using stone mill with excess water after subjected to soaking for 8 hours at rice to water ratio of 1:1 (w/v). The slurry obtained was filtered pressed and the semi dried residue was collected. The dried sample was reground using hammer mill. All flour samples were dried in a cabinet dryer to obtain moisture content of less than 15 % prior to the analysis. Flour samples were sieved through a 100 mesh sieve (Retsch, Germany) and packed in air tight plastic container until further use.

Starch damage determination
The damaged starch content in the flour samples was determined using the starch damage assay kit by Megazyme International Ireland in accordance with the approved method 76-31 of the American Association of Cereal Chemists (AACC) [9].

Particle size distribution
The particle size distribution and average particle size of rice flour samples were analyzed by using the Mastersizer (Malvern Instrument, UK) fitted with Scirocco 2000 unit for the dry samples at a refractive index of 1.54. The equipment was equipped with a laser beam for detection.

Scanning electron microscopy
The microstructure of rice flour was observed using a scanning electron microscope (SEM, JSM-6610, JEOL, Tokyo, Japan). The rice flour sample was coated with platinum and dispersed on a SEM specimen stub with double-sided conductive tape. The SEM was operated at an accelerated voltage of 10 kV.

Pasting profiles
The pasting profiles of rice flour were evaluated using the Rapid Visco Analyzer (RVA, Newport Scientific, Australia) following the AACC method 61-02 [10]. Parameters including pasting temperature (PT), peak viscosity (PV), final viscosity (FV), breakdown viscosity (BV), setback viscosity (SB), trough (T) and peak time were calculated from the pasting curve assisted by the Thermocline software program for Windows (TCW).

Gel texture
The gelatinized mixture in the canister, after the RVA measurement was being used to measure gel hardness. The paddle was removed immediately and the paste in the canister was covered by parafilm and left at room temperature for 1 hour to allow formation of a solid gel. Texture of the gel was then determined using a TA-XT2 texture analyser (Stable Micro Systems, Surrey, UK). Gel in the canister (with a dimension of 37 mm in diameter and 20 mm in height) was compressed at a speed of 1.0 mm/s to a distance of 10.0 mm with a stainless steel punch probe 6.0 mm in diameter. The maximum force peak in the TPA profile represented the gel hardness [11].

Statistical analysis
Values were expressed as mean with standard deviation of triplicate determinations. Data was analyzed by analysis of variance (ANOVA) using Statistical Analysis System (SAS) [12]. Differences among samples were considered significant at $p< 0.05$.

Results and Discussion

Means of damaged starch content, average particle size and gel hardness of dry, semi-wet and wet ground flours were summarized in Table 1. The damaged starch levels for the rice flour samples varied from 3.24 % to 13.07 %. Wet grinding process produced flour with significantly ($p< 0.05$) lowest percentage of damaged starch while dry ground flour exhibits the highest. The high percentage of damaged starch in dry ground flour is likely attributable to damage produced by the shears force and the heat during grinding [13] as the rice grains were directly ground as it is, whereby the hammer mill pressed the grains against an abrasive ring at high rotating speed to break the grain structure. In addition, high damaged starch also due to the higher grain hardness of dry grinding technique compared to others since there is no soaking step in the process that eventually provides softening effect to the rice kernels [14]. Starch damage profoundly changes starch granule structure and it influences functional properties of starch [15].

Particle size of flour, measured as the mean particle diameter, is a critical factor in determining the flour's usefulness and application in further processing [16]. Figure 1 shows the particle size distributions of dry, semi-wet and wet ground flour samples. The curves showed two distinct types among the rice flour samples: dry and semi-wet ground vs wet ground flour. Dry and semi-wet ground flours showed unimodal distributions while wet ground flour displayed bimodal distributions. The wet ground flour showed to distinct peaks consisted of two particle types, with size of 2-20 µm and 20-106 µm. Significant differences were found ($p< 0.05$) in the average flour particle diameter for each sample (Table 1). Average particle size of flours ranged from 9.70 to 51.44 µm, with wet ground

flour composed of the finest average particle size as compared to others. Though dry ground rice flour yield flour with smaller average particle size when compared with semi-wet ground flour, but the former exhibit significantly ($p< 0.05$) highest damaged starch. This is supported by Nishita and Bean [17] that claimed in dry milling, a high percentage of damaged starch was associated with finer particles. Nevertheless, the average particle size of dry ground rice flour obtained in this study was smaller (39.4 µm) than findings reported by Hossen et al.[18] of hammer-milled flour (72.3 – 141.2 µm), due to different manners in the technique. Noomhorn et al. [19] claimed that the starch granules of smaller rice particles are more resistant to swelling than those of larger particles and thus affecting the RVA measurement [20, 21] as it caused a decrease in peak viscosity. The peak viscosity of fine wet ground flour was significantly ($p< 0.05$) lower as compared to others, confirming the reports of Bryant et al. [22].

Table 1. Starch damage contents, average particle size distribution and gel hardness of dry, semi-wet and wet ground rice flours

Grinding Process	Starch Damage (%)	Average Particle Size (um)	Gel Hardness (g)
Dry Grinding	13.07±0.03[a]	39.37±0.14[b]	13.65±0.05[b]
Semi-Wet Grinding	4.85±0.03[b]	51.44±0.13[a]	13.70±0.11[b]
Wet Grinding	3.24±0.03[c]	9.70±0.17[c]	16.62±0.07[a]

Mean values with the same superscript letters within a column are not significantly different at $p > 0.05$

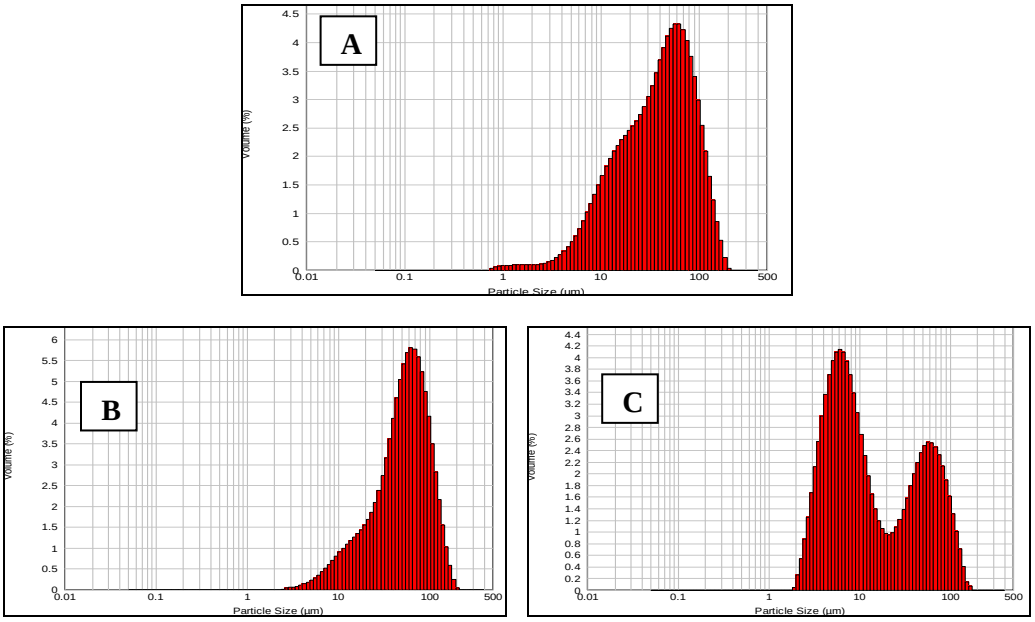

Figure 1. Particle size distributions of dry (A), semi-wet (B) and wet (C) ground rice flours

Scanning electron microscopy was used to observe the submicroscopic shape and surface characteristic of flour particles (Figure 2). Scanning electron micrographs of all flours showed irregular pentagonal or hexagonal shaped particles with protein matrix. Wet ground flour contains more free starch granules and smaller particles, plus more material adheres to the starch granules. On the other hand, some damaged granules were viewed in the dry ground

flour. As observed by Santhi and Poongodi [23], rice consists of several polyhedral starch granules in a single amyloplast and rice starch granules are the smallest of the starch grains produced by plants (3.8 µm) [24].

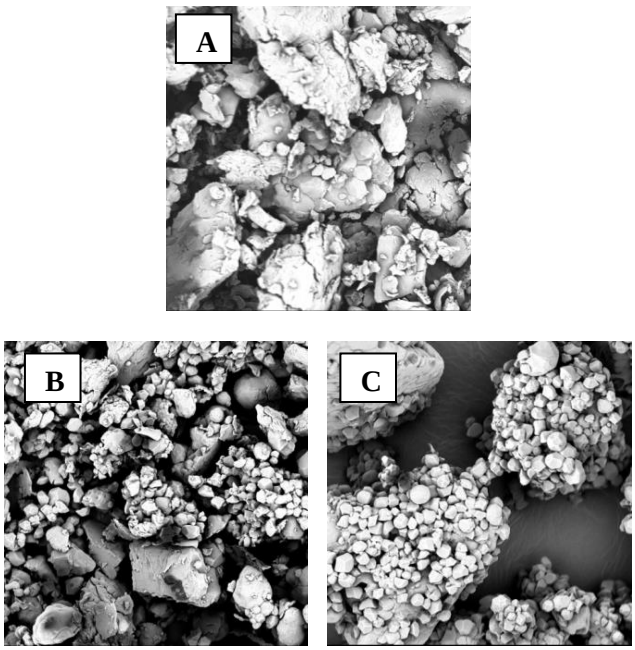

Figure 2. Microscopic structure of dry (A), semi-wet (B) and wet (C) ground rice flours

Hardness was derived from texture profile analysis curve with the starch gel from wet ground flour showed the highest hardness (16.62 g), whereas there is no significant difference ($p>0.05$) between dry and semi-wet ground flour samples. Starches that exhibit harder gels tend to have higher amylose content and longer amylopectin chains [25]. It is also associated with starch gel retrogradation, along with the crystallisation of amylose in a short time which leads to harder gels [26]. Miles et al. [27] also claimed that rigidity of starch gel is highly dependent on retrogradation of gelatinised starch granules, syneresis of water and crystallisation of amylopectin. Therefore, presence of certain level of soluble carbohydrates from wet ground flour could enhance starch gel retrogradation that would give rise to harder gels [28].

Pasting property is one of the most important properties that influence quality and aesthetic considerations in the food industry as they affect texture and digestibility as well as the end use of starch-based food commodities [29]. Pasting profile results from a complex interaction of the test material and water, affected by temperature and time, and it was performed using the rapid visco analyzer (RVA). The plot of viscosity of the flour samples against heating time was shown in Figure 3. Significant differences were found ($p< 0.05$) at each parameter of the RVA curve, except the pasting temperature (Table 2).

Peak viscosity is an index of the ability of starch-based food to swell freely before their physical breakdown [30]. The value ranged from 2777.67 – 2834.67 centipoise (cP). Dry ground flour had significantly ($p< 0.05$) highest peak viscosity followed by semi-wet and wet ground flour. High peak viscosity indicates high starch content [31] and is an indicative that the flour may be suitable for products requiring high gel strength and elasticity [32, 33] The peak viscosity of wet ground flour was significantly low ($p< 0.05$) compared to other samples and this indicates that the carbohydrate components of wet ground flour will not breakdown easily and quickly like the other samples until it is cooked properly [34].

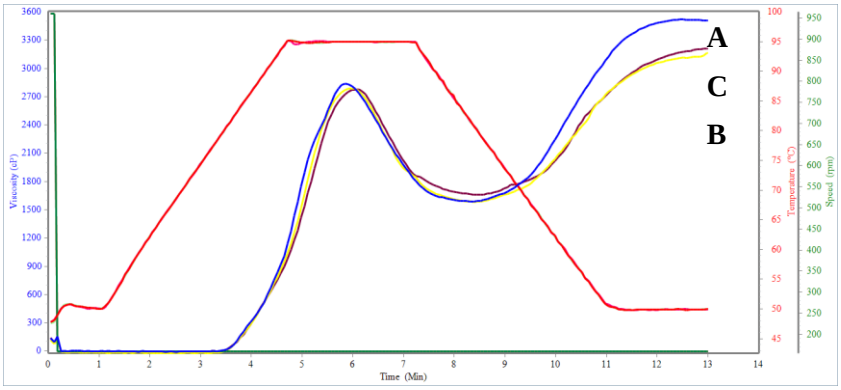

Figure 3. Pasting profiles of dry (A), semi-wet (B) and wet (C) ground rice flours

Table 2. Pasting profiles of dry, semi-wet and wet ground rice flours

Pasting Viscosity (cP)	Dry Grinding	Semi-Wet Grinding	Wet Grinding
Peak Viscosity	2834.67±6.51^{a}	2798.67±10.12^{b}	2777.67±6.51^{c}
Trough	1602.00±13.75^{ab}	1582.00±45.00^{b}	1656.67±9.71^{a}
Breakdown	1232.67±17.24^{a}	1216.67±45.63^{a}	1121.00±16.09^{b}
Final Viscosity	3548.67±44.19^{a}	3153.00±8.19^{b}	3195.00±22.52^{b}
Setback	1946.67±37.86^{a}	1571.00±39.96^{b}	1538.33±13.61^{b}
Pasting Temperature (°C)	80.37±0.45^{a}	80.42±0.54^{a}	80.15±0.57^{a}

Mean values with the same superscript letters across the row are not significantly different at $p > 0.05$

The ability of paste to resist breakdown during cooling is indicated by trough viscosity [35]. Trough is the minimum viscosity value in the constant temperature phase of the pasting profile [31]. The value ranged between 1582.00 – 1656.67 cP; with sample of semi-wet flour having the lowest value and wet ground flour having the highest value. Breakdown viscosity measured the starch paste resistance to heat and shear [8], while setback viscosity exhibited the tendency of starch pastes to retrograde, which is an index of starch retrogradation [36]. The breakdown value ranged from 1121.00 to 1232.67 cP while the setbacks ranged from 1538.33 to 1946.67 cP. Referring toTable 2, breakdown of dry and semi-wet ground flour was similar ($p > 0.05$), but was significantly ($p < 0.05$) higher than wet ground flour. The rate of the breakdown is dependent on temperature, shear stress applied to the system, and the nature of the starch tested [37]. Decrease in breakdown would cause less amylose molecules leached out into the matrix during cooking. Ultimately this could result in reduced retrogradation of amylose molecules [38]. High values in breakdown and low values in setback of semi-wet ground flour are indicative of high cooking quality since neither the cooked rice retrogrades nor becomes stiff upon cooling [39].

Final viscosity is commonly used to define the quality of particular starch-based flour, since it indicates the ability of the flour to form a viscous paste after cooking and cooling [35]; measure as the change in the viscosity after holding cooled starch at 50 °C [40]. It also represents the re-association of starch granules especially amylose during cooling time after gelatinization and the formation of gel network [41]. The final viscosity value recorded from this study ranged from 3153.00 to 3548.67 cP. Final viscosity, as well as setback viscosity values of dry ground flour were significantly ($p < 0.05$) higher than semi-wet and wet ground flour. The lower final viscosity of flours displayed the extension of the effect on the amylose chains, which might lose the ability to retrograde during

cooling due to their fragmentation [42], in this case, may due to mechanism involved in hammer mill when rice grains subjected to semi-wet grinding process.

Pasting temperature is the temperature at which the viscosity of the starch pastes begins to rise; indicates the minimum temperature required in cooking the sample [43].The pasting temperature ranged between 80.15 ^{o}C and 80.42 ^{o}C. There were no significant differences ($p > 0.05$) in pasting temperature among all the samples. These values are comparatively low as compared with values having been reported in a number of rice pasting studies e.g., 86 °C in long grain [44] and 90 – 95 °C in cryomilled and hammer milled rice [30, 35]. The attainment of the pasting temperature is essential in ensuring swelling, gelatinization and subsequent gel formation during processing [11]. Lower pasting temperatures were found to be associated with faster particle swelling and higher peak viscosity [45] while higher pasting temperatures indicates higher water binding capacity, higher gelatinization tendency and lower swelling properties of starch based flour due to high degree of association between starch granules [46]. The difference in damaged starch content and particle size distribution between flours is reported to affect the RVA profile [47]. Damaged starch granules can absorb water, swell and leach out amylose and amylopectin, which causes an increase in the viscosity of starch [48].

Conclusion

Dry, semi-wet and wet grinding techniques involved in rice flour production significantly ($p < 0.05$) affects the percentage of damaged starch, average particle size distribution, gel hardness and pasting profiles parameters except the pasting temperature. Wet grinding process exhibit flour of lowest amount of damaged starch granules 3.24 % with finest average particle size of 9.70 um. Flour samples had similar pattern of viscosity curves, but samples of dry ground flour showed significantly ($p < 0.05$) higher final viscosity. Overall, the findings suggest that wet grinding process can be regarded as the potential flour grinding practice since it produces flour with lowest starch damage, and finest average particle size as compared to others. Nevertheless, grinding method to be considered in producing the flour and to be utilized in rice based food products is depending on the specific uses.

Abstract

Protein hydrolysates from angelwing clam were obtained by enzymatic hydrolysis using bromelain. The bitterness of hydrolysates was evaluated based on the degree hydrolysis (DH), sensory analysis, molecular weight distribution and functional group. By using 3 % of enzyme substrate ratio bromelain resulted in high DH value at 12.57 % when angelwing clam was hydrolysed for 2 hours. Sensory analysis showed that angelwing hydrolysate was bitter. Angelwing hydrolysate had molecular weight below 50 kDa. The lower molecular weight indicated that the protein has been degraded into smaller peptide chains which contribute to bitter taste. Moreover, the high peak of amine group in angelwing hydrolysate (3385.6 cm^{-1}) suggested that bitterness exists. Angelwing hydrolysate had higher protein content, lower fat content and had good water holding capacity than the flesh. This result suggested that angelwing hydrolysate could be useful as food ingredient even though bitter taste developed after the hydrolysis. Thus, debittering should be considered in order to pave the way for full utilization of angelwing clam hydrolysate as a food ingredient.

Keywords: angelwing clam, sensory, hydrolysate, bromelain, bitterness, physicochemical properties

Abstrak

Hidrolisat protein daripada kerang mentarang diperolehi daripada hidrolisis proses menggunakan enzim bromelain. Kepahitan hidrolisat dinilai berdasarkan tahap hidrolisis (DH), analisis deria, pengedaran berat molekul dan kumpulan berfungsi. Dengan menggunakan 3 % daripada nisbah substrat enzim bromelain menyebabkan nilai DH tinggi pada 12.57 % apabila kerang mentarang telah dihidrolisiskan selama 2 jam. Analisis deria menunjukkan kerang mentarang hidrolisat adalah pahit. Hidrolisat kerang mentarang mempunyai berat molekul di bawah 50 kDa. Berat molekul yang rendah menunjukkan bahawa protein yang telah dipecahkan kepada rantaian peptida yang lebih kecil menyumbang kepada rasa pahit. Selain itu, kumpulan amina yang mempunyai puncak yang tinggi dalam mentarang hidrolisat (3385.6 cm^{-1}) menunjukkan bahawa kepahitan wujud. Hidrolisat kerang mentarang mempunyai kandungan protein yang lebih tinggi, kandungan lemak yang lebih rendah dan mempunyai keupayaan pegangan air yang lebih baik daripada daging. Hasil keputusan ini menunjukkan bahawa kerang mentarang hidrolisat boleh dimanfaatkan sebagai bahan makanan walaupun rasa pahit hadir selepas hidrolisis. Oleh itu, penyah-pahitan perlu dipertimbangkan untuk membuka jalan kepada penggunaan penuh kerang mentarang hidrolisat sebagai bahan makanan.

Kata kunci: mentarang, *Pholas orientalis*, hidrolisat, bromelain, kepahitan, ciri-ciri fizikokimia

Introduction

Angelwing clam (*Pholas orientalis)* is a marine bivalve found worldwide in countries such as France, Canada, Mexico, Japan, Australia, India, Papua New Guinea, Malaysia and Philippine [1]. In Malaysia, angelwing clam is

abundantly found in Perlis, Kuala Kedah, Kuala Limau, Yan, Penaga, Telok Ayer Tawar and Kuala Selangor [2]. Protein hydrolysate is well-known protein rich by product that can be utilized as functional ingredients in food systems [3]. According to Jin et al. [4] marine bivalves protein hydrolysate has good functionalities such as high in solubility, water holding capacity, oil holding capacity and surface hydrophobicity. Besides, these marine bivalves protein hydrolysate has high nutritive value such as all essential amino acids that make it suitable to be multifunctional food ingredients. Zhou et al. [5] studies showed that bivalve mollusks such as scallop and abalone protein hydrolysate possessed a significant antioxidant ability that can replace the synthetic antioxidant.

The degree of bitterness that developed during hydrolysis are associated with the level of hydrophobic amino acids and the release of bitter taste peptides [6, 7]. The size of peptide and lower molecular weight peptides are considered crucial to the sensation of bitterness [8].Therefore, the aim of this study was to investigate the development of bitter flavour in angelwing hydrolysate produced by bromelain.

Materials and Methods

Raw materials

Angelwing clam was purchased from Pantai Remis, Selangor, Malaysia. The clam was placed in ice and transported to the laboratory. Upon arrival the flesh was separated manually, washed and then stored at -20 ^{0}C. Bromelain (1.5 AU/g) was obtained from Novozymes.

Preparation of angelwing clam protein hydrolysates

Angelwing hydrolysate was prepared according to the methods by Normah and Fazlika [9] with some modification. An amount of 500 g angelwing clam flesh was mixed with 531.33 mL of distilled water and then minced. The mixture was transferred into 1 L beaker which was then placed in a water bath. The water bath was set at 45 ºC and the pH of the mixture was adjusted to 6. Once the temperature and pH were constant, bromelain was added at 3 % enzyme substrate ratio and the hydrolysis was performed for two hours. The mixture was continuously stirred at 200 rpm. The pH was kept constant throughout the hydrolysis by the addition of 1 N NaOH. At the end of the two hour hydrolysis, the reaction was terminated by heating at 90 ˚C for 15 minutes in a water bath. The mixture was then centrifuged (Hettich ZENTRIFUGEN, UNIVERSAL 320R) at 10000 rpm at 4˚C for 20 minutes. The supernatant was collected and freeze dried using SANYO-Biomedical freeze dryer.

Degree of hydrolysis

The percentage of solubilized protein in 10 g trichloroacetic acid (TCA), in relation to the total protein content of the sample was measured by the method of Silvestre et al. [10] with modification. After hydrolysis, 20 mL of protein hydrolysate was added to 20 mL of 20 % (w/v) TCA to produced 10 % TCA soluble material. The mixtures were left to stand for 30 minutes to allow precipitation followed by centrifugation at 7800 g for 15 minutes (Hettich ZENTRIFUGEN, UNIVERSAL 320R). Soluble protein content in 10 % TCA and total protein content was detected by Lowry method. The DH is calculated as formula equation 1:

$$\mathrm{DH} = \frac{\text{soluble protein content in 10 g TCA (mg)}}{\text{Total protein content (mg)}} \text{ x } 100 \quad (1)$$

Evaluation of bitter taste

The intensity of the bitter taste was conducted according to methods Nilsang et al. [7]. Samples were evaluated by 10 trained panelists who have been trained for three weeks using caffeine solution. Different concentrations of caffeine solutions at 0 to 1500 ppm were prepared and presented to panelists. Panelists were instructed to rate the bitterness by marking a point on a 15 cm line scale. After each tasting, they were asked to rinse their mouth with 10% v/w citrus water and twice with warm water.

