Abstract

An analytical method based on solid-phase extraction (SPE) liquid chromatography-tandem mass spectrometry (LC-MS/MS) for the determination of five illicit drugs, namely amphetamine (AM), methamphetamine (MA), 3,4-methylenedioxymethamphetamine (MDMA), 3,4-methylenedioxyamphetamine (MDA), and morphine (MOR) in municipal wastewater has been optimized and validated. Sample preparation was performed using Oasis MCX SPE cartridges. LC separation was performed using a Zorbax Eclipse Plus C_{18} RRHD column. The linearity of the calibration curve was between 5 ng/mL and 250 ng/mL, with determination coefficient (R^2) greater than 0.99, except for morphine. The mean recoveries of target analytes ranged from 91.6 to 112%, and the method demonstrated good inter-day repeatability (coefficient of variation, CV ranged from 2 to 19%). The limit of detection (LOD) for AM, MA, MDMA, MDA, and MOR was 0.29, 0.37, 0.86, 1.09 and 7.56 ng/mL, respectively. The method was applied to municipal wastewater samples collected from sewage treatment plants in Kuantan, Pahang, in which AM, MA and MDA were detected in all 3 samples.

Keywords: amphetamine, illicit drugs, LC-MS/MS, methamphetamine, municipal wastewater

Abstrak

Kaedah analisis berdasarkan spektrometri jisim kromatografi-tandem cecair (LC-MS/MS) untuk penentuan lima dadah berbahaya, iaitu amphetamine (AM), methamphetamine (MA), 3,4-methylenedioxymethamphetamine (MDMA), 3,4methylenedioxyamphetamine (MDA), dan morfin (MOR) dalam air sisa perbandaran telah dioptimumkan dan disahkan.

Penyediaan sampel dilakukan menggunakan kartrij SPE Oasis MCX. Pemisahan LC dilakukan dengan menggunakan turus Zorbax Eclipse Plus C_{18} RRHD. Kelinearan keluk tentukuran bagi semua analit sasaran berada di antara 5 ng/mL dan 250 ng/mL, kecuali morfin. Putara pemulihan analit sasaran berjulat antara 91.6 hingga 112%, dan kaedah ini menunjukkan kebolehulangan antara hari yang baik (pekali variasi berkisar antara 2 hingga 19%). Had pengesanan (LOD) bagi AM, MA, MDMA, MDA dan MOR adalah 0.29, 0.37, 0.86, 1.09 and 7.56 ng/mL. Kaedah ini digunakan untuk sampel air sisa perbandaran yang dikumpulkan dari loji rawatan kumbahan di Kuantan, Pahang, di mana AM, MA dan MDA telah ditemui dalam ketiga-tiga sampel.

Kata kunci: amphetamine, dadah berbahaya, LC-MS/MS, methamphetamine, air sisa perbandaran

Introduction

Drug abuse has been identified as a serious public health issue in Malaysia. Despite strict drug trafficking and possession laws, the Malaysian National Anti-drug Agency (AADK) reported 128,325 drug users and addicts in 2020, with Amphetamine-Type Stimulants (ATS) recorded the highest consumption (65.2%), followed by Opiates (30.9%) and Cannabis (2.7%) [1]. These official statistics, which are compiled from drug sweep operations conducted by The Royal Malaysia Police (PDRM) in cooperation with AADK, numerous ministries and governmental agencies as well as the Private Drug Rehabilitation Centers (PDRC), can provide a valuable overall picture of drug use in this country. However, since no extensive surveillance test is done, the actual consumption rates and drug use prevalence at the community, district or national level may be underestimated because these official figures are derived directly from consumers. Administered drugs are excreted as either unchanged parent drugs, conjugated forms or metabolites, flushed down the drain and eventually reach sewage treatment plants (STPs) [2]. By collecting STPs influent samples and quantifying the concentration of drug residues or metabolites in the samples, the population-normalized total consumption of a given drug within the population of a sewage treatment service area could be estimated. This wastewater-based epidemiology (WBE) method has been widely used to objectively monitor population-level drug usage, notably in the Western countries [3-6]. In a recent study conducted in Kuala Lumpur, Malaysia, 14 illicit drug residues with concentrations up to 1640 ng/L were found in municipal sewage samples [7]. This finding suggests that WBE could be used as a complementary monitoring approach in our country to estimate drug consumption.

Current analytical methods for quantifying illicit drugs in sewage commonly include a sample concentration step, such as solid-phase extraction (SPE) with various sorbent materials, followed by instrumental analysis with liquid chromatography-tandem mass spectrometry (LS-MS/MS) [8]. Direct injection and/or large-volume injection to LC-MS/MS (without pre-concentration) are also reported in the literature [9]. Before applying an analytical method to real samples, it is essential to determine whether it is suitable for the intended use. Therefore, in this study, an analytical method for the determination of ATS drugs, namely AM, MA, MDMA and MDA, as well as MOR (one type of opiates drugs) in sewage based on SPE and LC-MS/MS was validated. The method was tested on sewage samples taken from STPs in the Kuantan area to check if it was sensitive enough to detect these substances. The validated method will be used in the future to measure the usage of these drugs by utilizing the WBE approach.

Materials and Methods

Reagents and materials

The reference standards for the target compounds (AM, MA, MDMA, MDA and MOR) (Figure 1) as well as the deuterated internal reference standards used (AM-d_6, MA-d_5, MDMA-d_5, MDA-d_5 and MOR-d_3) were purchased from Lipomed AG (Switzerland) at concentrations of 1 mg/mL and 0.1 mg/mL in methanol (MeOH), respectively. Working solutions with concentrations ranging from 5 ng/mL to 250 ng/mL were prepared in MeOH. LC-grade MeOH and acetonitrile were purchased from Merck (Germany). Analytical grade ammonium hydroxide (NH_4OH) and hydrochloric acid (HCl) were obtained from Merck (Germany). Formic acid (Optima LC/MS) was obtained from Fisher Chemical (UK). Oasis MCX (60 mg, 3 mL) SPE cartridges were purchased from Waters Corporation (Milford, MA, USA). Glass fiber filters (0.7 µm) were obtained from Whatman (UK).

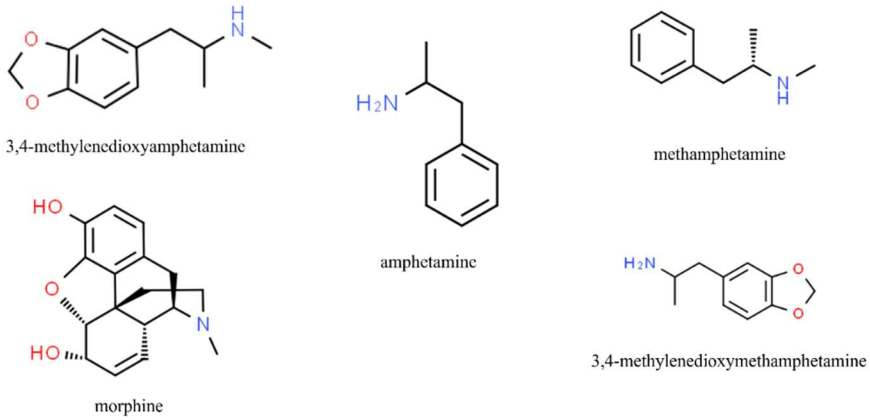

Figure 1. Chemical structures of the investigated of illicit drugs

Sample preparation, extraction, and sampling

A spiking test was used to validate the sample preparation and extraction method used by Kinyua et al. [10]. In brief, 500 mL of deionized (DI) water was spiked with reference standards (both native and deuterated internal standards at three concentration levels: 12.5, 50 and 100 ng/mL) and then analyzed to determine the extraction recovery, inter-day, and intra-day repeatability. For MOR, only 2 levels of spiking (50 and 100 ng/mL) were performed due to its high limit of detection (LOD). The samples were loaded onto Oasis MCX SPE cartridges preconditioned with 6 mL of methanol (MeOH), 4 mL DI water, and 4 mL of DI water at pH 2. After that, the cartridges were washed with 3 mL DI water before drying. The target analytes were eluted with 2 mL MeOH and 2 mL 5% NH_4OH in MeOH, evaporated to dryness under a gentle stream of nitrogen, and reconstituted in 100 µL of DI water containing 5% of acetonitrile and 0.1% formic acid. For each batch of extraction, one procedural blank (solvent blank spiked with internal standards) was included.

Three sewage samples were taken on August 10th, 17th and 24th, 2021, respectively, at the inlet of three STPs in Kuantan (designated STP-A, STP-B and STP-C). One 24-hour composite influent sample was collected at each station using a Watson-Marlow qdos 20 peristaltic pump at a flowrate of 5 mL/min. The samples were brought to pH 2 by adding 2M HCl, and they were then kept at -20 °C until analysis. Prior to extraction, the sewage samples were thawed and filtered through a 0.7 µm glass fiber filter to remove solid particles. For each sample, a 500-mL aliquot of the filtrates was spiked with internal standards at a concentration of 50 ng/mL and subjected to the previously described SPE procedure.

LC-MS/MS analysis

An Agilent 6410B Triple Quadrupole LC-MS/MS with an electrospray ionization (ESI) technique was used to detect and quantify target analytes. LC-MS/MS method used by Lai et al. [11] was adopted and optimized accordingly. In short, the chromatographic separation was performed using a Zorbax Eclipse Plus C18 RRHD column (2.1 × 50mm, 1.8µm). A mobile phase composed of A: 0.1% formic acid in water, and B: 0.1% formic acid in acetonitrile, was applied at a flow rate of 0.35 mL/min. The gradient was as follows: 0-2 min: 92% A, 2-2.1 min: 75% A, 2.1-3 min: 100% B. The total run time, which included column equilibration, was 5 minutes. The column and autosampler temperatures were set to 45°C and 4°C, respectively. The injection volume was set to 1 µL. Other MS parameters included gas temperature of 300°C, gas flow of 11 L/min, nebulizer pressure of 45 psi, and capillary voltage of 4000 V. Multiple reaction monitoring (MRM) was used to quantify the analytes. The mass spectrometer compound dependent parameters are listed in Table 1.