Determination of molecular weight distribution by Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis (SDS-PAGE)

An approximately 1 g of samples was mixed with 10 mL deionized water and then filtered using membrane filter with pore size 0.45µm. An amount 6.5 µL of the solution was mixed with 2.5 µL NuPAGE®LDS sample Buffer (4X) and 1µL NuPAGE® Reducing Agent (10X). The mixture was heated at 70 ºC for 10 minutes. 15µL sample was loaded into each well of the SDS-PAGE system comprising of 12 % resolving gel and 5 % stacking gel.

Benchmark™ protein ladder with the range of 220 to 4.6 kDa was used as a marker. Electrophoresis was performed using the XCell Surelock electrophoresis cell (Bio-Rad laboratories, Hercules, CA, USA). Electrophoresis was run for 50 minutes at 100-125 mA/gel. After the running process, the gels were washed with 100 mL of ultrapure water. Then, the gel was stained using Coomassie Brilliant Blue dye and heated in a microwave oven at 180 °C for one minute. The gel was shaken again in the orbital shaker for about 2 minutes. The process was repeated twice. The gels were destained using ultrapure water and shaken with orbital shaker for another 30 minutes.

Functional group analysis

The functional group analysis in samples was performed using Thermo Nicolet, Avatar 370a Fourier Transform Infer-Red Spectrophotometer (FTIR). This analysis was determined according to Normah et al. [6] with slight modification. The angelwing sample was ground using agate mortar until the particle size became so small (approximately 2.5 micron) that the surface of the solid appears shiny. An amount 0.08 g of powdered potassium bromide (KBr) was added and the mixture was ground for about 30 seconds. The mixture was scraped into the middle and ground for another 15 seconds. The sample and KBr should be finely ground to avoid the mixture from scattering the infrared radiation excessively. The mixture was then placed in an evacuable mold and subjected to a pressure of 10 to 20MPa. Perkin Elmer Spectrum Software was used to control the spectrometer and data were collected over a wavenumber range of 4000 – 400 cm^{-1} with resolution of 4 cm^{-1} and collection spectra of 16.

Determination of fat content

The extraction and determination of the fat content from the minced muscle or the hydrolysate sample were performed using the Soxhlet extraction method [11].

Protein concentration

Protein concentration was determined using the Lowry method based on the modified procedure of Hartree [12].

Water holding capacity

Water holding capacity (WHC) was determined using the centrifugation method according to Diniz and Martin [13].The samples (0.5 g) of hydrolysate was dissolved in 20 mL water in centrifuge tubes and dispersed with a vortex mixer for 30s. The dispersion was allowed to stand at room temperature for 6 hours, and subsequently centrifuged at 2800 g for 30 min. The supernatant was filtered through Whatman filter paper No. 1 and the volume recovered was accurately measured. The difference between the initial volume of distilled water added to the protein sample and the volume of the supernatant were determined. The results were reported as mL of water absorbed per gram of protein sample (Equation 2).

$$\text{WHC}\left(\frac{\text{ml}}{\text{g}}\right) = \frac{\text{Initial Volume of Distilled Water} - \text{Volume of supernatant (ml)}}{\text{Weight of Hydrolysate (g)}} \quad (2)$$

Results and Discussion

Degree of hydrolysis (DH)

Hydrolysis at pH 6, E/S 3% and at the duration of 2 hours produced 12.57 % degree of hydrolysis by using bromelain. DH has been shown to be affected by the percent and type of enzyme used during the hydrolysis. Increasing the enzyme substrate ratio increased the DH as reported by Haslaniza et al. [14]. By increasing the enzyme concentration, the released peptides were further hydrolysed into amino acid and smaller peptide. According to Bhaskar et al. [15] degree of hydrolysis was higher at elevated temperatures as the degree of hydrolysis increased at increasing hydrolysis time and temperature. Besides, enzyme at given pH also affect the DH percentage as the optimum pH for higher rate of hydrolysis by using bromelain was at pH 6 to 7 [16].

Evaluation of bitter taste

Quantitative descriptive analysis (QDA) was carried out by ten trained panelists and the result is presented in Figure1a. The scores of bitterness using a 15-cm QDA line scale was 0.47 for the flesh, 9.49 for angelwing hydrolysate and 8.37 for caffeine reference solution. Angelwing hydrolysate was significantly ($p < 0.05$) bitter compared to the reference solution. The angelwing hydrolysate taste mildly bitter when produced using bromelain.

The bitter taste perceived in angelwing hydrolysate was due to the high amount of enzyme (E/S %) used that contribute to the increased of DH [7]. This result was also supported by Seo et al. [17] where the small amount of S/E% at 0.5 % bromelain used could gave a bitter taste to soy protein hydrolysate. According to Imelda [18] samples showed hydrolysis with different proteases had varying level of bitterness, where alcalase and protamex showed high level of bitterness within 1500 to 2000 ppm caffeine.

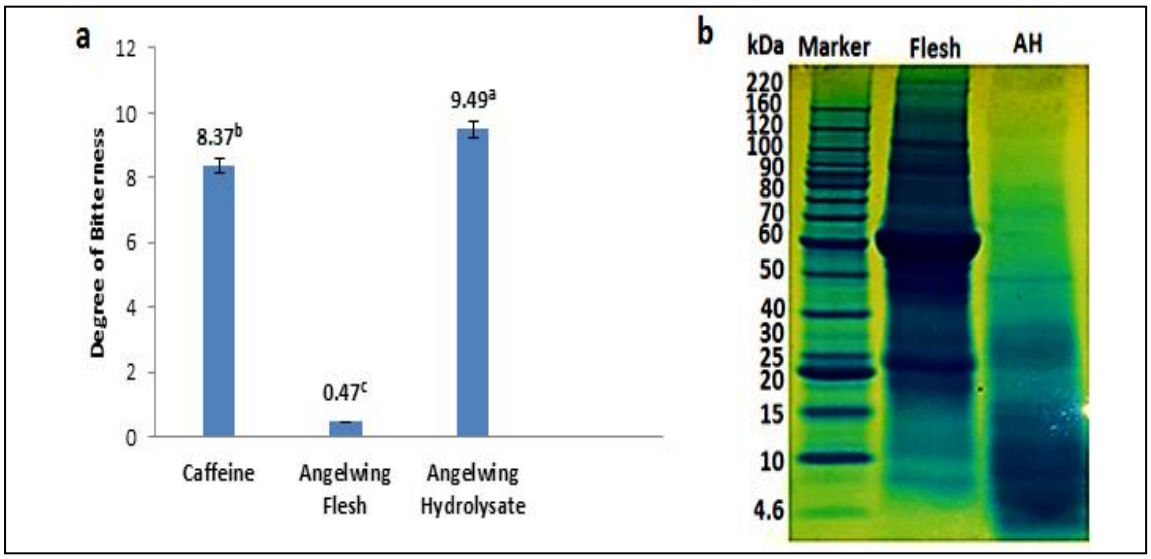

Figure 1. a) Degree of bitterness in caffeine solution, angelwing clam flesh and hydrolysate obtained by Quantitative Descriptive Analysis (QDA) where a, b, c (superscript) are significantly different ($p < 0.05$) and b) Electrophoresis patterns of angelwing clam flesh and hydrolysates produced at pH 6, 45◦C for 2 hours by using bromelain.

Molecular weight distribution of angelwing flesh and hydrolysate

The electrophoresis patterns of angelwing flesh and hydrolysate are shown in Figure 1b. The flesh consists of many clear bands ranging from 9 to 220 kDa compared to angelwing hydrolysate where clear bands were found very distinctly below 50 kDa. The absence of high molecular weight bands above 50 kDa and the fade bands were at 90, 80 and 60 kDa showed that bromelain is capable of degrading most of the larger protein. According to Jefferey et al. [19] the smaller the peptide, the bitter is the hydrolysate. As shown in Figure 2, angelwing hydrolysate had thick bands at 4.6 kDa and below compared to the flesh. This suggested that the bitterness was perceived after the hydrolysis. This result was in line with sensory analysis. According to Kristinsson and Rasco [20], molecular weight with protein below 10 kDa contributed to the bitterness of hydrolysate. While Jeffery et al. [19] stated that bitterness develops when small to medium-sized of hydrophobic peptides <18 kDa were produced after hydrolysis process. This was also supported in previous study by Normal et al. [6], where green muscle hydrolysate produced using alcalase had molecular weight of <3 kDa were bitter. In this study, angelwing hydrolysate had bands below 15kDa that indicated the hydrolysate has smaller peptide compared to the flesh that contribute to bitterness.

Functional group analysis

The peak ranges between 3500 – 3200 cm^{-1} in Figures 2 represent the N-H of amine group. The functional group of angelwing hydrolysate showed high peak at 3385.6 cm^{-1} while the flesh showed a peak at 3305.65cm^{-1}. According to Agrawal and Chiddarwar [21] the functional groups that are usually present in the bitter drugs were amine group. Therefore, this result is in accordance with the sensory analysis which showed that angelwing hydrolysate was bitter due to the presence of the high peak of N-H groups. Besides, Figure 2 showed angelwing hydrolysate has peak bands at 1640 cm^{-1} while the flesh has a peak bands at 1654 cm^{-1} which attributed to the carbonyl (C=0) stretch

vibration centered approximately between 1650 cm^{-1} – 1540 cm^{-1}[22]. These bands indicated the presence of functional compounds strong amide I and II in protein amide group (-$CONH_2$) which this amides of carboxylic acid ($RCONH_2$) were bitter [23].

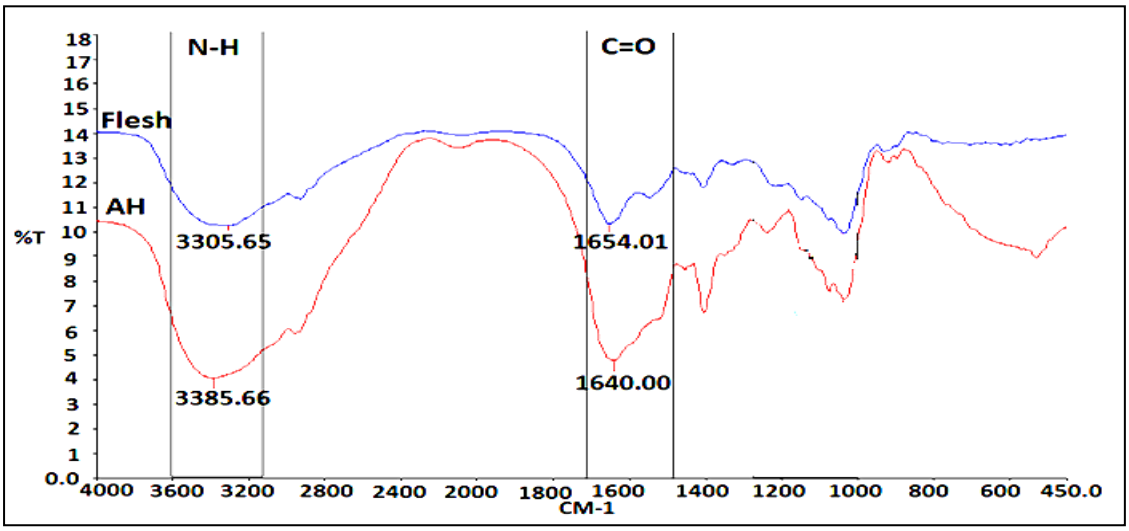

Figure 2. FTIR spectrums of angelwing clam flesh and hydrolysate (AH) produced at pH 6, 45 °C for 2 hours by using bromelain

Protein, fat and water holding capacity

Hydrolysis of angelwing clam increased the protein concentration in hydrolysate. Table 1, showed the hydrolysate contain 74.41% protein, which increased the protein content to 48.28 % more than the flesh. These results were in line with DH where angelwing hydrolysate had high DH (12.10 %).Previous study stated that the higher DH gave higher protein content [24]. This is because protein that solubilized during hydrolysis contained in the layer of supernatant compared to its precipitate.

Table 1. The properties of angelwing clam flesh and hydrolysate produced at pH 6, 45◦C for 2 hours by using bromelain

The properties of sample [a]	Flesh	Angelwing hydrolysate
Protein content (%)	25.91±0.19	74.41±0.35
Fat content (%)	6.43±0.09	3.43±0.11
Water holding capacity (ml/g)	-	4.60±0.25

[a]Mean ± SD from triplicate determination.

Fat content in the angelwing flesh (6.43 %) was higher compared to the hydrolysate (3.43 %). As the hydrolysis proceeds, the muscle cell membranes tended to roundup and form insoluble vesicles leading to the removal of membrane structured lipid [25]. The insoluble fraction (vesicles) was separated from the soluble hydrolysate in the form of pellet by centrifugation and removed prior to spray-drying [26]. Thus higher DH lead to higher fat removal.

The water-protein interaction is important factor for functional properties of proteins in food systems [27]. In this studies water holding capacity on powdered angelwing hydrolysate was 4.60 ml/g (Table 1). According to Amiza et

al. [25] water holding capacity increased with an increased in degree of hydrolysis. Besides, at higher hydrolysis, polar groups such as COOH and NH_2 increased thus gave significant effects on water absorption and tend to exert better water-holding capacity [22]. In this study the functional group analysis showed that NH group peak was higher in angelwing hydrolysate compared to the flesh thus support the finding by Kristinsson and Rasco [28]. Water holding capacity of partly unfolded and hydrolysed proteins is greater than that of the native proteins due to an increase in surface area to mass ratio with an exposure of some previously buried hydrophobic groups [29, 26]. Low-molecular weight peptides from high extent of enzymatic hydrolysis also appeared to be more effective in water-holding capacity than larger size peptides as smaller fragments of peptides are possibly more hydrophilic [30].

Conclusion

Angelwing hydrolysate has a potential to be good source of food ingredient. However the uses of bromelain in the preparation of angelwing hydrolysate resulted in bitter taste. Thus, further studies may need to be carried out using simple technique of debittering which can enhance the application of angelwing hydrolysate in the food industry.

Abstract

The aim of this study was to determine the chemical changes in muscle tissue of shortfin scad during storage at chilled (4 °C) and frozen (-18 °C) conditions for 18 days. The chemical changes were monitored every three days for Thiobarbituric acid (TBA), Peroxide value (PV), Total Volatile Base Nitrogen (TVBN) and Trimethylamine (TMA) content. Results show that there was a significant difference ($p<0.05$) in peroxide and TBA values between chilled and frozen shortfin scad starting from day 3. The highest PV values occured in chilled and frozen shortfin scad at day 12 (1.57 mEq/kg and 1.13 mEq/kg, respectively), and then decreased due to decomposition of hydroperoxides to secondary products such as aldehydes, alcohols and ketones. In contrast, TBA reached the highest values at day 15 for both chilled and frozen shortfin scad. For TVBN content, only the chilled sample shows significant increased ($p<0.05$) with storage time. The TVBN values declined significantly ($p<0.05$) for frozen shortfin scad. The TMA values for both chilled and frozen shortfin scad increased during storage. However, the TMA values increased at a faster rate in chilled compared to frozen shortfin scad. Based on the PV, TBA, TVBN and TMA values, chilled shortfin scad undergoes spoilage at a faster rate compared to the frozen shortfin scad.

Keywords: shortfin scad, thiobarbituric acid, peroxide value, total volatile base nitrogen, trimethylamine

Abstrak

Matlamat kajian ini adalah untuk menentukan perubahan kimia dalam tisu otot ikan selayang semasa penyimpanan pada suhu dingin (4 °C) dan sejuk beku (-18 °C) selama 18 hari. Perubahan kimia dipantau setiap tiga hari melalui ujian Asid Tiobarbiturik (TBA), Nilai Peroksida (PV), Jumlah Bes Nitrogen Meruap (TVBN) dan Trimetilamina (TMA). Hasil kajian menunjukkan terdapat perbezaan ketara ($p<0.05$) nilai peroksida dan nilai TBA antara ikan selayang yang disimpan pada suhu dingin dan sejuk beku bermula dari hari ketiga. Nilai PV tertinggi bagi ikan selayang berlaku pada hari ke 12 (masing-masing 1.57 mEq/kg dan 1.13 mEq/kg) bagi penyimpanan suhu dingin dan sejuk beku, dan kemudian menurun disebabkan penguraian hidroperoksida kepada produk sekunder seperti aldehid, alkohol dan keton. Sebaliknya, TBA mencapai nilai tertinggi pada hari ke 15 untuk ikan selayang yang disimpan pada kedua–dua suhu. Bagi nilai TVBN, hanya sampel dingin menunjukkan peningkatan ketara ($p <0.05$) bagi masa penyimpanan. Nilai TVBN menurun dengan ketara ($p<0.05$) bagi ikan selayang yang disejukbekukan. Nilai TMA untuk ikan selayang yang didingin dan disejukbeku meningkat semasa penyimpanan. Walau bagaimanapun, nilai TMA ikan selayang meningkat pada kadar yang lebih cepat dalam suhu dingin berbanding suhu sejuk beku. Berdasarkan nilai PV, TBA, TVBN dan TMA, ikan selayang yang disimpan pada suhu dingin mengalami kerosakan pada kadar yang lebih cepat berbanding dengan ikan selayang yang disimpan pada suhu sejuk beku.

Kata kunci: ikan selayang, asid tiobarbiturik, nilai peroksida, jumlah bes nitrogen meruap dan trimetilamina

Introduction

Fish is an important source of protein and is increasingly marketed due its health benefit to consumer [1]. Even though fish contains high nutritional content, it is very perishable. Fish is susceptible to biochemical, microbiological, and physico-chemical changes because of the high protein content, essential amino acids and unsaturated fatty acids that can reduce the quality of fish during storage [2].

Lipid oxidation is one of the main causes for the decline in fish quality [3]. The process of oxidation occurs at the double bond and resulted in the formation of short-chain fatty acid, aldehyde or ketone compounds, giving rise to rancidity which can cause a decrease in the quality of fish [4]. Lipid hydroperoxides which is the primary product of lipid oxidation are generally considered not to have a flavour impact. Secondary oxidation compounds, such as aldehydes and ketones derived from breakdown of hydroperoxides and are responsible for rancid flavour and odour [5].

Total volatile base nitrogen (TBVN) and trimethylamine is a general term which includes the measurement of trimethylamine (produced by spoilage bacteria), dimethylamine (produced by autolytic enzymes during frozen storage), ammonia (produced by the deamination of amino-acids and nucleotide catabolites) and other volatile basic nitrogenous compounds associated with fish spoilage. The TVBN is a good indicator in fish quality assessment [6].Chemical analysis has been used to measure the amount of breakdown product derived from enzymatic, bacterial or oxidation activity. Among these, trimethylamine, hypoxanthine, ammonia, formaldehyde and several other breakdown products should be determined in order to evaluate the fish quality [7].

Hence, the objective this study was to determine the chemical changes in muscle tissue of shortfin scad which was monitored based on the thiobarbituric acid, peroxide value, total volatile base nitrogen and trimethylamine contents during storage at chilled (4 °C) and frozen (-18 °C) conditions for 18 days.

Materials and Methods

Raw materials

Shortfin scad was purchased from wet market, Kuala Pilah, Negeri Sembilan, Malaysia and placed in boxes filled with ice and brought to laboratory immediately. Shortfin scad with average weight of 65 – 85 g was eviscerated and cleaned prior to storage in plastic containers. The fish was then stored at chilled (4 °C) and frozen (-18 °C) storage conditions for 18 days and subjected to chemical analysis such as peroxide value, thiobarbituric acid, total volatile base nitrogen and trimethylamine every three days.

Chemical analysis

All the chemicals used were of analytical grade and were obtained from CHEMOLAB Supplies, Seri Kembangan, Selangor, Malaysia.

Peroxide value (PV)

Extraction of the fish oil was done according to method proposed by Razak et al. [8]. Fish oil was extracted using mixture of chloroform and methanol (1:1) followed by evaporation of the solvent. The PV value of fish oil was determined according to AOAC guideline [9]. The results were expressed in terms of milliequivalent of free iodine per kg of lipid.

Thiobarbituric acid (TBA)

The TBA was determined according to Tokur et al. [10] using distillation method. An amount 10 gram of fish muscle was homogenised with 0.2 N hydrochloric acid and distilled using distillation unit (behr Labor-Technik GmbH, Germany). Five mililiter of distillate was pipetted into test tube and 5 mL of TBA reagent was added. The sample was heated in boiling water for 35 minutes and was allowed to cool immediately. The absorbance of the pink solution was read at 538 nm using a single beam spectrophotometer (Genesys 20 Thermo Scientific, USA). The absorbance was measured against a corresponding blank. The results were expressed as mg malonaldehyde per kg sample.

Total Volatile Base Nitrogen (TVBN) and Trimethylamine (TMA)

The TVBN and TMA were determined according to Sallam et al. [11]. An amount 100 g of fish muscle was homogenised with 200 mL 7.5 % (v/v) aqueous trichloroacetic acid solution and centrifuge at 3000 rpm for 5 minutes. The supernatant was filtered through Whatman No.1 filter paper. The TVBN was measured by distillation method. Accurately, 25 mL of fish extracts and 5 mL of 10 % (w/v) sodium hydroxide was poured into Kjedahl flask and distilled for 3 minutes. The distillate was collected into conical flask containing 15 mL of 4 % (v/v) boric acid and 0.04 mL methyl red and bromocresol green indicator. The titration was allowed to run against aqueous 0.05 M sulfuric acid solution. The same experimental procedure of TVBN was used for TMA analysis. The difference in TMA analysis is the addition of 20 mL of 35 % (v/v) formaldehyde into Kjedahl flask. The results were expressed as mg nitrogen per hundred g of sample and calculated using equation 1 [6]:

$$\text{TVBN/TMA} = \frac{14\ (\text{g/mol}) \times a \times b \times 300}{\text{Volume of filtrate}} \quad (1)$$

where, a is defined as volume (mL) of sulfuric acid and b is defined as normality of sulfuric acid

Statistical analysis

All the analysis was performed in triplicate and data were expressed as mean ± standard deviation. Data were analysed using SPSS 15.0. Duncan's multiple-range test was used to determine the difference between means. A significant difference was considered at the level of $p<0.05$.

Results and Discussion

Figure 1 shows the changes of PV, TBA, TVBN and TMA in shortfin scad muscle during chilled (4 °C) and frozen (-18 °C) storage. A significant increased ($p<0.05$) in PV was observed in shortfin scad muscle up to 12 days at both chilled and frozen conditions (Figure 1a). The initial PV was 0.38 mEq/kg and reached up to 1.54 mEq/kg and 1.15 mEq/kg for shortfin scad stored and chilled and frozen temperature, respectively. The decreased in PV was noticeable at day 15 for both conditions. Chaijan et al. [12] reported the decreased in PV occurred with extended storage time due to decomposition of hydroperoxide into aldehydes. The same trend was reported when sardine was stored at 0 °C up to 15 days. From the results, PV increase slowly at both conditions. The release of non-heme iron in fish muscle during prolonged chilled and frozen storage might influence the oxidation process in the fish muscle [12]. Based on Orak et al. [13] the accepted PV to indicate good quality of fish is below 2 mEq/kg. The PV was used to determine the formation of primary oxidation products during the storage period of fish [14]. Lipid oxidation is a process by which molecular oxygen reacts with unsaturated lipids to form lipids peroxide [7].