Table 1. LCMS/MS parameters for target drugs for MRM acquisition in positive mode

Drugs	Parent Ion (m/z)	Fragmentor Voltage (V)	Dwell (sec)	Collision Energy (V)	Product Ion (m/z)	Retention Time (min)
AM	136.1	60	160	23, 13	91, 119	1.18
MA	150.1	70	160	29, 17	91, 119	1.33
MDA	180.1	60	160	15, 33	163.1, 105	1.30
MDMA	194.1	80	120	17, 35	163, 105.1	1.40
MOR	286.1	150	160	80, 80	152, 128	0.55

Results and Discussion

LC optimization

During LC optimization, one mix native standard solutions (containing all targeted native compounds at a concentration of 500 ng/mL) and one mix internal standards (IS, deuterated standards at 500 ng/mL) were prepared and analyzed. A longer LC column (Zorbax RRHD Eclipse Plus C18, 2.1 × 150mm, 1.8µm) was initially tested with the LC method used by Lai et al. [11]; however, not all of the target compounds were well retained. A shorter column with the same stationary phase (2.1 × 50mm, 1.8µm) was then chosen due to its good retention and separation capacity for the target compounds. Different injection volumes (1 and 3 µL) were tested. Results showed that injection volume of 1 µL gave the best peak shape for the compounds compared to 3 µL (Figure 2). As all the target compounds eluted within 0.2 to 2 minutes, the gradient of the mobile phase was then modified to shorten the total run time to 5 minutes. An example of a chromatogram of a spiked sample is shown in Figure 3.

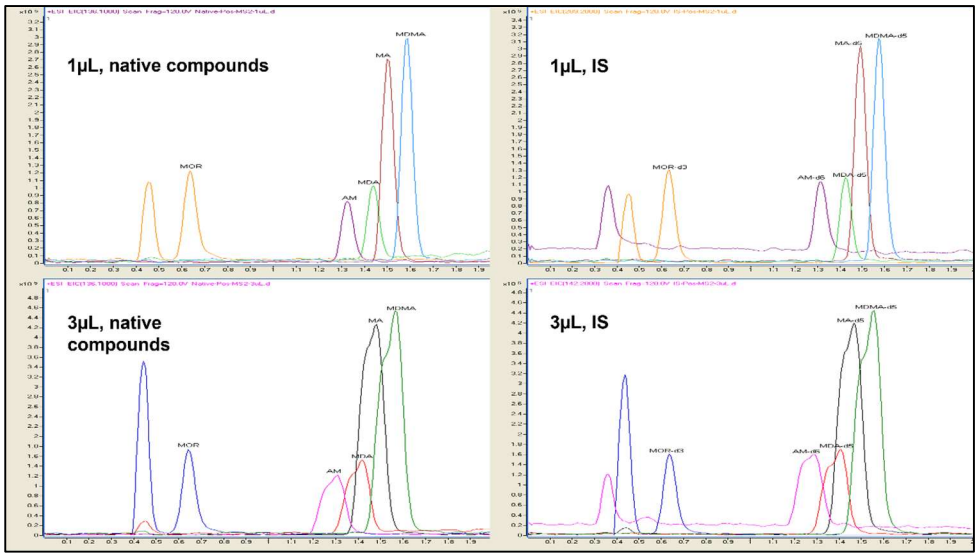

Figure 2. Chromatograms showing the peak shapes for different injection volumes

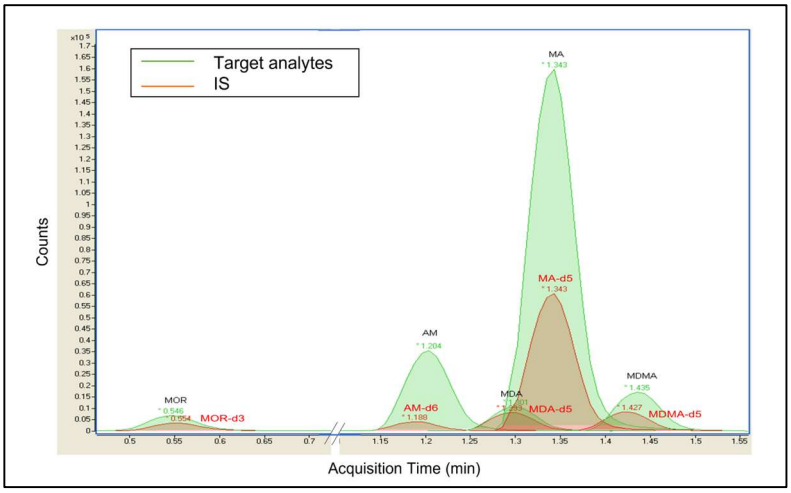

Figure 3. Typical LC-MS/MS chromatogram of a spiked sample

Method validation

The analytical method was validated in terms of linearity, recoveries, inter- and intra-day repeatability, and lower limit of quantification (LLOQ) according to the Bioanalytical Method Validation guidelines provided by the European Medicines Agency (EMEA) [12]. The method validation results were summarized in Table 2 and Table 3. The calibration curves were linear between 1 ng/mL and 250 ng/mL for AM and MA, 5 – 250 ng/mL for MDMA and MDA, and 10 – 250 ng/mL for MOR. The determination coefficients (R^2) for all calibration curves were higher than 0.99, except for MOR. The LOD and LLOQ were calculated based on the lowest concentration of standards with signal-to-noise ratio of 3 and 10, respectively. The mean recovery of spiked standards ranged between 91.6 and 112%, with the coefficient of variation (CV) between 2 and 19%, which was within the acceptable criteria of the EMEA guidelines. Target illicit drugs in all the procedural blanks were below LOD in all batches of extractions.

Table 2. Linear ranges, detection limits and calibration equations for the determination of illicit drugs

Drugs	Linear Range (ng/mL)	LOD (ng/mL)	LLOQ (ng/mL)	Calibration Equation	R^2
AM	1-250	0.29	0.95	y = 10.962427x -0.144109	0.9999
MA	1-250	0.37	1.22	y = 1.773839x + 0.029082	0.9999
MDA	5-250	0.86	2.86	y = 0.925804x + 0.026275	0.9999
MDMA	5-250	1.09	3.64	y = 1.361590x -0.021144	0.9997
MOR	10-250	7.56	25.2	y = 0.949434x + 0.031253	0.9494

Table 3. SPE-LCMS/MS method intra-day and inter-day precision at three spiking concentrations (low = 12.5 ng/mL, medium = 50 ng/mL, high = 100 ng/mL)

Drugs	Intra-day (n=3, 1 day) (mean ±SD) (CV) (%)			Inter-day (n=9, 3 days) (mean ±SD) (CV) (%)		
	Low	Medium	High	Low	Medium	High
AM	99.7±9.10 (9)	100 ±9.97 (10)	99.3±10.6 (11)	91.6±14.0 (15)	97.3 ±13.0 (13)	97.9±9.07 (9)
MA	97.5±17.5 (18)	111 ±6.27 (6)	107±11.1 (10)	98.3±15.1 (15)	106 ±13.0 (12)	105±14.7 (14)
MDA	101±18.8 (19)	97.6 ±5.62 (6)	96.3±12.2 (13)	94.1±18.1 (19)	109 ±10.2 (9)	108±15.8 (15)
MDMA	93.3±9.26 (8)	112 ±9.87 (9)	107±15.3 (14)	106±7.84 (9)	95.5 ±7.68 (8)	107±12.6 (12)
MOR	*	102 ±2.29 (2)	93.6±14.0 (15)	*	99.9 ±5.39 (5)	103±15.6 (15)

*: No data as spiking test for MOR was performed on 2 levels (50 and 100 ng/mL)

Sewage samples

The validated procedure was applied to 3 sewage samples collected from STPs in Kuantan. Results showed that AM, MA, and MDA were detected in all samples at concentrations ranging from 5.27 to 82.2 ng/L (Table 3). MDMA and MOR were below LOD in all sewage samples. This finding is consistent with the AADK official numbers, which show that ATS including AM, MA, MDMA and MDA, are the most commonly used illicit drugs in Malaysia [1]. The absence of MDMA in sewage samples could be explained by MDMA degradation in sewage [13-14]. The levels of AM, MA, MDA detected in this study were within the range of that reported by Du et al. [7] in 2 STPs at Kuala Lumpur. The absence of MOR in this study could indicate a different drug use patterns in different communities. However, due to the limited number of samples, the findings in this preliminary study require further research involving more communities.

Table 3. Concentrations (ng/L) of the target analytes in influent sewage from STPs in Kuantan

STP	Date of sampling	AM	MA	MDMA	MDA	MOR
STP-A	10/8/2021	5.28	82.2	ND	7.21	ND
STP-B	17/8/2021	10.1	423	ND	11.6	ND
STP-C	24/8/2021	11.7	443	ND	20.0	ND

ND: Below LOD

Conclusion

In this study, an analytical method based on SPE–LC-MS/MS was validated for the detection of five illicit drugs (AM, MA, MDA, MDMA and MOR) in municipal wastewater. Results from spiking test indicated satisfactory recoveries and good inter- and intraday repeatability. The validation demonstrates that the established analytical method is applicable for detecting the presence of illegal substances in STPs by providing good LODs, linearities, and recoveries. In the future, this analytical procedure will be applied in a large monitoring program in Kuantan, which aims at calculating the drug consumption from their concentrations in sewage.

Abstract

Glass ionomer cements (GIC) are produced via acid-base reaction between calcium fluoroaluminosilicate glass powders and freeze-dried polyacrylic acid powder. Shells from *Anadara granosa* or commonly known as cockle, consist of >90% calcium carbonate ($CaCO_3$), have been utilized as the source of $CaCO_3$ by incorporating it as part of glass components for production of GIC. The main objective of this research is to investigate the effect of *Anadara granosa* shells in setting reaction of GIC using FT-IR spectroscopy. Two types of GIC were synthesized, GIC-A (analytical grade $CaCO_3$) and GIC-B (replacing $CaCO_3$ with the shells). FT-IR spectra showed the setting reaction for both GICs with the occurrence of cross-linking between polyacrylate chain and metal ion from the glass by gradual conversion of COOH at 1690-1700 cm^{-1} into COO^-M^{n+} at 1550-1600 cm^{-1}. For compressive strength, GIC-B showed a lower compressive strength compared to GIC-A at 1-day aging time. However, it reached similar value as GIC-A after 28 days aging time. In conclusion, *Anadara granosa* shells can be utilized for Ca aluminosilicate glass in GIC production where it exhibited similar setting properties and compressive strength as GIC from glass synthesized using commercial $CaCO_3$.