Thiobarbituric acid (TBA) was used to determine fat oxidation based on total malonaldehyde in fish muscle which is a by-product of lipid oxidation. Figure 1b shows there was significant differences ($p<0.05$) between chilled and frozen shortfin scad started from day 3 where TBA value in chilled condition was 3.05 mg malonaldehyde/kg, while for frozen was 0.25 mg malonaldehyde/kg. The TBA values in shortfin muscle increased from day 12 to day 15 at both storage conditions. The TBA increased from 4.01 mg malonaldehyde/kg to 5.46 mg malonaldehyde/kg at chilled and from 0.69 mg malonaldehyde/kg to 1.06 mg malonaldehyde/kg at frozen storage but decreased at day 18 (4.68 and 0.46 mg malonaldehyde/kg, respectively). The decreased in TBA values might be as a result from interaction of malonaldehyde with other components of fish muscle [13]. The TBA value increased during storage due to breakdown of primary fat oxidation product to secondary oxidation which produce rancid odour [2]. These same trend was reported by Kilinc et al. [15] for sardine when stored at chilled and frozen temperatures. The maximum level of TBA value indicating good quality of frozen fish is 5mg malonaldehyde/kg [15]. Malonaldehyde and fat oxidation are not stable and very reactive towards protein content and amino acid in fish muscle [2]. The TBA value revealed an increase rate of lipid oxidation during chilled condition. It is also important to note that TBA value may not reveal the actual rate of lipid oxidation since malonaldehyde can interact with other components of fish body such as amines, nucleosides and nucleic acid, proteins, amino acids of phospholipids, or other aldehydes that are end products of lipid oxidation and this interaction may vary greatly with species of fish [5].

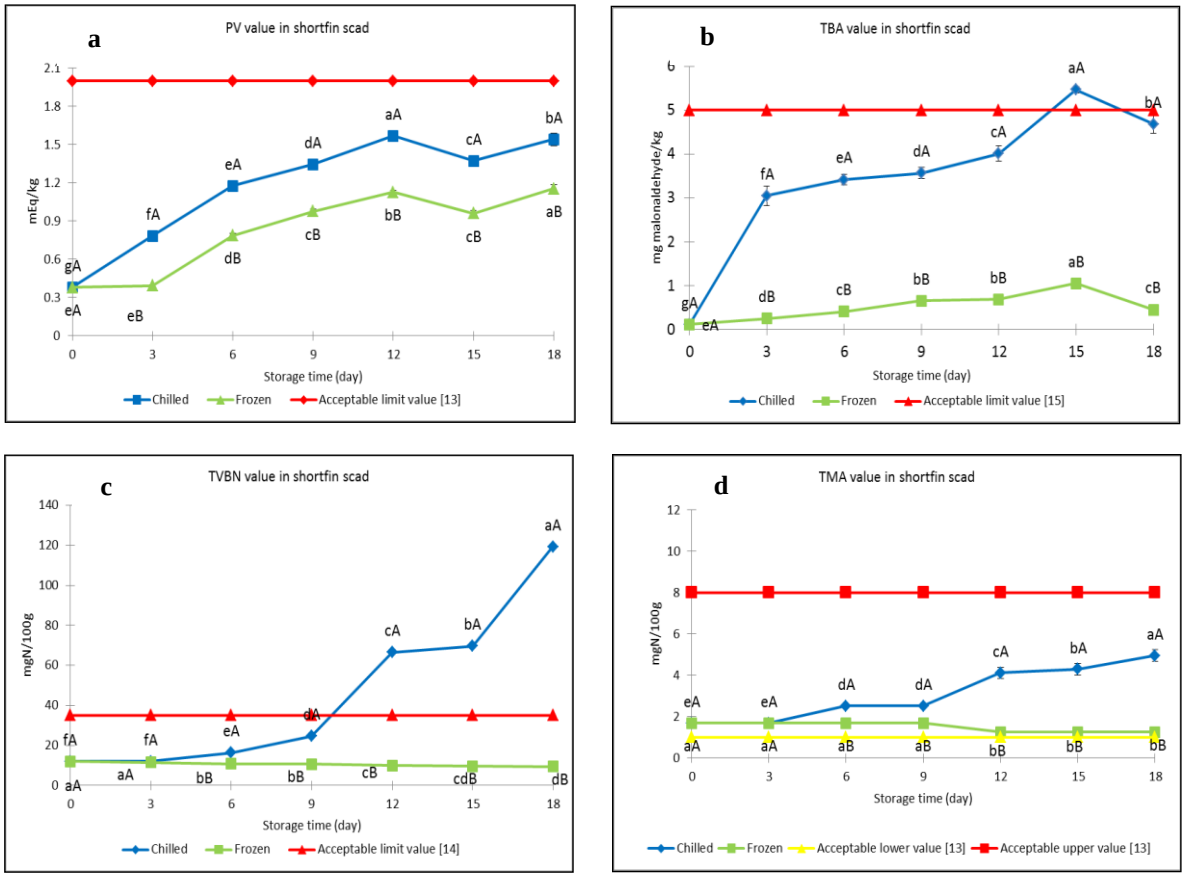

Figure 1. Changes in PV, TBA, TVBN and TMA for shortfin scad muscle at chilled (4 °C) and frozen (-18 °C) storage conditions for 18 days. *Values are expressed as mean (A, B) and (a, b, c) marked with different letters were significantly different at the level of $p<0.05$. Lower case letter indicate the effect of storage period of shortfin scad by day while upper case letter indicate the effect of storage condition at chilled (4°C) and frozen (-18 °C).

Figure 1c indicates there was significant differences ($p<0.05$) in TVBN between chilled and frozen shortfin scad started from day 3 up to day 18. The TVBN value in chilled condition increased rapidly from 11.95 mgN/100 g to 119.37 mgN/100 g and started to reach the upper limit at day 12, which was 66.55 mgN/100 g. This increased trend may be due to the production of amines by autolytic processes. The increment in TVBN in fish muscles during chilled condition is generally associated with activity of microorganisms during later stages of deterioration. This increase may be attributed essentially to ammonia produced from bacterial catabolism of nitrogen-containing compounds [6]. The TVBN are indices of the spoilage level of fish during the storage period [13, 15] and are affected by fish species [6, 16]. Based Ozyurt et al. [14] the TVBN value shall be less than 35mgN/100g to indicate the good quality for fishery product. Furthermore, Ozyurt et al. [14] reported that the TVBN value of red mullet at chilled condition increased from 26.19 mgN/100 g at day 8 to 47.18 mgN/100 g at day 11 of storage. For frozen condition TVBN value decreased slowly from 11.95 mgN/100 g to 9.33 mgN/100 g. Frozen fish quality can be determined from the amounts of TVBN, which is a product of proteolytic changes in fish meat. This decreased trend may due to prevention of changes in fish muscle caused by proteolysis. This same trend was reported by Jezek and Buchtova [17] that throughout the storage period of silver carp, no significant differences ($p>0.05$) in TVBN concentrations were found, and the TVBN concentration ascertained after 12 months of frozen storage was decreased from 15.99 mgN/100 g to 15.73 mgN/100 g. Hence frozen storage of fish is a reliable technique for prevention of changes in fish muscle caused by proteolysis.

Figure 1d reveals that there was significant difference ($p<0.05$) between chilled and frozen shortfin scad started from day 6 for TMA values. The TMA at chilled condition increased slowly from 1.68 mgN/100 g to 4.95 mgN/100 g during storage. For frozen shortfin scad, no significant difference ($p>0.05$) in TMA values was observed. The TMA values from day 0 to day 9 remained unchanged (1.68 mgN/100 g). The TMA value started to increase at day 12 ($p<0.05$) which was 1.25 ± 0.00 mgN/100g and also remained unchanged until day 18 ($p>0.05$). Temperature is very important in influencing TMA value. Natseba et al. [18] indicated that freezing inhibit bacterial activity and TMA accumulation. The TMA formation is due to activity of bacterial enzymatic decomposition of trimethylamine oxide (TMAO) and this occurs to a significant level only during logarithmic phase microbial growth [13]. The level of TMA in fish muscle depends on the species of fish and storage conditions [19]. According Orak et al. [13] TMA must be between 1 mg/100 g and 8 mg/100g to indicate good quality of fish.

Conclusion

The rate of chemical changes in muscle tissues of chilled and frozen shortfin scad differ significantly throughout 18 days of storage. Frozen storage delayed the spoilage of the fish due to oxidative and microbial activities compared to chilled storage. Hence, frozen storage is a reliable technique to preserve the quality of shortfin scad fish.

Abstract

In recent years, increasing consumption of herbal tea is a worldwide trend because of their refreshing taste, positive potential health effect, convenience, abundant resources and also cheaper in price. However, different maturity stages of plants being used as raw material could affect the antioxidant activity, colour and mineral content in herbal tea. Thus, this present study was aimed at determining antioxidant activity, colour and mineral content of herbal tea prepared from *Cosmos caudatus* (*C. caudatus*) leaves at three different maturity stages namely young, mature and old. All prepared herbal tea were analysed for total phenolic content (TPC), total flavonoid content (TFC), ferric reducing antioxidant power (FRAP), 2-2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging assay, colour and mineral content. The results demonstrated that herbal tea prepared from young leaves had strong ($p< 0.05$) antioxidant activity compared to mature and old leaves for all assays tested. Pearson's correlation coefficient also revealed that TPC and TFC exhibited a strong positive correlation with reducing power but negatively correlated with DPPH scavenging activity indicating that these compounds are major contributors to the antioxidant activity. In fact, the darker ($p< 0.05$) colour of *C. caudatus* herbal tea prepared from young leaves relates to their higher antioxidant activity as compared to mature and old leaves. However, *C. caudatus* herbal tea prepared from old leaves showed significantly higher in mineral content compared to mature and young leaves. Hence, it can be concluded that, as maturity increased, antioxidant activity and colour in *C. caudatus* herbal tea decreased and *vice-versa* for mineral content.

Keywords: herbal tea, *Cosmos caudatus,* maturity, antioxidant activity, colour, mineral content

Abstrak

Pada masa kini, peningkatan pengambilan teh herba menjadi ikutan terkini di seluruh dunia kerana rasa yang menyegarkan, mempunyai potensi yang positif terhadap kesihatan, sumber yang mudah didapati dan harga yang murah. Walaubagaimanapun, penggunaan sumber bahan mentah daripada tumbuh-tumbuhan pada peringkat kematangan yang berbeza mempengaruhi aktiviti antioksida, warna dan kandungan mineral di dalam teh herba. Oleh itu, kajian ini bertujuan untuk menentukan aktiviti antioksida, warna dan kandungan mineral di dalam teh herba yang dihasilkan daripada daun *Cosmos caudatus (C. caudatus)* pada tiga peringkat kematangan iaitu daun muda, matang dan tua. Semua sampel teh herba telah dianalisa untuk menentukan jumlah kandungan fenol (TPC), jumlah kandungan flavonoid (TFC), ujian penurunan ferik (FRAP), pemerangkapan radikal bebas 2-2-difenil-1-1pikrilhidrazil (DPPH), warna dan kandungan mineral. Keputusan menunjukkan bahawa, teh herba dihasilkan daripada daun muda mempunyai aktiviti antioksida yang tinggi ($p< 0.05$) berbanding dengan daun matang dan tua untuk semua asai diuji.

Pekali korelasi Pearson juga menunjukkan bahawa TPC dan TFC mempunyai korelasi positif yang kuat dengan pengurangan kuasa tetapi mempunyai korelasi negatif yang kuat terhadap aktiviti pemerangkapan DPPH, menunjukkan bahawa sebatian-sebatian ini merupakan penyumbang utama kepada aktiviti antioksida. Malah, warna teh herba yang dihasilkan daripada daun *C. caudatus* muda yang lebih gelap ($p< 0.05$), menunjukkan tahap aktiviti antioksida yang tinggi berbanding daun matang dan tua. Walaubagaimanapun, teh herba yang dihasilkan daripada daun *C. caudatus* tua menunjukkan kandungan mineral yang tinggi berbanding daun matang dan muda. Kesimpulannya, semakin meningkat kematangan daun, aktiviti antioksida dan warna semakin berkurang dan adalah sebaliknya bagi kandungan mineral.

Kata kunci: teh herba, *Cosmos caudatus,* kematangan, aktiviti antioksida, warna, kandungan mineral

Introduction

Increasing consumption of herbal tea is a worldwide trend because people believed that supplementation of human diet with herbal provides beneficial effects to their health [1]. Herbal tea has been used for health care and diseases prevention for thousands of years in many countries [2]. Moreover, numerous epidemiological studies link herbal tea consumption to a reduction in cardiovascular diseases, cholesterol levels, diabetes, arthritis, osteoporosis and dental carries [3]. Besides giving negligible side effects and mild in action, herbal tea is easy to prepare, richer in resources and cheaper in price [4]. Herbal tea can be prepared with fresh or dried flowers, leaves, seeds or roots, generally by pouring boiling water over the plant parts and letting them to steep for a few minutes [5]. In Malaysia, there are abundant herbal teas produced by Small Medium Enterprise (SME) industry such as misai kucing *(Orthosiphon stamineus)* tea, kacip fatimah *(Labisia pumila)* tea, sabung nyawa *(Gynura procumbens)* tea, kaca beling *(Strobilanthes crispa)* tea, ginger *(Zingiber officinale)* tea and lemongrass *(Cymbopogon)* tea.

Cosmos caudatus (*C. caudatus*) or commonly known as ulam raja by the Malay society has been developed in tea form because of its potential health-promoting properties. *C. caudatus* is used traditionally to reduce body heat, improving blood circulation, as an anti-aging agent, strengthening bone marrow (because of high calcium content), to treat infection associated with pathogenic microorganisms and to promote fresh breath [6]. These beneficial health properties have been attributed to the antioxidant content in *C. caudatus* plant particularly a number of proanthocyanidins that exists as dimers through hexamers, quercetin glycosides, chlorogenic, neo-chlorogenic acid and (+)-catechin [7]. With extremely high antioxidant activity, *C. caudatus* is believed to reduce oxidative stress because these compounds may have direct contribution in the defence against oxidative stress and could be considered to be active metabolites involved in the antioxidant activity in herbs [8]. From the nutritional point of view, other valuable components in herbs like minerals are also major contribution of health properties in *C. caudatus* plant. In fact, it has been established that deficiency of several minerals might induced phenolics and flavonoids content accumulation and supplementation of some minerals might promote antioxidant content [9]. However, maturation stages constitute an important factor in influencing antioxidant activity, chemical composition and mineral content of the *C. caudatus* plant. Usage of young leaves for herbal tea preparation might cause yield losses due to premature stages but usage of mature or old leaves could also possibly results in leaves senescence.

Therefore, this present study is designed to determine antioxidant activity, colour and mineral content of herbal tea prepared from *C. caudatus* leaves at different maturity stages since to the best of our knowledge antioxidant activity, colour and mineral content of these types of tea have not yet been reported.

Materials and Methods

Chemicals

Folin-Ciocalteu reagent, sodium carbonate (Na_2CO_3), sodium nitrite ($NaNO_2$), aluminium chloride ($AlCl_3$), ferric chloride ($FeCl_3$) and sodium hydroxide (NaOH), concentrated nitric acid (HNO_3), hydrogen peroxide (H_2O_2) and Inductively Coupled Plasma (ICP) multi-element standard solution IV were purchased from Merck, Germany. Gallic acid, quercetin, trolox, 2-4-6-tripyridyl-s-triazine (TPTZ), 2-2-diphenyl-1-picrylhydrazyl (DPPH) and ascorbic acid were supplied by Sigma-Aldrich Chemie, Germany. Sodium acetate was purchased from R & M Chemicals, U.K while glacial acetic acid was purchased from Friendemann Schmidt Chemicals, U.K.

Raw material collection and selection

The fresh leaves of 8-week-old *C. caudatus* plant were collected from Durian Tunggal, Malacca, Malaysia. The leaves were divided into 3 groups, classified as young leaves, mature leaves and old leaves as shown in Figure 1. The 8-week-old *C. caudatus* plant was selected based on the previous findings from Mediani et al. [8] where they reported that 8-week-old plant consist higher antioxidant activity compared to 10 and 12-week-old *C. caudatus* plant. Young leaves were selected from the first four tiers where the leaves are still tender, newly emerged and not attaining full expansion. Mature leaves are located at the middle part of *C. caudatus* plant where the leaves are fully developed while old leaves are located at the lower part of the plant and the leaves had showed initial sign of senescence. Mature leaves were selected between the fifth to eighth tiers and old leaves were selected starting from ninth tier and above.

Sample preparation

Each stage of *C. caudatus* leaves was prepared according to the normal procedure of herbal tea preparation by Small Medium Enterprise (SME) industry in Malaysia. The leaves at different maturity stages were dried at 50 °C for 8 hours in cabinet dryer until constant weight. *C. caudatus* herbal tea powder was prepared according to method described by Gião et al. [10] with some modifications. The dried leaves were ground using centrifugal mill, which were then sieved into 1to 2 mm mesh size. Two grams of ground leaves were collected and packed in a sachet of tea bag. The tea bag of *C. caudatus* herbal teas with different maturity stages were infused in 200 mL boiling distilled water for 3 minutes according to method as suggested by Horžić et al. [3]. The infused herbal teas were filtered through a Whatman filter paper No. 41 prior to further analyses.

Figure 1. Selection of 8-week-old *C. caudatus* leaves based on maturity. (A) Young leaves (B) Mature leaves (C) Old leaves

Antioxidant content and antioxidant activity: *Total phenolic content (TPC)*

The total phenolic content in herbal tea sample was determined by using the Folin-Ciocalteu assay [11]. Accurately, 0.5 mL Folin-Ciocalteu reagent, 1.5 mL 7.5 % sodium carbonate and 7.9 mL distilled water were introduced in a test tube containing 0.1 mL sample/standard. The solution was mixed thoroughly and allowed to stand for 2 hours in a dark place. The absorbance at 765 nm was read by using UV-VIS Spectrophotometer (Helios Zeta, Thermo Fisher Scientific, USA). The TPC of herbal tea sample was expressed as mg of gallic acid equivalents (mg GAE)/ml of tea sample.

Total flavonoid content (TFC)

The total flavonoid content was analysed according to method as described by Singh et al. [12]. Accurately 1 mL of sample/standard was diluted with 4 mL distilled water then 0.3 mL 5 % sodium nitrate solution and 0.3 mL 10 % aluminium chloride were added. The mixture was kept for 5 minutes. Then, 2 mL of 1M sodium hydroxide were added to the mixture and the mixture was vortexed thoroughly. The absorbance was measured at 510 nm using Helios Zeta UV-VIS Spectrophotometer. This was calculated as mg of quercetin equivalents (mg QE)/ml of tea sample.

Ferric reducing antioxidant power (FRAP)

The FRAP assay was carried out by the method of Deetae et al. [13]. FRAP reagent was freshly prepared by mixing 300 mM acetate and glacial acetic acid buffer (pH 3.6), 20 mM ferric chloride and 10 mM TPTZ was made to 40 mM HCl at a ratio of 10:1:1. Briefly, 0.1 mL sample/standard was mixed with 3 mL FRAP reagent and 3 mL distilled water. The mixture was incubated in the dark place at 37 °C for 8 minutes and the absorbance at 595 nm was then read using Helios Zeta UV-VIS Spectrophotometer. The total antioxidant activity of samples were determined against a standard of known FRAP value and was expressed as µM of trolox equivalent (µM TE)/ml of tea sample.

2-2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging assay

The DPPH assay was performed according to procedure as described by Nuengchamnong and Ingkaninan [14]. Accurately, 0.1 mL sample/standard was mixed with 2.9 mL of 0.05 mM DPPH in methanol and incubated in the dark at room temperature for 30 minutes. The absorbance of the sample/standard was measured using Helios Zeta UV-VIS Spectrophotometer at 515 nm where methanol was used as blank.

Colour

The colour of *C. caudatus* herbal tea was determined using a CR-400 Chroma Meter (Konica Minolta, Minolta Co., Osaka, Japan) according to Marete et al. [15] method. The Hunter L, a, b Colour Scale was used with L*, a*, b*, C and h^o axes expressing the lightness, redness-greenness, blueness-yellowness, chroma and hue angle respectively. Hue angle is defined by as a colour wheel with red-purple at an angle of 0^0, yellow at 90^0, bluish-green at 180^0 and blue at 270^0.

Mineral content

The mineral content determination was performed based on Pytlakowska [16] procedure. In determining the concentration of selected elements (Ag, Al, Ba, Ca, Cd, Cr, Cu, Fe, K, Mg, Mn, Na, Pb and Zn) in herbal tea, the prepared infused herbal tea was evaporated to near dryness. To the solid residue, 5 mL of concentrated HNO_3 solution and 5 mL of 30 % H_2O_2 solution were added, and sample was again evaporated to near dryness. Then, the residue was dissolved in 10 mL hot water, filtered and filled up to 25 mL with deionized water. Measurements were carried out using the Inductively Coupled Plasma-Optical Emission Spectroscopy (ICP-OES) (Optima 5300 DV, Perkin Elmer Inc., USA) based on the following parameter: autosampler model – AS-93 plus, sample flow rate – 1.5 mL/min, plasma gas flow rate – Ar, 15 l/min, auxiliary gas flow rate – Ar, 0.2 l/min, nebulizer gas flow rate – Ar, 0.65 l/min, back pressure – 75kPa and using both axial and radial plasma view.

Statistical analysis

All experiments were run in triplicates. Statistical analyses were conducted with the Statistical Analysis System (SAS) 9.1.3 software package. Analyses of variance were performed by ANOVA procedures. Significant differences ($p < 0.05$) were determined by least square means comparison.

Results and Discussion

Antioxidant content and antioxidant activity

The results for antioxidant activity for *C. caudatus* herbal tea prepared from three different maturity stages are presented in Table 1. The highest TPC and TFC were obtained from *C. caudatus* herbal tea prepared from young leaves and the values of TPC and TFC ranged from 66.30 to 18.38 mg GAE/ml herbal tea and 203.22 to 72.24 mg GAE/ml herbal tea respectively. In line the declined in TPC and TFC values, FRAP values also significantly decreased as maturity of *C. caudatus* leaves used to prepare herbal tea progressed with the values ranging from 502.21 to 239.18 µM TE/ml herbal tea. In contrast to FRAP values, the IC_{50} values of DPPH scavenging activity increased as maturity of *C. caudatus* leaves increased indicating that young leaves had strong antioxidant activity compared to mature and old leaves. The IC_{50} values of *C. caudatus* herbal tea prepared from young leaves, mature leaves and old leaves were 1055.37, 1409.99 and 2408.84 µg/ml respectively.