Keywords: *Anadara granosa*, glass ionomer cement, calcium carbonate, calcium fluoroaluminosilicate

Abstrak

Simen kaca ionomer (GIC) dihasilkan melalui tindak balas asid-bes di antara serbuk kaca kalsium fluoroaluminosilikat dan serbuk asid poliakrilik kering sejuk beku. Cengkerang dari *Anadara granosa* atau kebiasaannya dikenali sebagai kerang ini mengandungi >90% kalsium karbonat ($CaCO_3$), telah dimanfaatkan sebagai sumber kalsium karbonat dengan menggabungkannya sebagai sebahagian daripada komponen kaca untuk menghasilkan GIC. Objektif utama kajian ini adalah untuk menyiasat kesan cengkerang *Andara granosa* dalam tindak balas pengerasan GIC menggunakan spektroskopi FT-IR. Dua jenis GIC telah disintesis, GIC-A ($CaCO_3$ gred analisis) dan GIC-B (menggantikan $CaCO_3$ dengan cengkerang). Spektrum FT-IR menunjukkan bahawa tindak balas pengerasan bagi kedua-dua GIC berlaku dengan kehadiran rangkai silang antara rantai poliakrilat dan ion logam daripada kaca dengan pertukaran COOH secara beransur-ansur pada 1690-1700 cm^{-1} kepada COO^-M^{n+} pada 1550-1600 cm^{-1}. Untuk kekuatan mampatan, GIC-B menunjukkan kekuatan mampatan yang lebih rendah berbanding GIC-A pada masa penuaan 1 hari, namun, ia mencapai nilai yang sama seperti GIC-A selepas masa penuaan 28 hari. Kesimpulannya, cengkerang *Anadara granosa* boleh

digunakan untuk kaca Ca aluminosilikat dalam penghasilan GIC di mana ia mempamerkan sifat pengerasan dan kekuatan mampatan yang sama seperti GIC daripada kaca yang disintesis menggunakan $CaCO_3$ komersial.

Kata kunci: *Anadara granosa*, simen kaca ionomer, kalsium karbonat, kalsium floroaluminosilikat

Introduction

Blood cockle is a bivalve marine mollusc from the species *Anadara granosa* which is mostly used as a source of protein-rich food. Countries such as Malaysia, Indonesia, and Thailand are known for their extensive cockle industry [1]. The production of cockle in Malaysia is great and keeps increasing year by year. However, the shells are treated as waste with an unpleasant smell and are often just dumped in landfill or the sea [2-3]. From early 2000 until now, studies on seashells as a source of calcium carbonate, $CaCO_3$ are widely explored, especially in the medical field such as for bone and dental applications [4-11]. $CaCO_3$ in cockle shell consists of three polymorphs known as calcite, aragonite, and vaterite. Researchers are more interested in aragonite polymorph due to its biocompatible properties [12]. Aragonite has osteoregenerative potential and can be used for bone substitution [13]. On the other hand, calcite has good thermodynamic stability. Calcite nanoparticle is considered as an extremely effective material in biomedical due to their shape, non-toxic properties, and it is also easily metabolized by all cells. Calcite with nanostructure could supply calcium sources to retain Ca ions in the supersaturation state in the enamel minerals. Hence, calcite has great potential in preventing tooth erosion thereby it could be used for dental hypersensitive treatment [14]. While vaterite, less commonly occurs in nature because it is the least thermodynamically stable polymorph. Vaterite can rapidly transform into calcite and aragonite in an aqueous solution [15].

In dental applications, calcium hydroxide has been considered the gold standard for pulp capping materials for decades to stimulate the formation of tertiary dentin. Blood cockle shells are expected to be an alternative pulp protective material for initiating dentin tissue deposition so that the healing process can occur by the formation of reactionary dentin [16]. The cockle shell is also claimed to have anti-inflammatory properties as well as good stability due to calcite polymorph [17]. Researchers have also prepared zirconia stabilized by CaO known as calcia-doped zirconia using CaO derived from cockle shells for dental application [18]. The study was done by comparing the CaO from cockle shells with the commercial CaO and the research concluded that the calcia-doped zirconia with the CaO derived from cockle shells may be used as an alternative to the current zirconia available in the market for dental application due to its physical and mechanical properties. Apart from that, their flexural and compressive strength are also comparable with the commercial type. Cockle shell is also being studied as hydroxyapatite paste as a remineralization agent, to which the result showed that it can increase tooth enamel surface hardness with nearly the same effect as CPP-ACP (commercial GC Tooth Mousse®) paste [19]. Another study has applied CaO in the glass formulation derived from clamshell for the production of glass ionomer cement, GIC. The physical and mechanical properties of GIC derived from soda lime glass and clamshell improved with the addition of hydroxyapatite [20].

Even though studies using clamshell as $CaCO_3$ source in GIC had been done previously, the studies only focused on the influence of hydroxyapatite existence. In this study, the GIC was prepared using Ca aluminosilicate glass derived from cockle shell and the setting reaction was thoroughly investigated using FT-IR spectroscopy. A comparison study with a similar formulation of glass ionomer using analytical grade $CaCO_3$ was done to determine the suitability of the cockle shell as the $CaCO_3$ source in the synthesis of GIC for dental application.

Materials and Methods

Materials

Silicon dioxide, SiO_2 and calcium fluoride, CaF_2 were purchased from Sigma-Aldrich Co., US. Aluminium oxide, Al_2O_3, and calcium carbonate, $CaCO_3$ were purchased from Fisher Scientific, US, and phosphorus pentoxide, P_2O_5 from Acros Organics, US. All chemicals were analytical-grade reagents with more than 99% purity. *Anadara granosa* shells were obtained

from a fresh market at Lumut, Perak, Malaysia. These cockle shells were used as an alternative source to $CaCO_3$. A medical-grade freeze-dried poly(acrylic acid) was supplied by Advance Healthcare, Kent, England with a molecular weight of ~30,000. Throughout the experiment, analytical-grade ethanol was used to dehydrate the cement. In addition, liquid nitrogen was employed to terminate the setting reaction in GICs.

Preparation of *Anadara granosa* shells powder

Anadara granosa shells were washed thoroughly and immersed in water to remove surface impurities. The shells were then dried in an oven at 110 ℃. Heat treatment was applied to the shells at 400 ℃ for 2 hours. The shells were then crushed using stainless steel pounder and ball mill for 24 hours. After that, the ground shells were sieved to less than 45 µm particle size.

Preparation of glasses

Two Ca aluminosilicate glasses, glass GIC-A (analytical grade $CaCO_3$) and GIC-B ($CaCO_3$ from *Anadara granosa* shells), with similar formulations were synthesized. Weight percentages of each composition were 16.60% alumina, 16.91% calcium oxide, 37.57% silica, 16.68% phosphorus pentoxide, and 12.24% calcium fluoride. All chemical compositions (SiO_2, Al_2O_3, $CaCO_3$, and CaF_2) were homogenized by using a ball mill unit for 6 hours before melting. Phosphorous pentoxide was only added to the mixture just before the melting process to avoid hydration as it is a highly hygroscopic material. Approximately 30 g of the mixture in an alumina crucible was melted in a furnace at 1500 ℃ for 2 hours. The molten mixture was poured immediately into the water for shock quenching to produce non-crystallized glass frits. The glass obtained was air-dried before placing it in an oven for overnight drying at 37 ℃. It was then ground by dry milling in a rotary ball mill and sieved to ≤45 µm particle size.

Preparation of glass ionomer cement (GIC)

The preparation of GIC was done according to ISO 9917-1:2007 Dentistry Water Based Cements Part 1: Powder/liquid acid-base cements 2007 [21]. The glass powder was mixed with freeze-dried poly (acrylic acid), PAA and distilled water on a glass slab using a stainless-steel spatula in a weight ratio of 3:1:1. The GIC was then inserted into a cylinder mold with a dimension of 4.0 mm x 6.0 mm. Then, the GIC together with the mold was placed in an incubator at 37 ℃ for 1 hour. After that, the samples were transferred into containers with deionized water and left for a certain period according to their aging times studied. The aging time was from 5 minutes to 28 days. Liquid nitrogen and ethanol were applied to the GICs with aging time of less than 1 hour to terminate the setting reaction by dehydrating the GIC.

Setting reaction study of GIC

The setting reaction of GIC was studied at several time intervals: 5 minutes, 15 minutes, 30 minutes, 1 hour, 6 hours, 1 day, 7 days, and 28 days. Samples with time intervals ranging from 5 minutes to 1 hour were set in an incubator at 37°. GICs with aging time of more than 1 hour were placed in the incubator at 37 °C for 1 hour then it was transferred into a sample bottle containing deionized water and kept in the incubator for the remaining aging period. For GICs less than 1 hour of aging time, liquid nitrogen and ethanol were used to terminate the reaction and dehydrate the GICs. The GICs were then ground to a fine powder for the FT-IR analysis.

Characterizations of *Anadara granosa* and GIC

The *Anadara granosa* shell was characterized by energy dispersive x-ray (EDX), thermogravimetric analysis (TGA), and X-ray diffraction (XRD), while GIC samples were characterized using Fourier transform infrared spectroscopy (FT-IR), and compressive strength test.

Energy dispersive X-ray

Elemental analyses of *Anadara granosa* shells in powder form were determined using an energy dispersive X-ray analyzer (FEI-Quanta 200, The Netherlands) directly linked to a scanning electron microscopy, SEM operated with environmental mode at 15 kV and relative humidity of 96%- 99%.

X-ray diffraction

XRD is a non-destructive technique for qualitative analysis. XRD was used to compare the XRD pattern of *Anadara granosa* shells with the analytical grade $CaCO_3$. The analysis was conducted from 4° to 90° by

using a 2θ goniometer X-ray powder diffractometer (PANalytical X'pert-Pro MPD PW 3040), operated at Cu-K α radiation (λ = 0, 15406 nm). The diffractogram was scanned at a scan rate of 2° min^{-1}.