Table 1. Antioxidant activity in herbal tea prepared from *C. caudatus* leaves at different maturity stages. Values are expressed as mean ± standard deviation. Means with different letters are significantly different ($p < 0.05$)

Herbal tea sample	Assay			
	TPC (mg GAE/ml herbal tea)	TFC (mg QE/ml herbal tea)	FRAP (µM TE/ml herbal tea)	DPPH (µg/ml)
Young leaves	66.30 ± 5.20^{a}	203.22 ± 15.90^{a}	502.21 ± 21.18^{a}	1055.37 ± 42.38^{c}
Mature leaves	36.55 ± 2.77^{b}	124.55 ± 6.22^{b}	332.00 ± 8.81^{b}	1409.99 ± 103.17^{b}
Old leaves	18.38 ± 2.46^{c}	72.24 ± 3.04^{c}	239.18 ± 19.19^{c}	2408.84 ± 365.36^{a}

In previous study of antioxidant activity by Mediani et al. [8] and Siddiqui et al. [17], they believed that, the reduction of antioxidant activity with the advanced maturity might be contributed to the conversion of phenolics and flavonoids to other secondary metabolites such as sugar by enzyme action. The declining of secondary metabolites in mature and old leaves reduced the ability of plant defense systems to neutralise the overproduction of ROS which stimulates by aging process, eventually cause senescence of plant tissues. This is supported by Sreelatha and Padma [18], where they observed the components of both the enzymatic and the non-enzymatic antioxidant system correlates well with oxidative stress during senescence and plant development. Another possible reason could be due to the stoppage of new biosynthesis of the secondary metabolites during maturation [19]. In contrast, most of these new biosynthesis are took place at the early stages of plant growth which provide highest phenolic and flavonoid compounds in young leaves to react with ROS produced [20]. The ROS will be chelated and disengaged by the antioxidant in young leaves from participating in the initiation of oxidative stress [17] where the ROS will be converted to a more stable products and the radical chain reaction will be terminated [21]. Therefore, this will provide protection of plant tissues against pests and disease [22].

Interrelationship between antioxidant activity (FRAP and DPPH) with TPC and TFC using Pearson's correlation coefficient are shown in Table 2. The correlations between antioxidant activity with TPC and TFC are mainly due to their redox properties, hydrogen donors and singlet oxygen quenchers [18]. From the table, it revealed that FRAP had strong correlation with TPC and TFC with the values are $R = 0.9967$ and $R = 0.9980$ respectively while DPPH shows negative correlation with TPC ($R = -0.9224$) and TFC ($R = -0.9288$). This is in agreement with study by Baros et al. [23], where they highlighted the negative correlation between DPPH with TPC and TFC reflected that the sample with highest antioxidant content exhibited higher antioxidant activity and lower IC_{50} while sample with lowest antioxidant content exhibited lower antioxidant activity and higher IC_{50}. Therefore, from correlations, phenolic and flavonoid compounds might contribute to the antioxidant activity in *C. caudatus* herbal tea prepared from leaves at three different maturity stages. According to Villa-Rodríguez et al. [24] phenolics and flavonoids had been devoted to their antioxidant activity due to their ability to reduce *in vitro* free radical formation and to

scavenge free radicals which are responsible for inhibiting or preventing the deleterious consequences of oxidative stress [18].

Table 2. Pearson's correlation coefficient (R) between antioxidant activities of *C. caudatus* herbal tea prepared from leaves at different maturity stages

	FRAP	**DPPH**
TPC	0.997 ± 0.0018^{a}	-0.922 ± 0.058^{a}
TFC	0.998 ± 0.0024^{a}	-0.929 ± 0.060^{a}

Colour

Correlations between colour (L* - lightness, a* - redness/greenness, b* - yellowness/blueness, C - Chroma intensity, h^{o} - hue angle tonalities) of *C. caudatus* herbal tea prepared from leaves at three different maturity stages with antioxidant activity were significantly strong (Table 3). As expected, *C. caudatus* herbal tea prepared from young leaves has significantly darker and yellower (L* - 37.39, h^{o} – 97.46) than mature (L* - 36.48, h^{o} – 98.04) and old leaves (L* - 35.26, h^{o} – 99.45) since herbal tea prepared from young leaves has significantly highest antioxidant activity. It also showed that as maturity of *C. caudatus* leaves used to prepared herbal tea increased, the C value decreased significantly from 7.31 to 4.42. From the results in Table 3, colour of *C. caudatus* herbal tea prepared from three different maturity stages give negative value for a* and positive value for b* which contributed to greenness and yellowness characteristic.

These findings is corroborated by Alves et al. [25] where they confirmed that index of antioxidant power had influenced by colour of the sample in which generally they found their light-coloured honeys have lower antioxidant activity while their dark-coloured honeys have huge amount of antioxidant activity. Similar results have been reported by others literatures, for examples Harbourne et al. [11] found that the meadowsweet extracts were significantly darker and redder than willow extract due to higher total phenolic content in meadowsweet extracts while Schwarz et al. [26] found that the increase of red and yellow tonalities of Sherry wines present an extraordinarily high antioxidant activity. Marete et al. [15] believed that, the dark colour of sample is possibly due to higher total phenolic content in the sample. Futhermore, Alvarez-Suarez [27] explained that the colour intensity of sample is related to pigments such as flavonoids and carotenoids. In fact, the increasing of the colour intensity seems to be related to an increase of the concentration of these compounds. Therefore, the results of this study seem to confirm that antioxidant activity is directly affecting *C. caudatus* herbal tea colour.

Table 3. The colour values of herbal tea prepared from *C. caudatus* leaves at different maturity stages. Values are expressed as mean ± standard deviation. Means with different letters are significantly different ($p < 0.05$)

Herbal tea sample	**Colour**				
	Lightness (L*)	**Greenness (a*)**	**Yellowness (b*)**	**Chroma (C)**	**Hue angle (h^{o})**
Young leaves	35.25 ± 0.20^{c}	-0.95 ± 0.06^{c}	7.25 ± 0.08^{a}	7.31 ± 0.07^{a}	97.46 ± 0.53^{b}
Mature leaves	36.48 ± 0.15^{b}	-0.82 ± 0.04^{b}	5.79 ± 0.19^{b}	5.85 ± 0.16^{b}	98.04 ± 0.47^{b}
Old leaves	37.39 ± 0.28^{a}	-0.73 ± 0.03^{a}	4.36 ± 0.17^{c}	4.42 ± 0.18^{c}	99.45 ± 0.62^{a}

Mineral content

Most people believed that consumption of herbal tea can enhance human health. Hence, determination of mineral content is also important in herbal tea due to their responsibilities in providing medicinal and nutritional properties. According to Tokalıoğlu [28], the quantitative estimation of various mineral content is important in determining the effectiveness of the medicinal plants used in herbal tea preparation in treating various diseases and also to

understand their pharmacological action. Therefore this study involved the evaluation of some important macroelements (Ca, K, Mg and Na) and microelements (Ag, Al, Ba, Cd, Cr, Cu, Fe, Pb and Zn) in *C. caudatus* herbal tea prepared from three different maturity stages and results are shown in Table 4. Interestingly, among all the *C. caudatus* herbal tea samples, *C. caudatus* herbal tea prepared from old leaves had significantly higher minerals like Ca, Mg, Na (macroelements) and Ba, Cd, Cr, Cu, Mn (microelements) compared to mature and young leaves. However, for K (macroelements) Ag, Al, Fe, Pb, Zn (microelements) there were no significant difference among samples.

Table 4**.** Mineral content of *Cosmos caudatus* herbal tea sample prepared from leaves at different maturity stages. Values are expressed as mean ± standard deviation. Means with different letters are significantly different ($p<0.05$)

	Mineral (µg/ml of tea)	**Herbal tea prepared from young leaves**	**Herbal tea prepared from mature leaves**	**Herbal tea prepared from old leaves**
macro elements	Ca	13.5958 ± 0.9019^{c}	31.4583 ± 1.0670^{b}	51.0042 ± 4.6142^{a}
	K	94.5375 ± 1.7852^{a}	96.4208 ± 9.1021^{a}	98.6583 ± 5.1247^{a}
	Mg	8.3117 ± 0.2564^{b}	9.3179 ± 0.2905^{b}	13.6108 ± 1.0186^{a}
	Na	0.5463 ± 0.0055^{c}	0.6070 ± 0.0343^{b}	0.6830 ± 0.0253^{a}
microelements	Ag	0.0035 ± 0.0006^{a}	0.0035 ± 0.0001^{a}	0.0045 ± 0.0007^{a}
	Al	0.0310 ± 0.0035^{a}	0.0311 ± 0.0024^{a}	0.0318 ± 0.0010^{a}
	Ba	0.0052 ± 0.0003^{c}	0.0076 ± 0.0002^{b}	0.0149 ± 0.0021^{a}
	Cd	0.0073 ± 0.0006^{b}	0.0070 ± 0.0010^{b}	0.0011 ± 0.0020^{a}
	Cr	0.0321 ± 0.0031^{b}	0.0394 ± 0.0044^{ab}	0.0433 ± 0.0036^{a}
	Cu	0.0313 ± 0.0024^{b}	0.0319 ± 0.0004^{b}	0.0388 ± 0.0036^{a}
	Fe	0.0458 ± 0.0007^{a}	0.0454 ± 0.0044^{a}	0.0500 ± 0.0022^{a}
	Mn	0.0310 ± 0.0018^{b}	0.0675 ± 0.0012^{a}	0.0730 ± 0.0046^{a}
	Pb	0.0012 ± 0.0006^{a}	0.0011 ± 0.0012^{a}	0.0012 ± 0.0006^{a}
	Zn	0.0534 ± 0.0027^{a}	0.0533 ± 0.0083^{a}	0.0534 ± 0.0012^{a}

This result might be due to the location of old leaves in which they are located near to the roots, where generally, the roots contain the highest levels of elements followed by vegetative tissues [28]. This is because the plants readily assimilate the elements through the roots, which will dissolved in water and occur in ionic forms [29]. Another possible reason is that, the growth of tissues plants also profoundly influence the minerals absorption, in which as tissues mature, volume of water uptake by cell increased which may dilute the internal concentration of minerals, thus increase absorption activity [30]. This is supported by Flowers and Yeo [31] where they reported that the volume of mature cell increase with time, providing mineral-storage capacity at constant concentration. However, some authors believed that, the decrement in concentration of mineral content might be directly related to

the accumulation of antioxidant content in plants. Sulaiman et al. [32] reported that an imbalance of minerals in plants would change the content of flavonoids, a proven antioxidant compounds. For example, as found by some researchers, the deficiency of several minerals such as K, Mg, and Mn induced the flavonoid accumulation in plants [5, 32]. Therefore, this study revealed that, as maturity of *C. caudatus* leaves used to prepared herbal tea increased, it may increase some of mineral content due to decrement in antioxidant activity.

Table 5. Dietary Reference Intake (DRI) and percentage contribution of herbal tea prepared from *C. caudatus* leaves prepared from different maturity stages per 200 ml in a day

Mineral		**Recommended Dietary Allowances, RDA / Adequate Intake, AI (19 – 50 years old)(mg)**	**Percentage contribution of *C. caudatus* herbal tea per 200 ml in a day (%)**
Macro elements	Ca	Men = 1000* Women = 1000*	Men = 0.22 – 1.02 Women = 0.22 – 1.02
	K	Men = 4700 Women = 4700	Men = 0.40 – 0.42 Women = 0.40 – 0.42
	Mg	Men = 400 Women = 310	Men = 0.41 – 0.68 Women = 0.54 – 0.88
	Na	Men = 1500 Women = 1500	Men = 0.007 – 0.009 Women = 0.007 – 0.009
Micro elements	Ag	Men = na Women = na	Men = na Women = na
	Al	Men = na Women = na	Men = na Women = na
	Ba	Men = na Women = na	Men = na Women = na
	Cd	Men = na Women = na	Men = na Women = na
	Cr	Men = 35* Women = 25*	Men = 18.29 – 24.86 Women = 25.60 – 34.80
	Cu	Men = 900 Women = 900	Men = 0.70 – 0.87 Women = 0.70 – 0.87
	Fe	Men = 8 Women = 18	Men = 0.12 – 0.13 Women = 0.05 – 0.06
	Mn	Men = 2.3* Women = 1.8*	Men = 0.27 – 0.63 Women = 0.34 – 0.81
	Pb	Men = na Women = na	Men = na Women = na
	Zn	Men = 11 Women = 8	Men = 0.10 Women = 0.13

Note : Ordinary type represents source from [33] while bold type represents source from [34], Italic type represents the unit in µg, Value with asterisk (*) represent Adequate Intake (AI), na = not available

Macroelements (Ca, K, Mg and Na) were detected in highest concentration in all three *C. caudatus* herbal tea samples compared to microelements. This is because bioavailability of the elements depends on the bonding with the constituents of the soil [29]. In addition, as confirmed by Devlin and Witham [30] that Ca, K, Mg and Na are major elements that contributed to the plant growth. Nevertheless, the contribution of mineral content in herbal tea

on the average dietary intake must be taken into consideration. The consumption rate of *C. caudatus* herbal tea should be under strict control and should not exceed Dietary Reference Intake (DRI) since exceeding some of these minerals might cause toxicity. Based on the results obtained, none of the macro and microelements was exceed the DRI based on Recommended Dietary Allowances (RDA) or Adequate Intake (AI) as in Table 5 [33,34]. Besides, the toxic elements such as Ag, Al, Ba, Cd and Pb were detected in low concentration. Therefore, depending on the mineral content in *C. caudatus* herbal tea prepared from three different maturity stages, these herbal tea may be a good source of essential minerals.

Conclusion

In conclusion, usage of *C. caudatus* leaves for tea production at different maturity stages, affects the antioxidant activity, colour and mineral content of herbal tea. *C. caudatus* herbal tea prepared from young leaves possessed significantly strong antioxidant activity compared to mature and old leaves in all assays tested. Strong positive Pearson's correlations between reducing power with TPC and TFC, and strong negative Pearson's correlation between DPPH scavenging activity with TPC and TFC showed that phenolic and flavonoid compounds are major contributions to the antioxidant activity in *C. caudatus* herbal tea at all maturity stages studied. The darker colour of *C. caudatus* herbal tea prepared from young leaves compared to other two leaves relates to the high phenolic and flavonoid content in young leaves. In contrast, *C. caudatus* herbal tea prepared from old leaves exhibited significantly high in Ca, Mg, Na for macro elements and Ba, Cd, Cr, Cu Mn for microelements compared to mature and young leaves.

EFFECT OF EDIBLE LIPID-CHITOSAN FILM FORMING DISPERSION ON POSTHARVEST LIFE OF GUAVA STORED AT CHILLED TEMPERATURE

(Kesan Serakan Filem Lipid-Kitosan Ke Atas Jangka Hayat Jambu yang Disimpan Pada Suhu Sejuk)

Abstract

An edible lipid-chitosan film forming dispersion (FFD) was developed to delay ripening of guava. Four percent (v/v) of palm stearin (PS) and palm kernel olein (PKOo) in ratios of 0:100, 25:75, 50:50, 75:25 and 100:0 were added to a chitosan solution base and applied on guava by dipping technique. Surface appearance, weight loss, firmness, carbon dioxide, oxygen and ethylene concentrations were evaluated every 3 days during 31 days of storage at chilled temperature (5±2 °C). An application of FFD on guava significantly ($p < 0.05$) delayed chilling injury, reduced weight loss, maintained firmness, slowed down respiration and ethylene production as compared to uncoated guavas. PS:PKOo (75:25) coating was able to form compatible blends and showed good moisture and gas barrier properties when applied on guava surface, resulting in increased postharvest life of guava.

Keywords: guava, film forming dispersion, chitosan, palm stearin, palm kernel olein

Abstrak

Serakan filem lipid-kitosan yang boleh dimakan telah dihasilkan untuk melambatkan proses jambu untuk ranum. Empat peratus (v/v) stearin sawit dan olein isirong sawit dengan nisbah 0:100, 25:75, 50:50, 75:25 and 100:0 telah ditambah ke dalam larutan kitosan dan diaplikasikan ke atas jambu dengan menggunakan teknik celupan. Permukaan buah, kehilangan berat, kekerasan, kepekatan gas karbon dioksida, oksigen dan etilena telah dikaji setiap 3 hari sepanjang 31 hari penyimpanan di dalam suhu sejuk (5±2 °C). Penggunaan salutan ke atas jambu telah melambatkan kerosakan buah, mengurangkan kehilangan berat, mengekalkan kekerasan, melambatkan proses respirasi dan penghasilan etilena jika dibandigkan dengan jambu yang tidak disalut. Salutan PS:PKOo (75:25) telah menghasilkan campuran yang sesuai dan menunjukkan sifat-sifat penghalang air dan gas yang baik apabila diaplikasikan ke atas permukaan jambu dan telah meningkatkan jangka hayat jambu.

Kata kunci: jambu, serakan lapisan filem, kitosan, stearin sawit, olein isirong sawit

Introduction

Guava is an excellent source of vitamin C and is grown for both the domestic and exports markets. However, guava ripens rapidly during transportation and storage, thus often requiring rapid shipment in order to prolong postharvest life and decrease its respiration rate. Many postharvest diseases such as anthracnose, mucor rot and aspergillus rot can also limit the commercialisation of guava. Although refrigeration can increase the shelf life of guava, it adds cost and may cause chilling injury. Thus, coating the fresh fruit appears to be a cheaper alternative to preserve guava.

Materials that can be used to make edible coating includes polysaccharides [1], proteins [2] and lipids [3], or a combination of these materials [4]. Most hydrophilic films are excellent gas, aroma and lipid barriers with good mechanical properties, while hydrophobic films have high moisture resistance with poor mechanical properties. Improved film or coating performance can be obtained when hydrophilic and hydrophobic compounds are mixed.

Chitosan as a coating material has good antimicrobial [4] and gas barrier properties [5] with its tough and flexible film [6]. To date, there is no research data on the study of functional properties of chitosan based dispersion incorporated with palm stearin and palm kernel olein (PKOo). It can thus be combining with palm stearin and PKOo to provide moisture barrier properties, as PKOo has limited application because of excessive foaming due to medium-short chain fatty acids [7]. Results obtained from this study can be used to assess the potential of lipid-chitosan coating, besides diversifying the use of palm stearin and PKOo.

Materials and Methods

Chemicals and raw materials

Raw materials used were guava, chitosan, palm kernel olein and palm stearin. Refined, bleached and deodorised medium-hard palm stearin (IV: 33, SMP: 54) and palm kernel olein (IV: 24, SMP: 25) were obtained from Cargill Specialty Fats (M) Sdn. Bhd, Pelabuhan Klang, Malaysia. Guavas (*Psidium guajava* L.) at maturity index 2 were obtained from FAMA Chui Chak, Bidor, Perak, Malaysia. High molecular weight chitosan, with a deacetylation degree of 85 % was purchased from Saintifik Zener Sdn. Bhd, Kuala Lumpur, Malaysia. Glacial acetic acid (99.5 %), glycerol and Tween 80 were supplied by Merck Sdn Bhd, Petaling Jaya, Selangor, Malaysia.

Preparation of film forming dispersion (FFD)

An amount 3 g of chitosan was dispersed in an aqueous solution of glacial acetic acid (0.75 % v/v), at 40 °C. Tween 80 at 0.1 % (v/v) and 0.5 % of glycerol were added and the FFD was shaken by using an orbital shaker at 350 rpm, 65 °C. After 8 hours, palm stearin and palm kernel olein were added at 4 % (v/v) in ratios of 0:100, 25:75, 50:50, 75:25 and 100:0 to the chitosan solution. These mixtures were then emulsified at room temperature using a high speed homogeniser at 13500 rpm for 4 minutes [8].

Coating application

Guavas of uniform size, shape and colour and without any signs of mechanical damage or fungal decay were selected. The fruits were washed and immersed in 10 mg/L of sodium hypochlorite solution for 5 minutes and then drained prior to coating. The fruits were dipped in the FFD for 15 seconds [9] while control samples were dipped in distilled water. Fruits were allowed to dry at ambient temperature on trays, and were stored at chilled temperature (5 ± 2°C) and 80 – 95 % relative humidity for 31 days. Temperature and relative humidity were measured by using a Temperature and RH logger (HOBO U12 – O13) [10].

Physicochemical analyses

Physicochemical analyses of guava were performed at 1, 4, 7, 10, 13, 16, 19, 22, 25, 28, and 31 days of storage.

Determination of surface appearance

Guavas samples were assessed by visual inspection on overall appearance, colour changes and acceptability at 1, 4, 7, 10, 13, 16, 19, 22, 25, 28, and 31 days of storage. Pictures of guavas were captured by using a digital camera (Canon IXUS HS115). Guava that showed any sign of fungal development was considered decayed [11].

Determination of weight loss

Weight loss was determined by weighing the samples on a laboratory digital balance (A & D HF-300, Japan) after air-drying the FFD and thereafter at 1, 4, 7, 10, 13, 16, 19, 22, 25, 28, and 31 days of storage. Results were expressed as percentage loss of moisture based on the original mass [12].

Determination of firmness retention

Firmness of guava was determined by using a TA-XT2i Texture Analyzer (Stable Microsystems, Surrey, UK) equipped with a compression cell of 10 kg and a cylindrical and flat acrylic probe of 1 cm in diameter, 10 mm/s crosshead speed, a 1 N force and a 75 % strain to penetrate the fruit. Determination was performed at three different

parts of guavas. Results were expressed as percentage of firmness retention (compression force at storage time was compared to force on day 1) [13].

Determination of gas concentrations

Carbon dioxide and ethylene concentrations were measured by enclosing each fruit in a 0.5 L plastic jar, hermetically sealed with a rubber stopper for one hour. One milliliter of the atmosphere in the plastic jar was withdrawn into a gas tight syringe. Carbon dioxide and ethylene concentrations were quantified using a Gas Chromatograph (Agilent 78990A) equipped with Thermal Conductivity Detector (TCD) and Flame Ionization Detector (FID), respectively. Column and detector temperatures were 55 ˚C and 180 ˚C, respectively. The carrier gas was helium at a flow rate of 50 ml/min. Results from the means of triplicate determinations were expressed in ppm (10). Oxygen concentration was analysed in the same headspace gas by using a carbon dioxide and oxygen analyzer (Mocon Pac Check 200). Results from the means of triplicate determinations were expressed as percentage of oxygen [14].

Statistical analysis

SPSS for Windows Evaluation (version 15.0) was used for all statistical analyses. Analysis of variance and Duncan multiple comparisons were performed at 5 % confidence level.

Results and Discussion

Surface appearance

The overall acceptability of fruit was evaluated based on the appearance of fruit skin. The results obtained on the visual appearance of guavas are shown in Figure 1. The uncoated guava showed sign of chilling disorder at day 13 with the chilling injury becoming more prominent as storage progressed. Lipid-chitosan coating (PS:PKOo 75:25) delayed the chilling injury of guava by shifting the chilling disorder to day 22 of storage. The coating delayed disease development and retarded the ripening process. The intensification of chilling injury during storage of guava was also observed by Gonzalez-Aguilar et al [15]. Meanwhile, Vargas et al [9] reported that surface moisture loss could be responsible for the darker colour of fruits's skin.