Thermogravimetric analysis

Thermogravimetric analysis (TGA) was used to analyze the thermal decomposition of *Anadara granosa* shells by using Metter-Toledo thermogravimetric analyzer. Shell in powder form with particle size ≤45 μm was placed in a 40 μl alumina crucible and subjected to heating in the range of 25 to 1000 ℃ at 10 °C/min under the flow of nitrogen gas at 50 ml/min.

Fourier transform infrared (FT-IR) spectroscopy

FT-IR Spectroscopy is a non-destructive method for both qualitative and quantitative analysis. In this study, FT-IR was used to study the setting reaction of GIC from aging time of 5 minutes to 28 days. Perkin- Elmer FT-IR spectrometer coupled with UATR accessory was used to record FT-IR transmittance spectra. Approximately 0.001 g of sample was used and scanned within the wavenumber of 280 cm^{-1} to 4000 cm^{-1}.

Compressive strength test of GIC

Compressive strength of the GIC was done according to ISO7489:1986 specifications [22, 23] with the dimension of 6.0mm × 4.0mm cylindrical-shaped cement. GIC samples were tested at 1, 7, and 28 days. The test was performed using Instron 4082 Universal Testing Machine with a 1kN load cell at a crosshead of 1mm/min until the cement fractured. Five specimens of each GIC were tested. The mean compressive strength and standard deviation of GIC were calculated.

Results and Discussion

Energy dispersive X-ray (EDX) of *Anadara granosa* shell

Table 1. shows the weight percentage of the composition of *Anadara granosa* shell. It was found that the major component of the shell was $CaCO_3$ with the presence of a small amount of other metal oxides such as Na_2O, Al_2O_3 and SiO_2. The presence of a small amount of sodium oxide may come from the sodium content of seawater during the *Anadara granosa* growth in the sea [9]. The percentage of $CaCO_3$ in *Anadara granosa* powder was 97.53%. Other oxides were all detected in very small amounts in the sample. Moreover, the result in this study is in good agreement with the findings of previous studies. Previous studies in Malaysia reported that *Anadara granosa* shells were composed of 98.7% $CaCO_3$, 0.05% Mg, 0.9% Na, 0.02% P and 0.2% of other elements (Fe, Cu, Ni, Zn, B, and Si) [24, 25].

Table 1. The weight percentage of *Anadara granosa* shell

Composition	Percentage in Weight (%)
Na_2O	0.73
$CaCO_3$	97.53
Al_2O_3	1.76
SiO_2	0.07

X-ray diffraction analysis

XRD analysis shows that *Anadara granosa* shell exhibited similar XRD patterns as analytical grade calcium carbonate as shown in Figure 1. The diffraction lines for *Anadara granosa* shells were well matched with pure analytical grade $CaCO_3$ and thus indicates that it is suitable to be utilized as a source of CaO in the synthesis of Ca aluminosilicate glass.

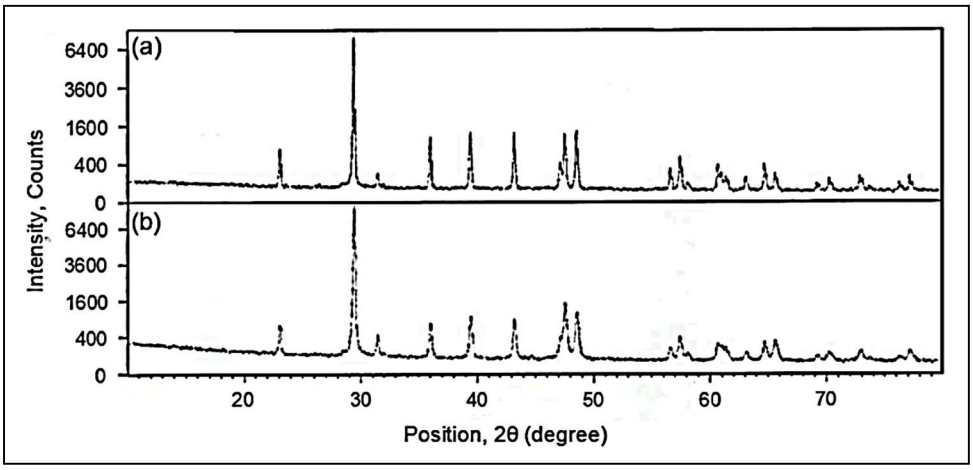

Figure 1. XRD pattern for (a) analytical grade $CaCO_3$; (b) *Anadara granosa* shells powder

Thermogravimetric analysis

From XRD analysis, it is found that the main component of *Anadara granosa* shell is $CaCO_3$. Generally, $CaCO_3$ will undergo thermal decomposition when the heating temperature is more than 550 ℃. In this experiment, the *Anadara granosa* shell was heated up to 1000 ℃, hence the calcium carbonate in *Anadara granosa* shell was expected to decompose to calcium oxide eventually.