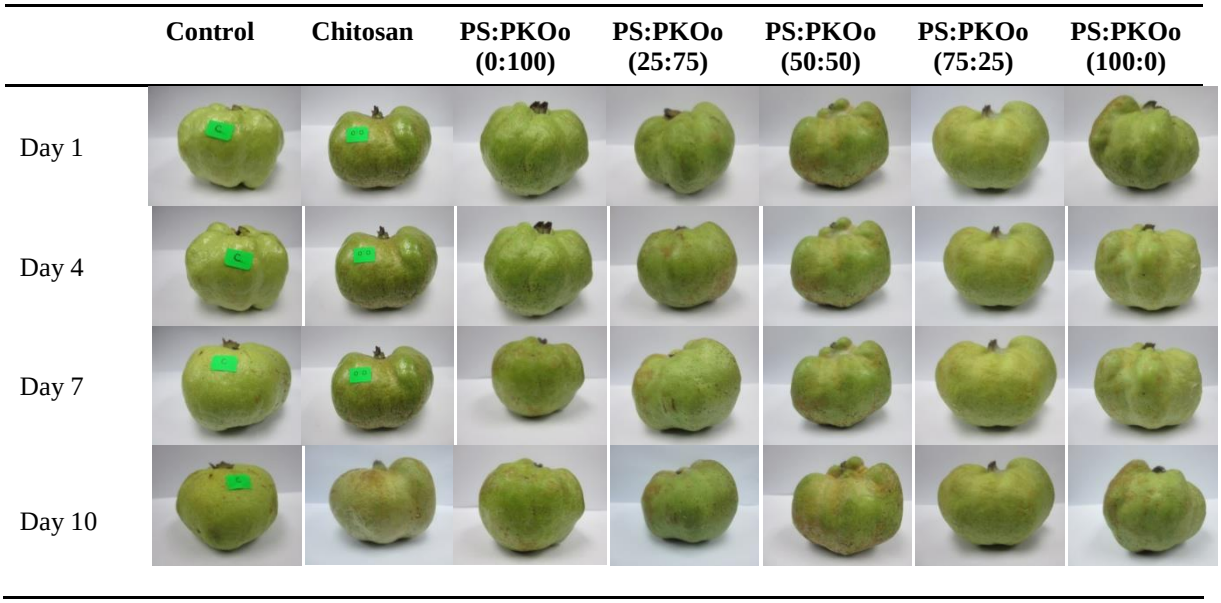

Figure 1. Appearance of seedless guavas stored at chilled temperature

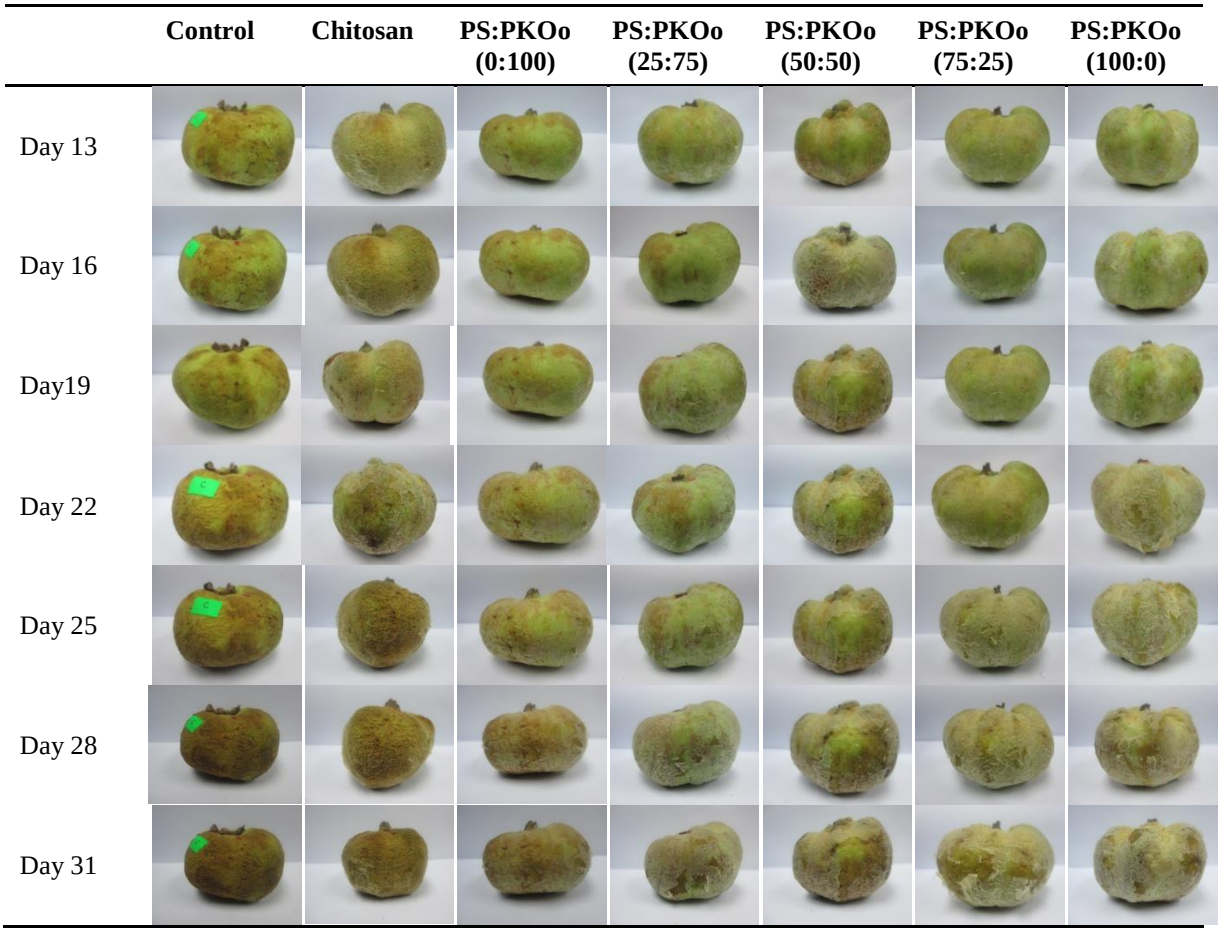

Figure 1 (cont'd). Appearance of seedless guavas stored at chilled temperature

Weight loss

Figure 2 shows the increases in weight loss of both coated and uncoated guavas. The results obtained showed that chitosan coating significantly reduced the weight loss of guava. Similar results were also observed with chitosan coating on sliced mango fruit at chilled temperature [5]. In this study, lipid-chitosan coatings exhibited smaller weight loss as compared to chitosan coating, with PS:PKOo (75:25) coated guava showing the lowest percentage of weight loss. This phenomenon happened probably due to the optimum interaction of PS and PKOo with chitosan during the drying process.

In this study, lipid-chitosan coatings showed good moisture barrier properties due to the combination of PS and PKOo. The lipids gave better protection on moisture loss of the seedless guava hence slowing down the weight loss of fruits. These results agreed with the findings of other researchers who reported that coatings made from lipids have good water vapour barrier properties. This is because lipids are not miscible with water, hence water is retained and shrinkage of fruits is prevented [16].

Firmness retention

Results on firmness retention of guavas are shown in Figure 3. Firmness of guava coated with chitosan coating decreased slower compared to uncoated guava because the chitosan coating provided the barrier to gases in the fruit. Lipid-chitosan coating could retain the firmness of guava better than chitosan coating alone, because the incorporation of lipid into chitosan coating was able to provide both moisture and gas barrier properties. PSPKOo

(75:25) coating appeared to be the best formulation in preventing the loss of water vapour and maintained the firmness of seedless guavas. Yaman and Bayoundurh [17] reported that the decrease of oxygen and increase in carbon dioxide concentrations reduced the activity of enzyme that is responsible for texture loss, hence allowing the retention of fruit firmness.

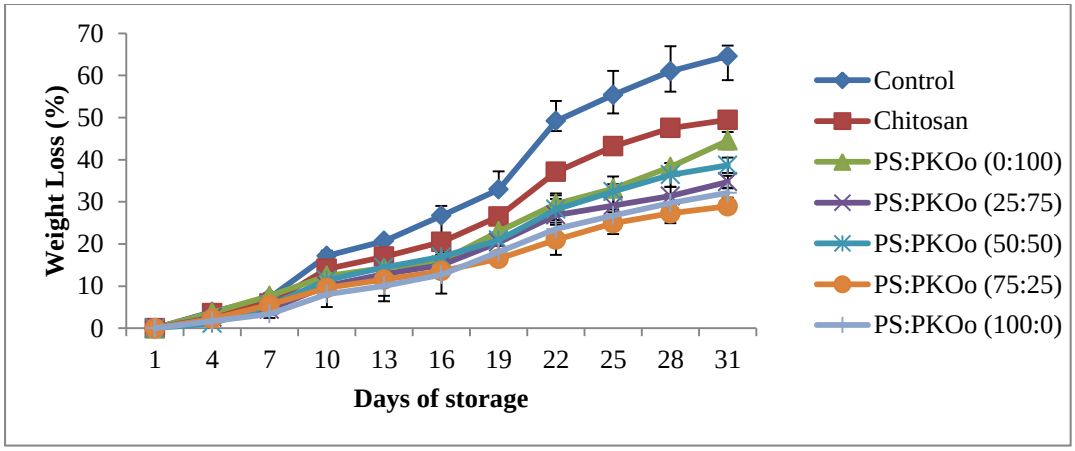

Figure 2. Weight loss of seedless guavas during storage at chilled temperature

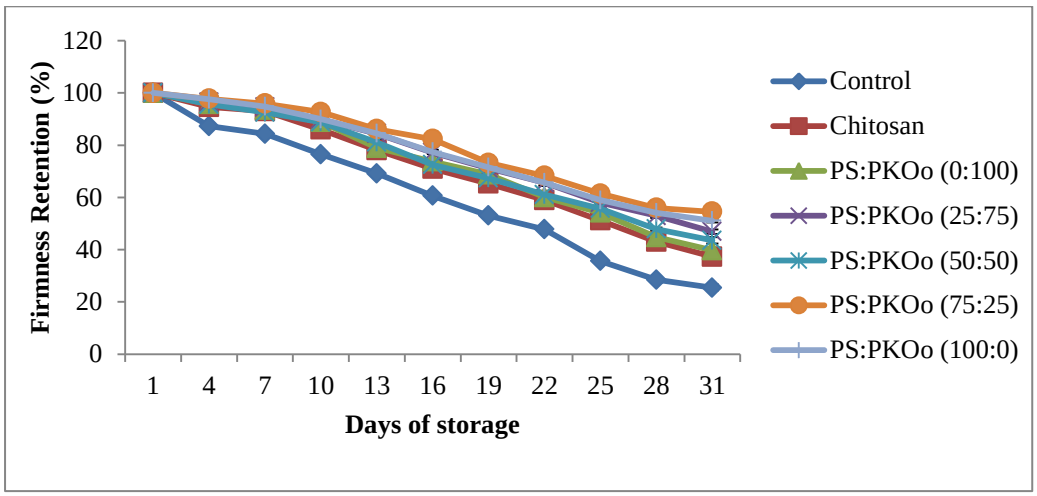

Figure 3. Firmness retention of seedless guavas during storage at chilled temperature

Ethylene concentration

Figure 4 shows the ethylene production of guavas during storage at chilled temperature. Chilled storage is one of the methods used to delay fruit maturation by reducing respiration and synthesis of ethylene, which cause maturation. The ethylene production during ripening of guava exhibited a typical climacteric pattern of respiration for climacteric fruits. The uncoated guava reached the climacteric peak at day 13 while chitosan coated guava reached the climacteric peak after day 16.

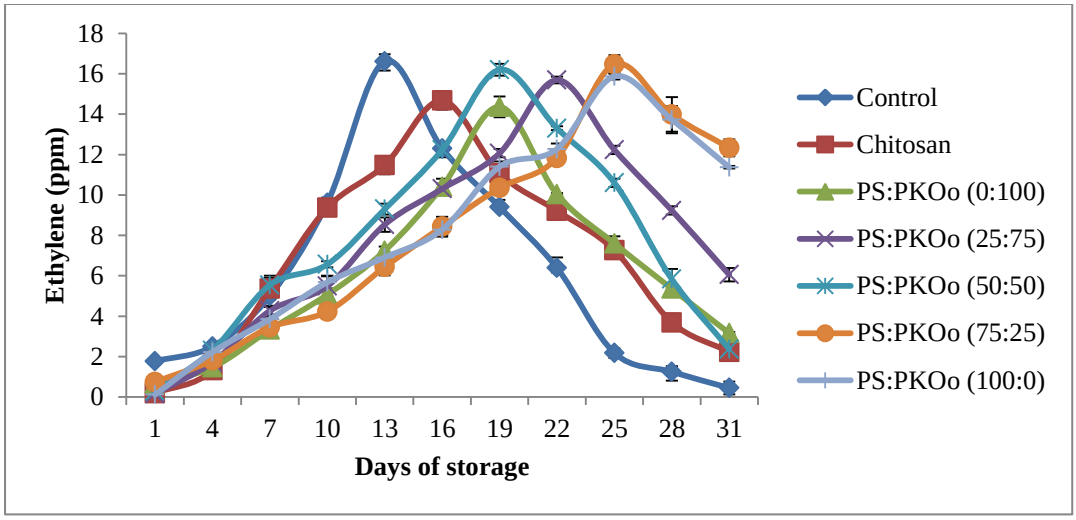

Figure 4. Ethylene concentration of seedless guavas during storage at chilled temperature

The amount of ethylene release for guavas that were coated with chitosan coating, PS:PKOo (0:100), PS:PKOo (25:75), PS:PKOo (50:50), PS:PKOo (75:25) and PS:PKOo (100:0) increased with storage time and reached the highest values of 14.67 ppm, 14.36 ppm, 15.69 ppm, 16.20 ppm, 16.47 ppm and 15.87 ppm, respectively. Ethylene production decreased gradually after reaching the climacteric peaks. The decrease in ethylene concentration was probably due to the emergence of chilling injury on the fruit surface. Guavas that were coated with PS:PKOo (75:25) and PS:PKOo (100:0) shifted the climacteric peak of uncoated guava from day 13 to day 25. The results showed that both coatings showed greater gas barrier properties compared to the other coatings.

Carbon dioxide and oxygen concentrations

Figure 5 presents the concentration of carbon dioxide throughout chilled storage of guava. Coated guavas showed significantly lower amount of carbon dioxide than the uncoated guavas during chilled storage.

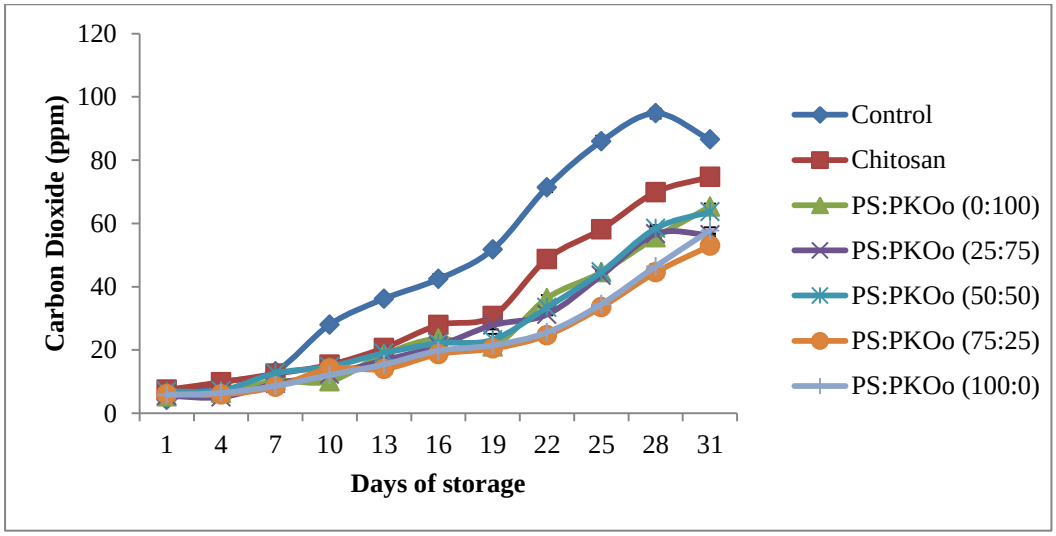

Figure 5. Carbon dioxide concentration of seedless guavas during storage at chilled temperature

Application of lipid-chitosan coatings could control the production of carbon dioxide by the guava, with PS: PKOo (75:25) coating showing the lowest amount of carbon dioxide throughout the 31 days of storage. All the guavas showed increases in carbon dioxide concentration which agrees with the increase in the metabolic activity of guava. Carbon dioxide in internal tissue of fruits should be decreased to control the ripening process [18]. Carbon dioxide concentration is related to tissue senescence and cell breakdown [19]. The reduced rate of respiration in coated guava might be correlated with a delayed senescence and reduced susceptibility to decay. Hence, the chitosan-lipid coatings can be used to modify the internal atmosphere, thereby delaying the ripening of fruits.

As the amount of carbon dioxide is important to be decreased, the amount of oxygen surrounding the fruit should be maintained in order to control fruit ripening. The results of oxygen concentration (Figure 6) showed that all coatings had significantly prevented the decline of oxygen concentration surrounding the coated guavas ($P < 0.05$) indicating a delay in fruit ripening as compared to the control. This indicates that coating acted as an oxygen barrier that limited the acceleration of aerobic respiration. According to Singh and Pal [14], the increase in oxygen concentration in storage atmosphere accelerated the loss of green colour in guava.

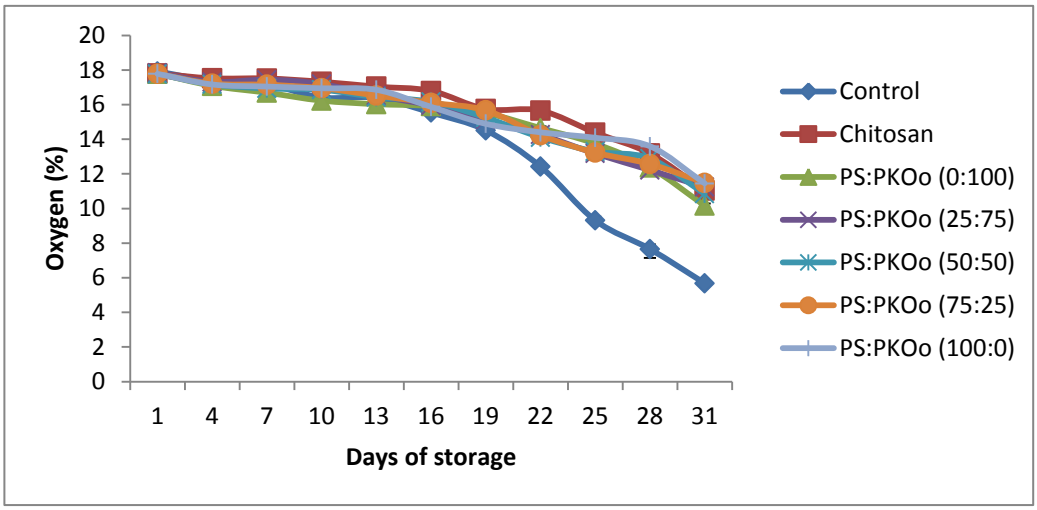

Figure 6. Oxygen concentration of seedless guavas during storage at chilled temperature

Conclusion

Application of edible lipid-chitosan coating was able to improve the quality and shelf-life of seedless guavas throughout 31 days of storage at chilled temperature. Results showed that the edible lipid-chitosan coating reduced the weight loss and increased the firmness retention. The coatings decreased ethylene and oxygen concentrations indicating a delay in fruit ripening as compared to the control. Application of lipid-chitosan coating showed beneficial effects on guava as it slowed the increases in carbon dioxide concentration of fruits. Overall, PSPKOo 75:25 was the best coating formulation as it showed good moisture and gas barrier properties. Hence, PS and PKOo showed potential to be used as cheap sources of edible coating.

Although the FFD in this study was found to have good moisture and gas barrier properties, chemical degradation of FFD could occur during storage. In order for this FFD to be used in commercial applications, future research is necessary to find methods to protect the FFD from degradation during storage. Incorporation of other types of lipids such as fatty acids or palm olein can be used as alternative lipids to improve FFD properties. Sensory evaluation can also be conducted to determine the perception of consumers towards the appearance and overall acceptability of coated fruits.

Abstract

Turmeric is one of the prominently use herbal plants due to its diverse beneficial effects especially in Indian medicine. The rhizome part of the turmeric contains valuable compounds which have been said to owe its antimicrobial effects, anti-cancer, anti-inflammatory and enhance wound healing. Due to its short-life span and perishable properties, the conversion of the rhizome into turmeric extract is desirable. Several methods have been used for extraction such as Soxhlet extraction and pressurized liquid extraction (PLE). However, these techniques are tedious, laborious, time consuming and involves the usage of toxic organic solvent, of which safeness of the end product is doubtful. In this study, a rapid, reliable and green extraction method of supercritical fluid extraction (SFE) and ultrasonic assisted extraction (UAE) were used. SFE without modifier has resulted in 0.0006 mg/100 g of curcuminoids concentration and 5.62 % of yield (dry weight basis). UAE using ethanol was able to produce significantly the highest yield (6.40 %, dry weight basis) and the highest curcuminoids concentration (0.1020 mg/100 g). However, SFE was able to produce extract that contain significantly higher major volatile compounds; tumerone, ar-turmerone and curlone. Therefore, this study proves that both extraction methods were able to produce high quality turmeric extract.

Abstrak

Kunyit merupakan tumbuhan herba yang terkenal disebabkan kebaikannya yang pelbagai terutamanya dalam perubatan masyarakat India. Bahagian rizom kunyit mengandungi sebatian berkhasiat yang dipercayai mempunyai kesan antimikrobial, anti-kanser, anti-keradangan dan juga mempercepatkan kadar penyembuhan luka. Disebabkan kitar hidup yang singkat dan ciri mudah rosak yang terdapat pada kunyit, maka penukaran rizom kunyit kepada ekstrak kunyit adalah amat wajar. Beberapa kaedah pengekstrakan telah digunakan seperti pengekstrakan Soxhlet dan pengekstrakan cecair bertekanan (PLE). Bagaimanapun, kaedah-kaedah tersebut amat rumit, sukar, mengambil masa yang lama serta melibatkan penggunaan pelarut organik bertoksik yang menyebabkan keraguan terhadap tahap keselamatan produk iaitu ekstrak kunyit. Di dalam kajian ini, kaedah pengekstrakan yang pantas, dipercayai serta mesra alam iaitu pengekstrakan cecair supergenting (SFE) dan pengekstrakan ultrasonik berbantu (UAE) telah digunakan. SFE tanpa bahan pengubahsuai telah menghasilkan 0.0006 mg/100 g kepekatan kurkuminoids dan 5.62 % hasil ekstrak kunyit (berdasarkan berat kering). UAE menggunakan etanol telah menghasilkan hasil ekstrak yang ketara tinggi (6.40 %, berdasarkan berat kering) dan nilai kepekatan kurkuminoids tertinggi iaitu 0.1020 mg/100 g. Walaubagaimanapun, SFE telah menghasilkan ekstrak yang mengandungi sebatian meruap yang

signifikan tingginya iaitu tumerone, ar-turmerone dan curlone. Maka, kajian ini membuktikan bahawa kedua-dua kaedah berupaya menghasilkan produk ekstrak kunyit yang berkualiti tinggi.

Kata kunci: Pengekstrakan cecair supergenting, Pengekstrakan ultrasonik berbantu, peratusan hasil, kurkuminoids, sebatian meruap

Introduction

Turmeric (*Curcuma longa* L.) is an economically important plant for the production of turmeric based products. It is well known worldwide as one of the major source of drug both in modern and traditional system of medicine for possessing number of biomolecules credited with myriad of therapeutic activities [1]. The extract of turmeric rhizome consisting of a light (volatile oil) fraction and a heavy (non volatile) fraction of yellowish-brown colour [2]. Ar-tumerone is the marker compound in turmeric oil which contributes to its camphory note [3,4] while curcumin, demethoxycurcumin and bisdemethoxycurcumin and the non-volatile compounds of turmeric acts as colouring agent [2].

Currently, there are several extraction techniques have been used to extract turmeric oils and bioactive components from plant such as Soxhlet distillation, hydrodistillation, solid-liquid extraction and blending. Some of the disadvantages of using these techniques are long extraction time, large consumption of toxic organic solvents and low percentage of oil yield. Supercritical fluid extraction (SFE) and ultrasonic assisted extraction (UAE) are recent techniques that can overcome the shortcomings of traditional methods. SFE has advantages such as environmental friendly as it does not use toxic organic solvent, able to select thermally labile compounds under mild conditions and has a shorter time. Other than SFE, UAE is also one of the alternative methods to replace conventional extraction processes [5]. In most previous literatures, UAE has been known as a tool that assists in the extraction of medicinal compounds or different vegetal materials [6]. It has many advantages such as it can improve extraction efficiency, extraction rate and reduce extraction temperature [7]. UAE also utilizes the ultrasound during extraction that can disrupt the biological cell wall, and thus facilitating the release of contents [8].

In this present work, the efficiency of SFE and UAE techniques on the extraction of *Curcuma longa* L. extract been compared based on the percentage yield, curcuminoids concentration and volatile components.

Materials and Methods

Chemicals and raw materials

Ethanol used for GC-MS and UV-Visible spectrophotometer was of analytical grade and purchased from Merck Sdn. Bhd (Selangor, Malaysia). Fresh turmeric rhizomes (*Curcuma longa* L.) were bought from a local cultivator in Selangor, Malaysia.

Preparation of dried turmeric powder

Fresh turmeric rhizomes were cleaned with water and sliced about 3 mm thick and air-dried at room temperature until the moisture content reached to 10 – 15 % as reported by Zaibunnisa et al. [9]. Samples were then ground and sieved to 2 mm size and were put into sealed plastic bags at chilled temperature until further analysis.

Determination of moisture content

The moisture content of dried turmeric rhizome was determined using AOAC method [10].

Extraction methods

Supercritical Fluid Extraction (SFE)

Extractions were carried out using supercritical carbon dioxide (SC-CO_2) laboratory scale extraction system (TST, Ltd., Taiwan). Turmeric sample was extracted with supercritical carbon dioxide in a continuous-flow extractor. For the first cycle, sample (211 g) of the dried turmeric powder was accurately weighed and packed inside 1 L extraction vessel and fixed into extraction oven. Incoming and outgoing tubes were attached at the bottom and upper part of the vessel, respectively. Liquid CO_2 from the cylinder was passed, delivered and compressed to 22.5 Mpa by air compressor and heated up to the supercritical condition. For the second cycle, similar process was done, but, for the second cycle, organic modifier (ethanol) was introduced into the system by mixing 211 grams of sample

with 50 mL of ethanol before putting it inside the vessel. Operating temperature was set to 40 °C for each cycles. The temperature was measured using a thermocouple device. Both extraction cycles; with and without modifier, were conducted at similar pressure and temperature. The extract was collected in a glass vial and kept for further analysis.

Ultrasonic Assisted Extraction (UAE)

Ultrasonic assisted extraction was performed in an ultrasonic water bath with temperature control. Dried turmeric powder (50 grams) were placed in two glass beaker and mixed with 400 mL water and ethanol, respectively. Samples were exposed to ultrasonic waves for pre-defined time periods (15 minutes) consecutively at 40 °C with frequency about 40 kHz until extraction fully completed. The extracts were collected, filtered and dried using rotary evaporator for further analysis.

Extraction yield

The weight of the extracts were obtained and used for the calculations of the percentage yield as carried out by Zaibunnisa et al. [9].

Curcuminoids concentration

The curcuminoids concentration in the turmeric extract was determined by spectrophotometric method according to Haiyee et al. [11]. Turmeric extract (0.002 g) was dissolved with 10 mL of 95 % ethanol. The absorbance was measured at 425 nm using 95 % ethanol as blank. Curcuminoids concentration in the sample was quantified using standard calibration curve of pure curcumin, concentration of 0.25, 0.50, 0.75, 1.00 and 1.25 ppm. Triplicate analysis were carried out for each treatment.

Volatile compounds

The volatiles were analyzed using Agilent Technologies 6890N Network GC system equipped with an Agilent Technologies 5973 Inert Mass Selective Detector and Agilent 7683 Series Injector [9]. A HP-5MS column was used. GC-MS detection was done using an electroionization system with ionization energy of 70 eV in the 50 to 550 a.m.u. mass range. Column temperature was increased from 60 °C to 325 °C at the rate of 10 °C/min. Initial and final time were 6 minutes and 10 minutes, respectively. Helium was used as the carrier gas, at a flow rate of 1.0 mL/min in splitless mode. Identification of the compounds was done by comparing their relative retention indices and mass spectral fragmentation pattern with those of NIST data inbuilt library provided along with instrument [9].

Results and Discussion

Extraction yield

Percentage yield of *Curcuma longa* L. extract obtained from different extraction methods are shown in Table 1 below.

Table 1. Percentage yields of turmeric extract obtained from different extraction techniques

Extraction techniques	**Yield (%)**	
Ultrasonic assisted extraction	Ethanol 6.40 ± 0.80^{a}	Water 4.72 ± 0.66^{b}
Supercritical fluid extraction	Without modifier 5.62 ± 0.19^{a}	With modifier 5.21 ± 0.46^{a}

Data shown as mean ± S.D. from triplicate determinations, Superscript $^{a\ b}$ within row showed significant differences at (p<0.05)

Generally, extraction using ultrasonic assisted extraction (UAE) were able to produce higher yield compared with supercritical fluid extraction (SFE). Ethanol and water have been chosen as the extraction solvents for ultrasonic study due to the fact that they are safer in handling as compared to other organic solvents like methanol and acetone.

For ultrasonic assisted extraction, with ethanol resulted in significantly higher yield compared to with water. This is due to the function of ethanol that acts as a liquid which received the ultrasonic waves with high intensity and forms bubbles or cavities [7]. This acoustic cavitation, when triggered close to solid surfaces like dried turmeric powder will make the cavity collapse and thus produces high-speed jets of liquid that impact strongly to the solid surface [7] of dried turmeric powder. Eventually, it will lead to pitting and errosion [7] of the dried turmeric surface and easier for the materials being extracted out from the plant matrices. However, the yield obtained from UAE with water was lower which might be due to insolubility of some turmeric compounds in water.

Since SFE only extracting the volatiles, the yield obtained was significantly lower than UAE. This probably due to extraction can be done without the usage of modifier as the carbon dioxide used in the SFE itself will be able to extract out all compounds at supercritical point whereby the temperature and pressure set has reaches the critical point. This was also supported by previous research done by Chang et al. [5], which reported that the use of supercritical carbon dioxide was possible without the addition of co-solvents. Carbon dioxide have been widely used as extracting solvent for SFE as it is non-toxic, available abundantly, non-explosive, can be removed easily from the final extract without leaving a solvent residue [7] and the most important is the low viscosity of carbon dioxide enables it to penetrate into the matrix of the analyte to reach the material being extracted and extract out the material selectively [7]. Additionally, Daneshvand et al. [7] reported that the most effective factors for SFE were pressure and extraction time. The addition of modifier in SFE method did not have an apparent effect to the process since the result showed only slight differences between SFE, with or without modifier. The volume of modifier added to the dried sample might be too little for the modifier to aid in the extraction process. Chang et al. [5] supported this claimed by stated that larger solvent volume can dissolve target components more effectively and thus increase the extraction yield.

Curcuminoids content

The curcuminoids concentration was higher in UAE in comparison to SFE as shown in Table 2.

Table 2. Curcuminoids concentrations (mg/100g) in the extracts obtained from SFE and UAE

Extraction techniques	**Curcuminoids concentration (mg/100g)**	
Ultrasonic assisted extraction	Ethanol 0.1020 ± 0.0013^{a}	Water 0.0014 ± 0.0012^{b}
Supercritical fluid extraction	Without modifier 0.0006 ± 0.0002^{a}	With modifier 0.0005 ± 0.0002^{a}

Data shown as mean ± S.D. from triplicate determinations, All values were standardised to 100 g of turmeric extract, Superscript $^{a\,b}$ within row showed significant differences at ($p<0.05$)

Extraction using UAE has affected to the high concentration of curcuminoids since the fascinating role of UAE is it can avoids degradation of bioactive compounds by quenching of radical in aqueous system and also its ability to achieve targeted hydroxylation of polyphenolics like curcuminoids by potential use of the radical sonochemistry [12]. Results also indicated that curcuminoids concentration is the highest when extracted using UAE with ethanol which was 0.1020 mg/100g. These results correlate well with the findings by Wakte et al. [13] and Li et al. [14] which reported that ethanol gave the highest curcuminoids content among different extraction solvents as more compounds will be dissolved in a polar organic solvent.

Carbon dioxide, the non-polar extracting solvent for SFE causes curcuminoids to only slightly soluble in it. The non-polarity and poor solvation power of SFE-CO_2 causes the failure to quantitate extraction of polar analytes from solid matrices [7]. Although SFE can alter carbon dioxide properties to behave either as a polar or non-polar solvent depending on pressure and temperature employed [7], by subjecting it to the supercritical fluid state and extract certain classes of compounds easily [15], however, it can be concluded that the temperature and pressure used in this study might be not sufficient enough to fully extracted the targeted curcuminoids based on the result presented.

According to Herrero *et al*., [16], the solubility of target compounds in supercritical fluid is strongly influenced by the properties of solvent such as density whereby the properties of solvent are greatly influenced by pressure and temperature.

Volatile compounds composition

Traditionally, volatile compounds of turmeric extract were obtained by hydrodistillation techniques which require long extraction times and causes heat-sensitive volatile compounds easily be destroyed [17]. While solvent extraction of plant materials causes safety hazards in term of the toxic solvent residue in the extract and also may lead to oxidation of aroma of the volatile compounds, especially in the presence of air [17].

The chemical components present in the turmeric extract were identified and presented in Table 3, according to their order of elution from a HP-5MS column. Compounds identification was based on NIST library.

Table 3. Volatile compounds of *Curcuma longa* L. identified from turmeric extract

Volatile compounds	Extraction techniques			
	SFE (modifier)	SFE	UAE (Ethanol)	UAE (Water)
	Relative proportion (area %)			
β-cymene	0.58	n.d.	n.d.	n.d.
β-caryophyllene	n.d.	0.23	n.d.	n.d.
ar-curcumene	0.70	0.55	0.33	n.d.
α-zingiberene	1.15	2.09	1.26	n.d.
ar-turmerone	21.50	10.84	6.84	n.d.
Turmerone	36.14	45.68	33.87	n.d.
Curlone	22.30	21.27	13.92	n.d.
Cuparene	n.d.	0.55	n.d.	n.d.
β-bisabolane	0.21	0.28	0.17	n.d.
β-sesquiphellandrene	1.38	1.74	1.01	n.d.
β-farnesene	0.60	1.74	n.d.	n.d.

n.d. = not-detected

Ten compounds were identified in turmeric extract obtained from SFE, nine compounds for SFE with modifier and seven compounds for UAE with ethanol while no compound was detected for UAE with water. Major compounds found using those techniques were ar-turmerone, turmerone and curlone, while the minor compounds presented using those methods were α-zingiberene, β-sesquiphellandrene, ar-curcumene and β-bisabolane, except for SFE with and without modifier, of which β-farnesene was also detected. In addition, β-cymene was also detected in the extract of SFE with modifier.

The result for this current studies is in accordance with the result obtained from Singh et al. [18] which studied the chemical compositions of four different species of turmeric and they found out that the rhizome of *C. longa* contain mostly sesquiterpinoids and its major constituents are ar-turmerone, β- bisabolene, ar-turmerol, zingiberene, β-caryophyllene while 1,8-cineole was not present. Some volatile compounds such as 1,8-cineole was not present in the extract and this might be due to its low boiling point as well as high volatility characteristics which resulted in their loss during sample preparation like cutting and grinding steps [19] and post-treatment of the extract such as solvent removal using rotary evaporator. Though the major compounds found were similar among them, the composition of each volatile compound was differed based on the percentage area. This is in agreement with the report from Li et al. [14], which stated that different extraction methods gives variation in the contents of volatile compounds.

Most of the compounds for SFE extract show higher percentage area composition than SFE with modifier extract, for instance, SFE contains 45.68 % of turmerone while SFE with modifier extract contains only 36.14 % of turmerone. For UAE technique, only UAE with ethanol reported the presence of volatile compounds but in small percentage area as compared to SFE extract. It is clearly show that SFE will be able to produce more volatile compounds with high percentage area. Extraction techniques that uses organic solvent like ethanol contains lacks of volatile compounds composition due to the losses of the compounds during evaporation process of the solvents [3]. UAE using water as extracting solvent shows the absence of volatile compound since removing of water by evaporation takes longer time and requires high boiling point of water which leads to the losses of more volatile compounds than UAE with ethanol because ethanol was evaporated faster than water. Acoustic cavitation of UAE during vibration also has the probability to cause the loss of light fraction of volatile compounds from dried turmeric material.

Conclusion

Ultrasonic assisted extraction (UAE) was able to produce worthy *Curcuma longa* L. extract in term of high percentage yield and high curcuminoids content. While supercritical fluid extraction (SFE) was also able to produce worthy *Curcuma longa* L. extract based on the volatile compounds present. Both techniques have been chosen as no toxic organic solvent involves in the extraction. In this regard, it can be concluded that a selection of extraction techniques to obtain turmeric extract is dependent on the proposed use of the extracts whether it is based on percentage yield of oleoresin, curcuminoids concentration or volatile compounds composition.

Abstract

Solid acid composites $CsH_2PO_4/NaH_2PO_4/SiO_2$ with different mole ratios of CsH_2PO_4 and NaH_2PO_4 to SiO_2 were synthesized and characterized. Preliminary infrared measurements of CsH_2PO_4 and its composites indicated that hydrogen bonds breaking and formation were detected between 1710 to 2710 cm^{-1}, while the rotation of phosphate tetrahedral anions occurred between 900 and 1200 cm^{-1}. The superprotonic transition of $CsH_2PO_4/NaH_2PO_4/SiO_2$ composite was identified at superprotonic temperatures between 230 and 260 °C, under atmospheric pressure. This study reveals higher conductivity values for composites with higher CsH_2PO_4 (CDP) content. Solid acid composite CDP 613 appeared as the composite with the highest conductivity that is 7.2 x 10^{-3} S cm^{-1} at 230 °C. Thermal stability of the solid acid composites such as temperature of dehydration, melting and decomposition were investigated. The addition of NaH_2PO_4 lowers the dehydration temperature of the solid acid composites.

Keywords: solid acid, conductivity, thermal analysis, caesium dihydrogen phosphate, fuel cell

Abstrak

Asid pepejal komposit $CsH_2PO_4/NaH_2PO_4/SiO_2$ dengan nisbah mol CsH_2PO_4 kepada SiO_2 dan NaH_2PO_4 kepada SiO_2 yang berbeza telah disintesis dan dicirikan dalam ujikaji ini. Pencirian awal sinar inframerah menunjukkan bahawa pemecahan dan pembentukan ikatan hidrogen dikesan antara 1710 cm^{-1} dan 2710 cm^{-1}, manakala putaran anion tetrahedron fosfat berlaku diantara 900 cm^{-1} dan 1200 cm^{-1}. Fasa peralihan berkonduktiviti tinggi bagi asid pepejal komposit $CsH_2PO_4/NaH_2PO_4/SiO_2$ telah dikenal pasti antara suhu 230 hingga 260 °C, di bawah tekanan atmosfera. Nilai kekonduksian proton adalah lebih tinggi bagi komposit yang mempunyai kandungan CsH_2PO_4 (CDP) yang lebih tinggi. Asid pepejal komposit CDP 613 telah muncul sebagai komposit dengan kekonduksian tertinggi iaitu 7.2 x 10^{-3} S cm^{-1} pada suhu 230 °C. Kestabilan terma asid pepejal komposit seperti suhu dehidrasi, takat lebur dan penguraian telah dikenal pasti melalui analisis termogravimetri dan kalorimeter imbasan perbezaan. Penambahan NaH_2PO_4 merendahkan suhu dehidrasi asid pepejal komposit.

Introduction

Solid acids emerged as a potential solid electrolyte for fuel cell applications due to its high proton conductivity, also known as superprotonic conductivity as the conductivity values increases by 2 to 3 orders of magnitude at intermediate temperatures between 100 to 250 °C, accompanied by phase transition [1]. Solid acids are defined by the basic chemical formula $M_aH_b(XO_4)_c$ where M is a monovalent or divalent metal cation, XO_4 is a tetrahedral oxy-anion, and a, b, c are integers [2]. Solid acids caesium dihydrogen phosphate, CsH_2PO_4 (CDP) and caesium

hydrogen sulphate, $CsHSO_4$ (CHS) have high conductivity values of 2.2 x 10^{-2} S cm^{-1} at 240 °C [3, 4] and 10^{-2} S cm^{-1} at 141 °C [1], respectively. They are comparable to Nafion®, a perfluorosulfonic acid polymer with conductivity value ranging from 9 x 10^{-3} S cm^{-1} to 1.2 x 10^{-1} S cm^{-1} [1, 5] between 80 °C and 100 °C [6], which has been commercialized for application in proton exchange membrane fuel cells (PEMFC), direct methanol fuel cell(DMFC) [7] and micro DMFC [8] due to its stability and robustness.

The disadvantage of Nafion membrane is that humidification is needed during operation of the fuel cell, hence limit the operating temperature to about 100 °C. This escalates the issues of catalyst inefficiency and intolerance to carbon monoxide associated with PEMFC working at low temperatures. Therefore, solid acid emerged as a potential alternative to Nafion as it is able to operate without hydration at higher temperatures, which lowers the operating costs and eliminate the issues of catalyst inefficiency due to carbon monoxide poisoning associated with PEMFC working at low temperatures [9].

It has been found that solid acids with sulphates (SO_4) and selenates (SeO_4) gradually decompose in hydrogen-rich surroundings [10], producing H_2S and H_2Se that are poison to the Pt catalyst at the anode [11, 12] and is further accelerated by the presence of anode catalyst [1]. CHS reacts in hydrogen-rich surroundings to produce H_2S such as in Equation 1.

$$2CsHSO_4 + 4H_2 \rightarrow Cs_2SO_4 + 4H_2O + H_2S \quad (1)$$

Studies have been focusing on CDP [3, 4, 13, 14] due to its stability in hydrogen-rich surroundings. Solid acid is mixed with another solid acid and/or a hygroscopic oxide to produce a solid acid composite with higher conductivity values and improved thermal properties and stability. Two or more solid acids are mixed to widen the temperature range of superprotonic conductivity and induce superprotonic conductivity in solid acids without superprotonic conductivity at atmospheric pressure [15]. Martsinkevich and Ponomareva [16] in the study of CDP partially substituted with sodium dihydrogen phosphate, NaH_2PO_4 (SDP) found that mixed salt solid acid $Cs_{1-x}Na_xH_2PO_4$ with x value up to 0.2 increases the low temperature conductivity of CDP up to 2 orders of magnitude. This study investigates the effect of adding SDP into the CDP/SiO_2 composite. Addition of hygroscopic oxides such as silica (SiO_2), ZrO_2, TiO_2 and Al_2O_3 produces solid acid composites which are more robust and less brittle [2, 15]. The hydrophilic property of SiO_2 enhance proton conductivity of the solid acid composite CDP/SiO_2 [17, 18] and the structure of SiO_2 matrix in the composites of CDP/Al_2O_3 [15] and CDP/SiP_2O_7 [19] enhance the thermal stability of the composites.

Studies on CDP composites include synthesis and characterization of CDP/SiO_2 such as phase transition and proton transport characteristics [20], effects of different types of silica material [18] and different models of protonic conductivity at the ionic salt and oxide interface [21]. In this study, we investigate the properties of solid acid composite $CsH_2PO_4/NaH_2PO_4/SiO_2$, such as the conductivity of the composite via electrochemical impedance spectroscopy, functional groups identification via Fourier-transform infrared spectroscopy and thermal stability via thermogravimetric analysis and differential scanning calorimetry.

Materials and Methods

CDP was synthesized by mixing stoichiometric amounts of caesium carbonate, Cs_2CO_3 (ReagentPlus®, ≥ 99% Sigma Aldrich) and phosphoric acid H_3PO_4 (≥85 wt% in H_2O, Sigma Aldrich) according to the following reaction (Equation 2):

$$Cs_2CO_3 + 2H_3PO_4 \rightarrow 2CsH_2PO_4 + CO_2 + H_2O \quad (2)$$

In CDP synthesis, measured amount of Cs_2CO_3 was dissolved in distilled water. Surfactant powder, Cetyltrimethylammoniumbromide, CTAB (BioXtra®, ≥ 99 % Sigma Aldrich) was dissolved in ethanol separately and added to the Cs_2CO_3 solution to reduce water surface tension and hence assist particle dispersion. The mixture was then stirred for 10 minutes until clear solution was produced. Phosphoric acid was added, drop-wise into the mixture with continuous stirring for another 10 minutes. Acetone is added excessively to the mixture while stirring for another 30 minutes and the solution is vacuum-filtered to produce CDP in the form of white precipitate. The

white precipitate is washed several times by mixing with excess acetone and vacuum-filtered to remove remaining surfactants. The synthesized CDP is dried at 130 °C for 24 hours to eliminate absorbed water and grinded to produce powdered CDP.

Solid acid composites $CsH_2PO_4/NaH_2PO_4/SiO_2$ of different molar ratios as tabulated in Table 1 were synthesized via the sol gel method, the similar method used synthesize electrolyte of a solid oxide fuel cell[22]. The synthesized CDP and NaH_2PO_4, SDP (ReagentPlus®, ≥ 99 % Sigma Aldrich) powders were mixed prior addition to tetraethyl orthosilicate, TEOS solution. TEOS solution was prepared by mixing TEOS (Reagent Grade®, 98 % Sigma Aldrich) with ethanol, water and hydrochloric acid (1 mol L^{-1}, Merck) in mole ratio of 1:8:30:0.05. The solid acid and TEOS mixture was stirred until all powders were dissolved. The mixture was kept at 40 °C for 24 hours and further dried at 150 °C for 15 hours to produce white precipitate solid acid composite, $CsH_2PO_4/NaH_2PO_4/SiO_2$. The resultant precipitate was then grinded to produce fine solid acid composite powders.

Table 1. Solid acid composites synthesized

Solid acid sample	**CsH_2PO_4:NaH_2PO_4:SiO_2 molar ratio**
CDP 631	6:3:1
CDP 721	7:2:1
CDP 811	8:1:1
CDP 613	6:1:3
CDP 523	5:2:3
CDP 433	4:3:3

Solid acid CDP and its composites were characterized via electrochemical impedance spectroscopy, Fourier-transform infrared spectroscopy, thermogravimetric analysis and differential scanning calorimetry. The solid acids were tested for its protonic conductivity via electrochemical impedance spectroscopy (EIS). The pure CDP and its composite powders were pressed into pellets of 1 mm thickness and 13 mm diameter by uniaxially pressing at 3 tonnes cm^{-2} at room temperature for 1 minute. The pellets were calcined at 260 °C for 1 hour in air, painted with silver (Ag) suspension and heat-treated to improve contacts of the surfaces to the current collector, prior to assembly in the pellet holder for impedance measurements. The pellet was sandwiched between two square platinum meshes which acts as the current collector, placed inside a metal pellet holder with ceramic lining and connected to an Autolab impedance analyser. The impedance readings were taken in air at 180 °C, 210 °C, 230 °C 250 °C and 260 °C with frequency of 1.0 x 10^{-2} to 1.0 x 10^{6} Hz and current of 0.01A. The measured data was analyzed using the Nova software package where the proton conductivity value was determined from the impedance data plotted on real and imaginary axes, Z' and -Z'' respectively, known as Nyquist plot. The curve was fitted using the equivalent circuit as in Figure 1. The proton conductivity value, σ for pure CDP and $CsH_2PO_4/NaH_2PO_4/SiO_2$ composites were calculated using the resistance value, R and is given by the following Equation 3:

$$\text{Conductivity, } \sigma \text{ (S cm}^{-1}) = {}^{1/R(\Omega)}\Big/_{A(cm^2)/l(cm)} \quad (3)$$

Fourier-transform infrared spectroscopy (FTIR) is used to identify functional groups that are present in the solid acid materials. Solid acid samples were mixed with grounded KBr with solid acid to KBr weight ratio of 1 to 300 and pressed into a pellet for FTIR measurements. The spectrum was collected via Perkin-Elmer 125 spectrometer between 200 and 4000 cm^{-1} wavenumbers at room temperature.

Thermal stability of the solid acid materials were measured via thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). Solid acid decomposition is identified by measuring mass loss as a function of temperature via TGA analysis. DSC measurements display endothermic or exothermic peaks that appear during

heating of the solid acid, which are usually related to the phase transition of solid acid. Both TGA and DSC tests were run simultaneously using STA 449 F3 Netzsch simultaneous TGA-DSC between 30 °C and 600 °C with heating rate of 5 °C min^{-1} under nitrogen flow.

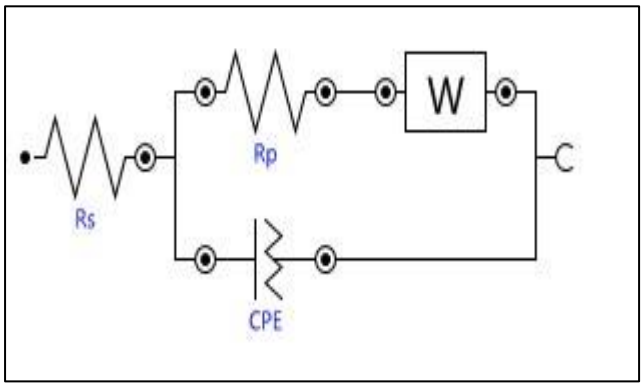

Figure 1. The equivalent circuit used to analyze the impedance data

Results and Discussion

Proton conductivity of $CsH_2PO_4/NaH_2PO_4/SiO_2$ composites

The Nyquist plot for each CDP composite has a similar pattern to the plot for CDP 613 at various temperatures as shown in Figure 2. The semi-circle of the fitted plot represents the impedance of the bulk of the solid acid electrolyte and the straight line represents the semi-infinite diffusion behaviour of the solid-gas interface of the solid acid electrolyte. The conductivity of CDP 613 increases as temperature increases from 180 °C to 210 °C and 230 °C where the conductivity is the highest. However, as temperature is increased to 250 °C and 260 °C, the conductivity drops slightly, indicating that the optimum temperature with highest conductivity value is at 230 °C for CDP 613.

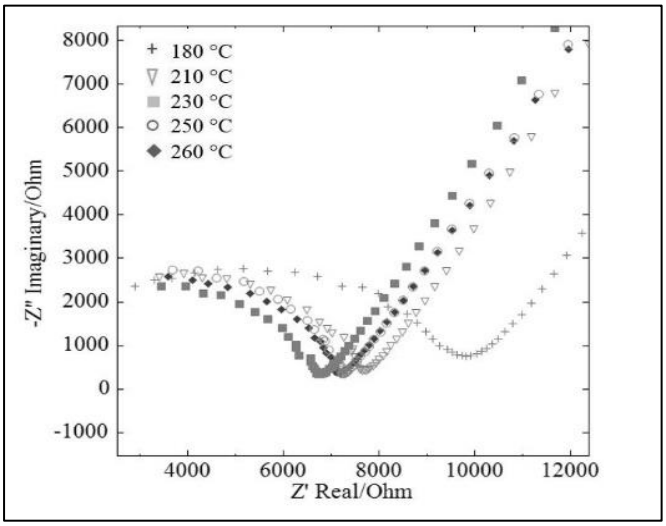

Figure 2. The impedance measurement of CDP 613 at 180 °C, 210 °C, 230 °C, 250 °C and 260 °C plotted in Nyquist plot.

Conductivity measurements were conducted for all CDP composites at 180°C, 210°C, 230°C, 250°C and 260°C. The highest conductivity values of pure CDP and its composites are tabulated in Table 2. It was found that the superprotonic conductivity of pure CDP occurs at about 230 °C with conductivity value of 1.9 x 10^{-2} S cm^{-1}, comparable to proton conductivity value of 2.2 x 10^{-2} S cm^{-1} at 240 °C obtained by Haile et al. [3]. Solid acid composite CDP 613 has the highest conductivity value of 7.2 x 10^{-3} S cm^{-1} at about 230 °C compared to other composites. The conductivity of CDP 613 composite is lower than the conductivity of pure CDP at the same temperature. The presence of SiO_2 which is non-conductive, slightly reduces the conductivity of solid acid composites, due to the imperfect interconnections between the solid acid and SiO_2 [15].

Table 2. The highest conductivity value for each solid acid

Solid acid	**Highest conductivity value, σ (S cm^{-1})**	**T_{sp} (°C)**
CDP [3]	2.2 x 10^{-2}	240
CDP (pure)	1.9 x 10^{-2}	230
CDP 631	5.0 x 10^{-3}	230
CDP 721	1.7 x 10^{-3}	250
CDP 811	8.5 x 10^{-4}	250
CDP 613	7.2 x 10^{-3}	230
CDP 523	2.0 x10^{-3}	260
CDP 433	2.6 x 10^{-3}	250

In previous work by Boysen [2], it was found that SDP alone melts without reaching the superprotonic phase. A recent study by Marsinkevich [16] highlights the effect of adding SDP up to 20 % of CDP/SDP composite, where conductivity increases by 2 orders of magnitude around 160 °C to 200 °C compared to pure CDP. In this study, we found that the addition of SDP into the CDP/SiO_2 composites increases the conductivity value of composites with 10 % SiO_2 that are CDP 631, CDP 721 and CDP 811, whilst reducing the temperature where superprotonic conductivity of the composites occur. The conductivity of $Cs_{1-x}Na_xH_2PO_4$ composite increases by 2 orders of magnitude with x values up to 0.2 at 160 °C to 200 °C, lower than the superprotonic temperature of pure CDP that is 240 °C [16]. This is associated with the structural order-disorder movements caused by Cs^+ and Na^+ cations coexisting within the lattice of the solid acid composites.

Structure and thermal stability of $CsH_2PO_4/NaH_2PO_4/SiO_2$ composites

The infrared spectra of CDP is shown in Figure 3 where well separated peaks were observed at 2710 cm^{-1}, 2310 cm^{-1} and 1710 cm^{-1} which are assigned to the stretching of oxygen-hydrogen bonds in and out of planes also known as the 'ABC bonds of OH', while the strong absorption bands between 900 cm^{-1} and 1200 cm^{-1} were attributed to the internal vibrations of $H_2PO_4^-$ oxyanion that are the vibrations of two main groups PO_2 and $P(OH)_2$. The PO_2 stretching modes result in more intense bands compared to the $P(OH)_2$ stretching modes. The wavelength of PO_2 stretching modes are due to PO_2 symmetric and asymmetric stretching measured at 941 cm^{-1} and 1070 cm^{-1} respectively. Weaker bands of $\delta_{P\text{-}O\text{-}H}$ in-plane bending and $\gamma_{P\text{-}O\text{-}H}$ out-of-plane bending are identified at 1130 cm^{-1} and 1213 cm^{-1} respectively and is comparable to the bands of CDP nanoparticles that are 1140 cm^{-1} and 1185 cm^{-1} respectively [23]. The generated Cs···O-H bond is represented by the peaks within 300 cm^{-1} to 500 cm^{-1} region. The IR spectra of CDP and its composites measured in this work is compared to previous works as in Table 3.

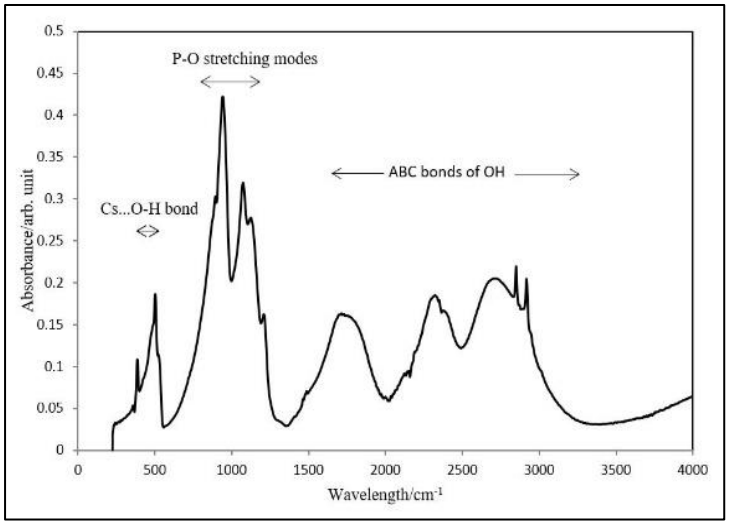

Figure 3. The FTIR absorbance bands for CDP.

Table 3. The comparison of functional groups present in solid acid materials

Solid acid sample	Reference	Wavelength (cm^{-1})					
		Cs …O-H bond	P-O_2 stretching		O-H stretching		
			symmetric	asymmetric			
CDP (pure)	This study	502	941	1070	1710	2310	2710
CDP nanoparticles	[23]	490	940	1070	1650	2300	2650
CDP	[18]	N/A	950	1100	1700	2300	2700

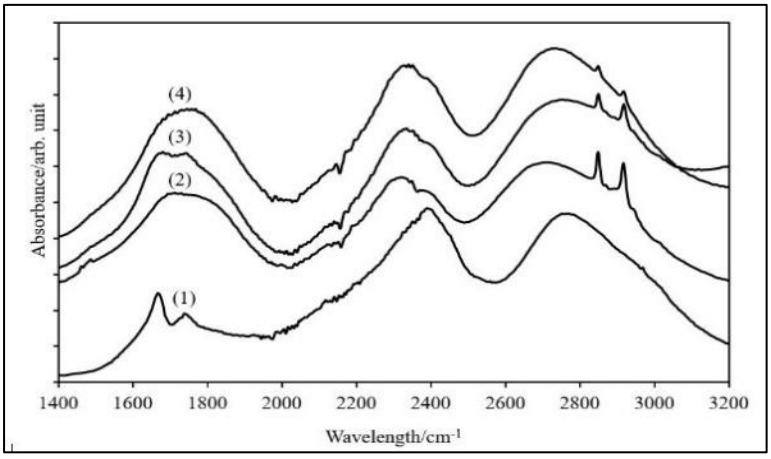

Figure 4. Infrared spectra of (1) sodium dihydrogen phosphate, (2) caesium dihydrogen phosphate, (3) CDP 811 composite and (4) CDP 631 composite.

The FTIR measurement conducted for CDP composites found that the addition of SDP into the solid acid composite did not produce any obvious change in the pattern of the absorbance bands for ABC bonds of OH, as depicted in Figure 4 for CDP 631 and CDP 811. However, it increases the frequency of the absorbance bands slightly, indicating lengthening of P-O¨H and shortening of P-O bonds. This is similar to the trend observed by Martsinkevich and Ponomareva [16].

The DSC measurements for CDP and its composites are presented in Figure 5. Decomposition occurs in these solid acids according to the following dehydration pathway (Equation 4) [24-26]:

$$CsH_2PO_4 \rightarrow Cs_2H_2P_2O_7 \rightarrow CsPO_3 \quad (4)$$

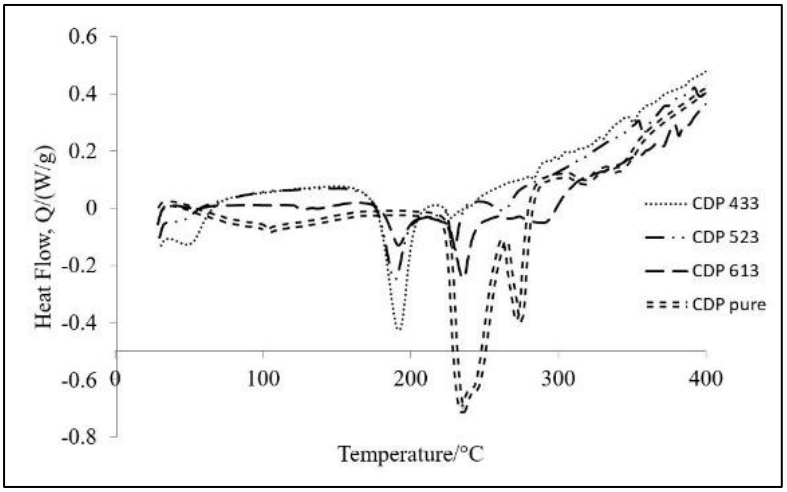

Figure 5. DSC curves for CDP and its composites.

The first reaction pathway ($CsH_2PO_4 \rightarrow Cs_2H_2P_2O_7$) occurs over temperature range of 220 °C to 260 °C due to thermal decomposition of CDP to form another compound, dicaesium dihydrogen pyrophosphate $Cs_2H_2P_2O_7$. This is followed by the formation of $CsPO_3$ around temperature range of 265 °C to 285 °C. At about 320 °C, decomposition occurs. This is in agreement with the findings by Hosseini et al. [24]. The CDP composites that are CDP 433, CDP 523 and CDP 613 with different ratios of SDP and SiO_2 shows two distinctive peaks in DSC measurements at lower temperatures around 190 °C and 230 °C as compared to the DSC curve of pure CDP. The first reaction pathway of the composite producing $Cs_2H_2P_2O_7$ occurs over temperature range of 175 °C to 210 °C followed by the formation of $CsPO_3$ around temperature range of 220 °C to 255 °C, both occurrence at lower temperature than pure CDP.

The lower temperature dehydration of CDP composites may be associated with the presence SDP in the composite. DSC analysis of SDP revealed three distinctive peaks at 60 °C, 210 °C and 345 °C as in Figure 6. It is noteworthy that due to the hygroscopic nature of the solid acid, the first peak at 60 °C represent the release of water molecules at the surface of the solid acids during the DSC measurement. This is supported by thermal analysis of SDP [16], where dehydration peaks were identified at 208 °C and 280 °C. Similarly, prior studies indicated that SDP undergo dehydration at a lower temperature such as at 169 °C [27] and 200 °C [2]. Therefore, by adding SDP into the solid acid composites, dehydration occurs at a lower temperature than pure CDP.

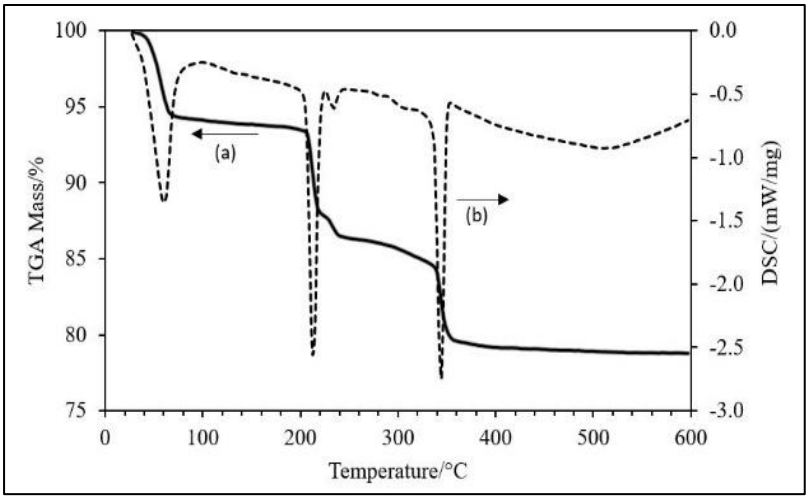

Figure 6. TGA (a) and DSC (b) curves for solid acid NaH_2PO_4, SDP

Conclusion

Conductivity measurements revealed solid acid composite CDP 613 as the composite with the highest conductivity that is 7.2 x 10^{-3} S cm^{-1} at about 230 °C compared to the other composites. This conductivity value is lower than the conductivity of pure CDP due to the defective interconnections between the solid acid and the non-conductive SiO_2 particles. The addition of SDP into the CDP/SiO_2 composites increases the conductivity of composites whilst reducing the temperature at which the superprotonic transition occur. Thermal analysis showed earlier onset of dehydration for CDP/SDP/SiO_2 composites compared to pure CDP, which is most likely due to the presence of SDP which has lower dehydration and melting point. The mechanism of proton transport within CDP was confirmed to occur by breaking and formation of hydrogen bonds and rotation of the phosphate tetrahedron anions, as identified via the FTIR analysis where distinctive peaks were observed from 1710 to 2710 cm^{-1} and 900 to 1200 cm^{-1} respectively.

Abstract

Yttria-stabilized tetragonal zirconia polycrystalline (Y-TZP) is a popular material for dental restoration because of its outstanding mechanical properties and biocompatibility. Cold isostatic pressing (CIP) and slip casting are among several consolidation methods for Y-TZP. These methods produce Y-TZP with high mechanical properties. This study aims to enhance the mechanical properties of Y-TZP by combining slip casting and CIP. Y-TZP samples were fabricated using CIP, slip casting, and their combination. Subsequently, the green bodies of the samples were sintered at 1600 °C. Their mechanical properties (density and hardness) were tested and their microstructures were scrutinized under a scanning electron microscope. Compared with the other two methods, the combined method significantly improved the mechanical properties of Y-TZP. In addition, the combined method also produced a compact and homogeneous microstructure. Therefore, the combination of slip casting and CIP is recommended in the production of Y-TZP with high mechanical properties for dental crown applications.

Keywords: cold isostatic pressing, slip casting, colloidal processing

Abstrak

Polikristal tetragon zirkonia yang distabilkan dengan yttria (Y-TZP) merupakan bahan restorasi pergigian yang popular disebabkan sifat mekanik dan bioserasi yang baik. Kaedah penekanan isostatik sejuk (CIP) dan penuangan buburan adalah kaedah pengukuhan yang lazim digunakan untuk Y-TZP. Kedua-dua kaedah ini berupaya menghasilkan Y-TZP yang bersifat mekanik tinggi. Kajian ini bertujuan meningkatkan sifat mekanik Y-TZP melalui gabungan penuangan buburan dan CIP. Sampel Y-TZP dihasilkan melalui kaedah penuangan buburan, CIP dan gabungan kedua-dua kaedah tersebut. Seterusnya, jasad anum yang terhasil disinter pada suhu 1600 ˚C. Sifat mekanik sampel Y-TZP (ketumpatan dan kekerasan) diuji dan mikrostruktur juga diteliti di bawah mikroskop elektron imbasan. Kaedah gabungan didapati meningkatkan sifat mekanik Y-TZP dengan ketara. Selain itu, mikrostruktur yang padat dan homogen juga diperolehi. Justeru, gabungan kaedah penuangan buburan dan CIP dicadangkan untuk penghasilan Y-TZP yang bersifat mekanik tinggi dalam aplikasi korona gigi.

Kata kunci: penekanan isostatik sejuk, penuangan buburan, pemprosesan berkoloid

Introduction

Tetragonal zirconia polycrystalline partially stabilized by 3 mol% of yttria (3Y-TZP) is well known for its superior mechanical properties among other dental ceramics [1, 2]. Piconi et al. [3] remarked that Y-TZP has high flexural strength (> 900 MPa, four-point bending), high fracture toughness (approximately 10 $MPa.m^{1/2}$) and high hardness (12-14 GPa). The outstanding mechanical properties of Y-TZP are associated with the transformation toughening mechanism that involves phase transformation from tetragonal (*t*) to monoclinic (*m*) [4]. Given this mechanism, Y-TZP possesses adequate mechanical properties for clinical use as fixed prostheses when subjected to high stresses. Meanwhile, the excellent biocompatibility and optical properties of Y-TZP make it a suitable material for aesthetic and metal-free dental restoration [5, 6]. Recently, Y-TZP has been extensively applied in dental crown applications because it offers better aesthetics and biocompatibility compared with metal restoration [4, 5].

Most advanced ceramics, including Y-TZP, are processed through powder metallurgy methods, in which ceramic powders are compacted and undergo densification under elevated temperatures. Every procedure during ceramic processing (powder preparation, consolidation, and densification) can introduce detrimental heterogeneities, such as agglomerates and defects, which remain and exacerbate after sintering [7]. These heterogeneities may form large pores or flaws in the microstructure during densification and deteriorate the mechanical properties of the final products [8, 9]. Hence, minimizing the possibility of heterogeneity formation and achieving the desired spatial distribution phases (including pores) in green bodies is crucial [7].

There are many forming methods of ceramics such as micro-powder injection molding, pressing and sol-gel [10-12]. Uniaxial pressing, cold isostatic pressing (CIP), and hot isostatic pressing (HIP) are among several consolidation processes that involve pressing in ceramic processing. Pressing is a dry-forming technique in ceramic processing that is known for producing critical parts in near net shape [13]. Compared with traditional methods such as uniaxial pressing, CIP can pressurize the powder compact from all directions. Thus, CIP produces green compacts with relatively high density and uniform packing using inexpensive tooling [14, 15].

Colloidal processing methods such as slip casting and tape casting have recently emerged as popular consolidation methods for ceramics. Colloidal processing methods have a great potential to offer high-quality green bodies with a high packing factor, thereby providing excellent mechanical properties for the final products [16-18]. Colloidal processing methods are highly recommended for submicron ceramic powder because submicron particles tend to agglomerate owing to their high specific surface area [17]. These agglomerates are invariably detrimental to the mechanical properties of ceramics. Colloidal processing controls the interparticle forces of ceramic particles through three mechanisms namely electrostatic, steric and electrosteric [7]. This method can effectively minimize the agglomeration of particles and thus improve the quality of green bodies. However, a suspension with excellent colloidal stability and rheological properties is required for a successful colloidal processing [19].

Slip casting and CIP are known for producing Y-TZP with excellent mechanical properties. This study aims to improve the mechanical properties of Y-TZP for dental crown applications by combining both slip casting and CIP.

Materials and Methods

Materials

Y-TZP nanopowder partially stabilized with 3 mol% of Y_2O_3 (US Research Nanomaterials Inc., Houston, USA) was used in this study. This powder has a BET specific surface area of 30 m^2/g and a true density of 5.89 g/cm^3. The transmission electron micrograph (TEM) of the as-received powder in Figure 1 shows that the primary particle size of the powder was approximately 20 nm. Polyethyleneimine (PEI, Sigma–Aldrich) with an average molecular size of 50,000 was employed as a dispersant agent in colloidal processing.

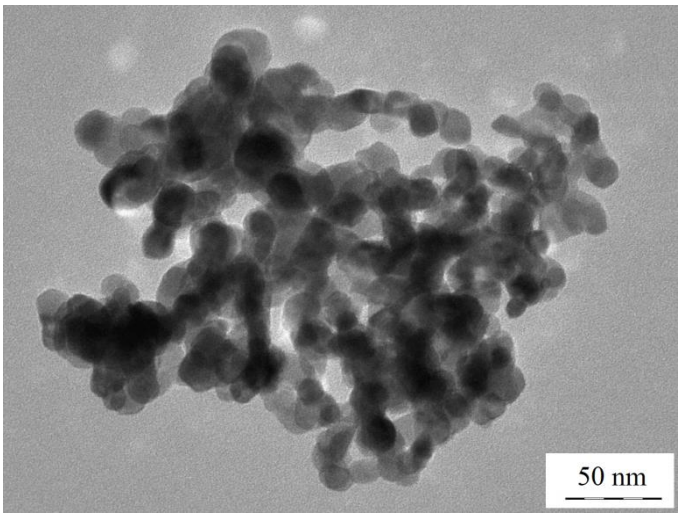

Figure 1. TEM image of the as-received Y-TZP powder

Fabrication of Green Body

A Y-TZP suspension with 30 wt.% powder loading was prepared. The dispersing medium was distilled water. The suspension was added with 0.4 wt.% of 0.005 M PEI, thoroughly mixed using a magnetic stirrer for 45 min, and then ultrasonicated for 15 min to break the agglomerates. A HNO_3 solution was used to adjust the pH of the suspension to pH 2. The PEI amount and pH used in suspension preparation are optimized parameters from a previous study [20]. Slip casting was used to fabricate green bodies. The Y-TZP suspension was poured into a 15 mm-diameter Teflon mold placed on top of a plaster of Paris block, which was then left for consolidation at room temperature. After 24 h, the green bodies were carefully extracted from the mold.

For CIP, approximately 0.6 g of Y-TZP powder was measured and pressed into cylindrical disc shape through uniaxial pressing (Carver 4369, USA) in a 13 mm-diameter mold (#3619, Carver, USA). The powder was pressed at 25 MPa and 10 s dwell time. Subsequently, the Y-TZP disc was subjected to CIP (Riken Seiki Co. Ltd., Japan) at 200 MPa for 1 min.

Combined method of slip casting and CIP was also used to fabricate green bodies. Y-TZP green bodies were first produced using slip casting method with the same procedures and parameters discussed previously. Then, the slip-casted green bodies were subjected to CIP at 200 MPa for 1 min.

Sintering method

The green bodies were sintered at 1600 °C by a two-step sintering method in a high-temperature furnace (VMK-1800, Linn High Therm, Germany). The sintering profile is shown in Figure 2. The green bodies were initially heated to 600 °C at a rate of 3 °C/min and maintained for 45 min. Next, the green bodies were further heated to 1600 °C, with a soaking time of 2 hours.

Sample characterization

The sintered densities of the Y-TZP samples were measured with a density meter (Newclassic MS, Mettler Toledo, Columbus, OH, USA) by applying Archimedes' immersion method. A field-emission scanning electron microscope, FESEM (Hitachi SU8000, Hitachi, Tokyo, Japan) was used to observe the microstructure of the Y-TZP samples. Before the examination, the sample surface was prepared by grinding using silicon carbide paper (600, 800, and 1200 grit) and then polishing with diamond paste (3 and 1 µ grit sizes). After surface preparation, thermal etching at 1200 °C was conducted on the samples so that the grain boundaries can be observed clearly under the FESEM machine. During etching, the temperature increased to 1200 °C at a rate of 20 °C/min and maintained for 1 h. Then, the temperature decreased to room temperature at the same rate. The Vickers hardness machine (EW422-

DAT, Eseway, Bowers Group, Camberly, UK) was used to examine the hardness of the Y-TZP samples. The Vickers hardness test was performed in accordance with ASTM C 1327-03 (Standard Test Method for Vickers Indentation Hardness of Advanced Ceramics). Six indentations were rendered on the prepared surface of the Y-TZP samples at 0.2 kgf load and 10 s dwell time, and the average values were obtained. Similar procedures of surface preparation in the morphological test were also employed in this test. Finally, X-Ray diffraction (XRD, D8 Advance, Bruker, Billerica, MA, USA) was performed to observe the phase changes in Y-TZP after sintering.

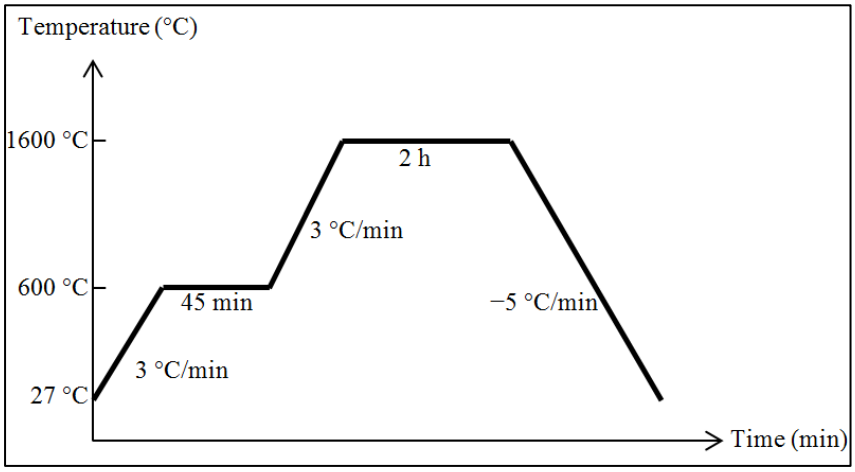

Figure 2. Sintering profile of Y-TZP samples

Results and Discussion

Sintered density

The sintered densities of the Y-TZP samples fabricated through different methods are shown in Figure 3. The sintered density of the Y-TZP sample fabricated through CIP was 98% of the theoretical density of Y-TZP (6.1 g/cm^3). Meanwhile, the sample processed with slip casting had the lowest sintered density, i.e., 92% of the theoretical density. The highest density of 99% was observed in the sample fabricated with the combination of slip casting and CIP.

Density is correlated with porosity, which is undesirable in ceramic processing because it deteriorates the mechanical strength of a ceramic body. The samples fabricated by CIP and the combined method achieved full densification (> 98 %). The full densification of grains has been proven in many studies [18, 20] to yield high mechanical properties in Y-TZP. This result can be attributed to the high powder packing factor of the green bodies. The powder packing factor of a green body determines its quality. Inadequate packing of powder granules before sintering often results in irregularities such as pores and agglomerates after sintering which lead to low mechanical properties. Hence, high powder packing factor usually yields high sintered density. A consolidation process in ceramic processing must be carefully controlled to eradicate irregularities that deteriorate the mechanical properties of the final product. The density test results showed that the Y-TZP green bodies produced using CIP and the combined method had better powder packing than those produced using slip casting. This result indicates that the two methods are more suitable for consolidation than slip casting. Moreover, the CIP method significantly increased the density of slip-casted Y-TZP from 92 % to 99 %.

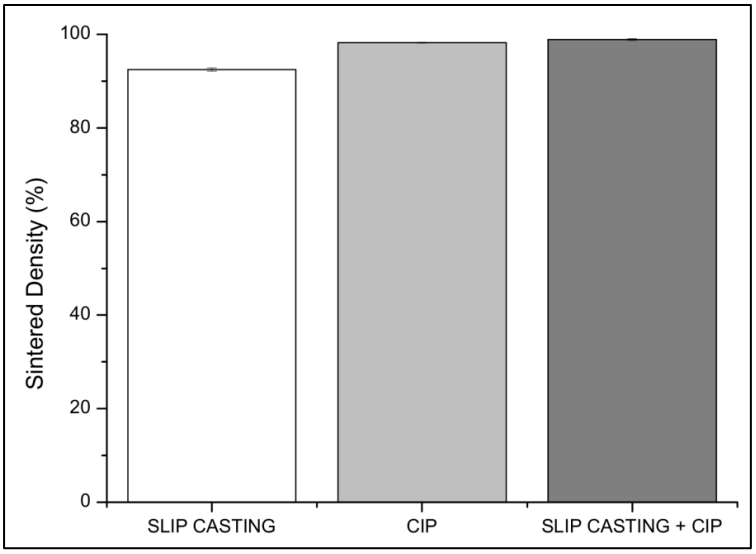

Figure 3. Relative sintered densities of Y-TZP samples

Morphological analysis

The scanning electron micrograph of the samples in Figure 4 shows that CIP produced a more compact and less porous microstructure compared with slip casting. This finding is corresponding to the density test results, in which the CIP sample showed a higher density than the slip casting sample. Average grain sizes of 614 and 569 nm were recorded in CIP and slip casting samples, respectively. However, the combined method produced a highly homogeneous and compact microstructure with an average grain size of 517 nm. This compact and fine microstructure favors the production of Y-TZP samples with promising mechanical strength. Chin et al. [20] reported a smaller average grain size of 486 nm in the Y-TZP sample fabricated via slip casting method and a hardness of 10 GPa. In the present study, a higher hardness value was achieved with the combined method of slip casting and CIP (hardness test results will be discussed in following section) although the average grain size is larger compared to that of Chin et al. [20]. This is attributed to the compact microstructure with extremely low porosity yielded via the combined method in this study.

The microstructure of the CIP sample exhibited excessive grain growth primarily because uniaxial pressing and CIP cannot eliminate the agglomerates inherited from the raw Y-TZP powder. Ceramic powders in submicron size generally appear in the form of agglomerates, which are formed by bonded primary particles. Agglomeration always occurs because fine particles tend to reduce their surface energy [21]. These agglomerates, if left untreated, will persist until the end of processing and bring undesired sintered characteristics, such as high porosity, exaggerated grain growth, and flaws [22]. Coarse grains brought about by exaggerated grain growth in CIP samples (refer to Fig. 4b) are very detrimental to the mechanical properties because large grains are highly vulnerable to trans-granular cleavage, in which the crack propagates across the grain. Muchtar and Lim [23] also explained that trans-granular cleavage is not likely to occur in fine grains. Hence, a ceramic body with fine grain size is more resistant to trans-granular fracture and possesses higher mechanical properties.

The combined method of slip casting and CIP yielded the most desired microstructure, which is compact and homogeneous because most agglomerates had been eliminated during colloidal processing. CIP further enhanced powder packing. Consequently, a nonporous homogeneous microstructure was obtained.

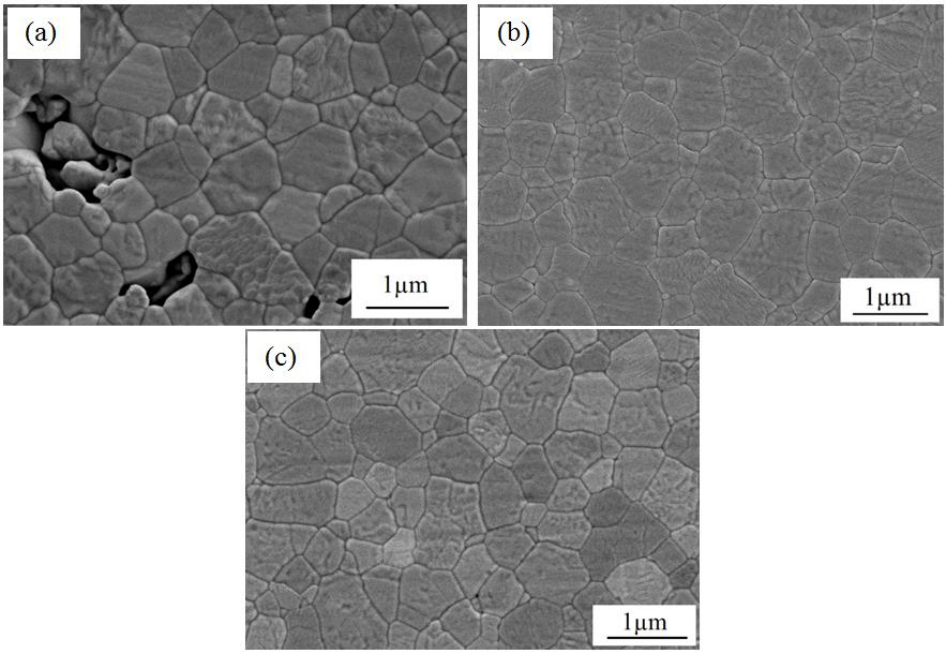

Figure 4. SEM images of Y-TZP samples fabricated through (a) slip casting, (b) CIP and (c) slip casting + CIP

Hardness

The materials of the crown should have high hardness values to prevent failure of the dental crown. The Vickers hardness of the samples fabricated with different methods is shown in Figure 5. The hardness of the CIP sample was slightly higher than that of the slip casting sample. However, CIP considerably improved the hardness of the slip-casted Y-TZP sample. Thus, the combined method yielded the highest hardness of 14.4 GPa. This is comparable to the highest hardness value of Y-TZP reported by Piconi et al. [3] which is 14 GPa. This result proves the effectiveness of CIP in improving the mechanical properties of slip-casted Y-TZP. The high hardness value of the sample fabricated by the combined method is ascribed to its compact and homogeneous microstructure. As stress concentrators that promote crack propagation, pores deteriorate the mechanical properties of the final products [18]. Thus, a compact microstructure can ensure favorable mechanical properties. A homogeneous and fine microstructure is also effective in impeding trans-granular fracture that usually results in low mechanical properties.

X-Ray Diffraction (XRD)

The XRD results in Figure 6 reveal a portion of monoclinic zirconia in the Y-TZP sample fabricated by CIP. This result can be attributed to the high stress level subjected to the Y-TZP powder during uniaxial pressing. *t-m* phase transformation can be triggered by high stress level and exaggerated grain growth. Previous studies [24-26] reported that the grain size threshold for spontaneous *t-m* transformation is approximately 1 μm. Coarse grains > 1 μm in size were found in the microstructure of the CIP sample (Fig. 4b). Thus, this morphology encouraged the formation of monoclinic zirconia. The existence of the monoclinic phase is highly undesirable in dental crown applications because it poses the problem of low temperature degradation (LTD). LTD deteriorates the mechanical properties of Y-TZP at a fast rate in oral circumstance. Therefore, LTD limits the efficiency of Y-TZP in dental crown applications. Slip casting offers extra phase stability to the tetragonal phase because it produces the monophase of tetragonal zirconia. The combined method also offers good tetragonal phase stability because only a negligible amount of monoclinic zirconia was detected.

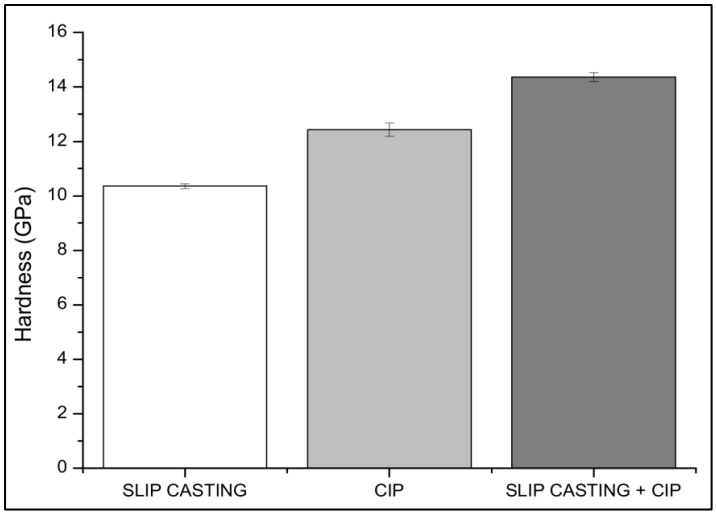

Figure 5. Hardness of Y-TZP samples

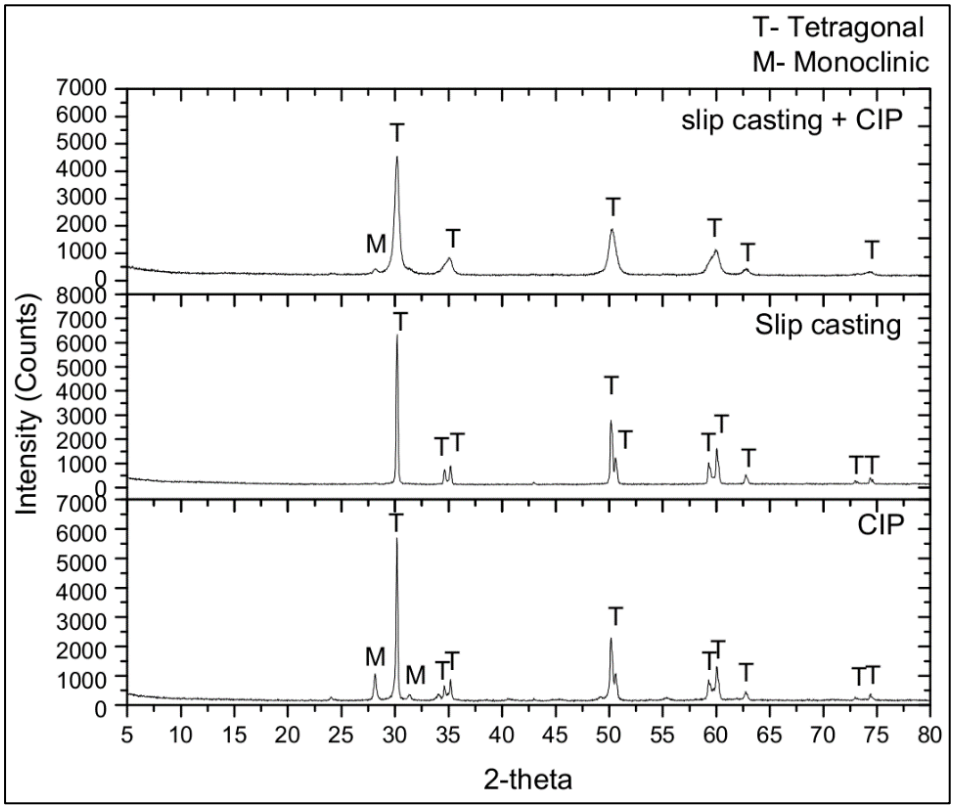

Figure 6. XRD results of Y-TZP samples processed with different methods

Conclusion

Both slip casting and CIP can produce Y-TZP with high mechanical properties. The CIP method offers better mechanical properties than the slip casting method. However, CIP method also encourages the formation of monoclinic zirconia, which can potentially jeopardize the mechanical properties of the final products. The combined method of slip casting and CIP is proven to be a better alternative processing route for Y-TZP. This method significantly enhances the mechanical properties of Y-TZP, for example, there was approximately 20 % improvement in the hardness of Y-TZP fabricated via the combined method. This method also offers favorable tetragonal stability.

EFFECT OF USING PITAYA PEEL AS DYE-SENSITIZER AND DYE MOLECULES IN ELECTROLYTE FOR PHOTOELECTROCHEMICAL REACTION

(Kesan Penggunaan Kulit Buah Naga Sebagai Pemeka-Pewarna dan Molekul Pewarna di dalam Elektrolit bagi Tindak Balas Fotoelektrokimia)

Abstract

Natural dye sensitizer in photoelectrochemical shows a great potential in improving the efficiency of metal oxide semiconductor especially Titanium dioxide (TiO_2) due to its prominent in absorbing visible light and also low cost. In this work, the effect of using pitaya peel as natural dye sensitizes to TiO_2 has been studied through characterizations analysis and PEC test. The bare TiO_2 thin films were fabricated on Fluorine-doped tin oxide (FTO) glass substrate by doctor blade method meanwhile dye-sensitized TiO_2 thin films prepared by immersion of TiO_2 in the dye extracts. The fabricated thin films were characterized with Scanning Electron Microscopy (SEM), X-ray difractometer (XRD), UV-Vis spectrophotometer and photoelectrochemical analysis. The surface of TiO_2 was porous and uniform meanwhile dye particles could not been observed due to very small size. The energy band gap of dye-sensitized TiO_2 from the UV-Vis spectrum is 2.1 eV which is smaller than bare TiO_2 (3.7 eV). Meanwhile, photoactivities of dye-sensitized TiO_2 has the highest compared to bare TiO_2 photoelectrodes which is 127µA/cm^2 in 6.25% v/v of pitaya dye in the electrolyte.

Keywords: titanium dioxide, dye-sensitizers, betalains, photoelectrochemical cell, water splitting

Abstrak

Pemeka-pewarna semulajadi di dalam fotoelektromia (PEC) menunjukkan potensi yang bagus untuk meningkatkan keupayaan semikonduktor logam oksida terutamanya titanium dioksida (TiO_2) disebabkan kemampuannya untum menyerap cahaya nampak dan kos yang rendah. Di dalam penyelidikan ini, kesan menggunakan kulit buah naga sebagai pemeka-pewarna semulajadi terhadap TiO_2 telah dikaji melalui pencirian dan analisis fotoelektrokimia. Filem nipis TiO_2 asli telah dihasilkan melalui kaedah Doctor blade di atas kepingan kaca bersalut FTO (Stanum oksida terdop fluorin) manakala filem nipis TiO_2 dengan pewarna-pemeka telah dihasilkan dengan merendam TiO_2 ke dalam larutan ekstrak pewarna. Filem nipis yang telah terbentuk telah melalui beberapa analisis pencirian iaitu, Mikroskopi Elektron Imbasan (SEM), Difraktometer Pembelauan Sinar-X (XRD), Spektrofotometer Ultralembayung dan Cahaya Nampak **(**UV-Vis**)** dan juga ujian fotoelektrokimia. Permukaan TiO_2 adalah berliang dan seragam manakala zarah pewarna tidak dapat dilihat disebabkan saiznya yang terlalu kecil. Jurang tenaga filem nipis TiO_2 dengan pewarna-pemeka adalah lebih rendah iaitu 2.1 eV jika dibandingkan dengan TiO_2 asli (3.7 eV). Manakala, fotoaktiviti bagi fotoelektrod TiO_2 dengan pewarna-pemeka adalah lebih tinggi daripada TiO_2 asli dengan 127µA/cm^2 di dalam kepekatan 6.25% v/v pewarna di dalam elektrolit.

Kata kunci: titanium dioksida, pemeka-pewarna, betalain, sel fotoelektrokimia, pembelahan air

Introduction

The hydrogen gas production by using solar energy is deliberated as one of the most significant sustainable and clean energy technologies [1]. Photoelectrochemical (PEC) water splitting is the most promising method in generating hydrogen gas. Metal oxide semiconductor such as TiO_2, SnO_2, and WO_3 is widely studied as having a great potential as photoelectrodes in PEC system [2]. Nonetheless, TiO_2 semiconductor is more favorable due to its good stability in thermal and chemical properties, inexpensive and non-toxic [3]. However, TiO_2 is characterized by its wide band gap of 3.2 eV (anatase phase) and required Ultra-Violet (UV) irradiation which only absorb small fraction (< 10 %) of the sunlight energy [3, 4]. An improvement of TiO_2 semiconductor can be achieved by using dye sensitizer plays as a main role in absorbing light energy in production of hydrogen [4]. Dye sensitizer has been widely studied caused by its great potential as sunlight harvester and improved PEC efficiency by increased light absorption in solar spectrum to visible light range [5]. The advantages of dye sensitizer includes low cost, minimal and simple fabrication process [6]. However, dye-sensitizer should have strong attachment to the surface of metal oxide semiconductor to achieved higher efficiency in PEC system [7]. Other than that, recombination also influenced the photocurrent generation in PEC reaction. Yet, the electron injection of dyes sensitizer is very fast while the back reaction is slow, hence the rate of recombination believed to be very small [8].