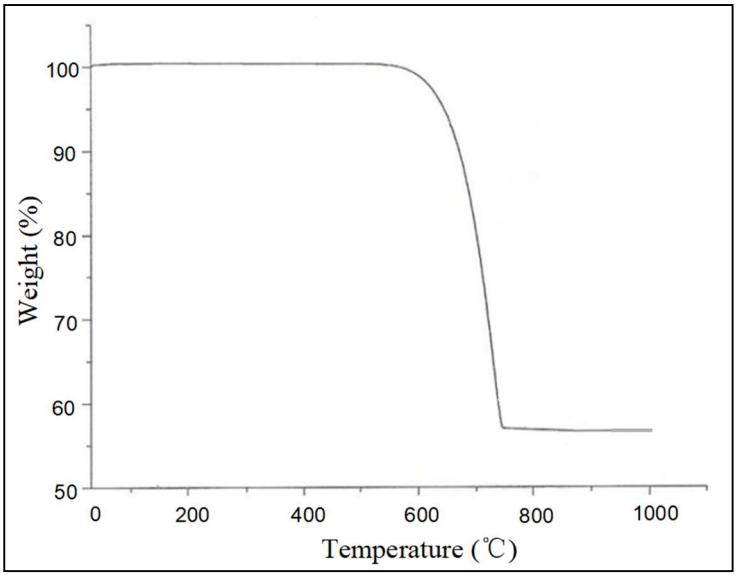

Figure 2. TGA decomposition graph of *Anadara granosa* shell

Based on the thermal decomposition curve in Figure 2, single-stage decomposition with an onset decomposition temperature of 508.6 ℃ was observed. The single decomposition step suggested calcium carbonate only undergoes a reaction in which bound carbon dioxide was released upon heating. At 508.6 ℃, calcium carbonate in *Anadara granosa* shells started to decompose and evolve into carbon dioxide. The offset temperature of 768.3 ℃ indicated the ending of the decomposition process and calcium oxide together with trace metals constituted the residue.

The process of decomposition of $CaCO_3$ to CaO can be presented using the equation shown below:

$$CaCO_3(s) \longrightarrow CaO(s) + CO_2(g) \quad \text{(eq. 1)}$$

Based on the equation, it shows that 1 mol of $CaCO_3$ will produce 1 mol of CaO. The percentage of calcium carbonate in *Anadara granosa* shells can be calculated as below:

$$Percentage(\%)\ of\ CaCO_3\ in\ Anadara\ granosa = \frac{CO_2\ weight\ loss}{Mr\ CO_2} \times \frac{Mr\ CaCO_3}{Mass\ of\ Anadara\ granosa} \quad \text{(eq. 2)}$$

Based on the formula above, 98.68% of calcium carbonate was found in *Anadara granosa*. This result agrees with the percentage of $CaCO_3$ obtained from the EDX analysis. According to a previous study, the total mineral content of cockle shells in west coast Malaysia comprises 98.7% of calcium carbonate and an insignificant amount of trace metals [24]. A high percentage of calcium carbonate in the shells suggested that it is suitable to be utilized as a source of calcium carbonate for the synthesis of Ca aluminosilicate glass.

Setting reaction of GIC-A and GIC-B by using FT-IR spectroscopy

The setting reaction of GIC-A and GIC-B were studied by using FT-IR spectroscopy. Generally, setting reaction in GIC involves the formation of metal polyacrylate and silica gel repolymerization. Figure 3 shows the FT-IR spectra of GIC-A (analytical grade $CaCO_3$), and GIC-B ($CaCO_3$ from shells) in the range of 2000 cm^{-1} to 600 cm^{-1} for setting time from 5 minutes to 28 days. Both GICs show similar trends in FT-IR spectra.

The formation of metal polyacrylate takes place between carboxylic part (-COOH) of polyacrylic acid with metal ions such Al^{3+} and Ca^{2+} from the glass particle. This reaction is known as cross-linking reaction and produced COO^-M^{n+} species in the GIC. In FT-IR spectroscopy, COO^-M^{n+} is assigned as asymmetric vibration of $(COO^-)Ca^{2+}$ and $(COO^-)Al^{3+}$ with respect to Ca^{2+} and Al^{3+} present in the glass [26]. From Figure 3, the absorption band of COOH at wavenumber 1730 cm^{-1} is observed at 5 minutes aging time and at the same aging time, a shoulder peak corresponds to the cross-linking absorption band, COO^-M^{n+} at wavenumber 1620 cm^{-1} also appeared. As the aging time increased, the absorption band of COOH began to disappear and the intensity of the COO^-M^{n+} band increased. The disappearance of COOH band is due to the cross-linking between the PAA and the glass proceeds to a higher extent with aging time. It is also found that the absorption bands of COOH group for GIC-A and GIC-B slightly shifted to lower wavenumbers from 1745 to 1720 cm^{-1}.

As the aging time increased from 5 minutes to 28 days, the intensity of the absorption band of COOH decreased while COO^-M^{n+} absorption band increased gradually. This suggests that the cross-linking of carboxylate group, COO^- by metal cations occurred to a greater extent and corresponded to progressive proton removal from carboxyl groups. At 28 days of aging time, there was still a shoulder band at 1700 cm^{-1} corresponding to the unreacted COOH of PAA. COOH group of PAA did not undergo complete ionization as PAA is generally a weak acid. Furthermore, the remaining protons were strongly attracted by electrostatic forces due to greater ionization of polyacrylate chains as setting reaction continued. Due to strong binding forces, protons on the unionized COOH group were hard to be replaced by metal cations for cross-linking [26].

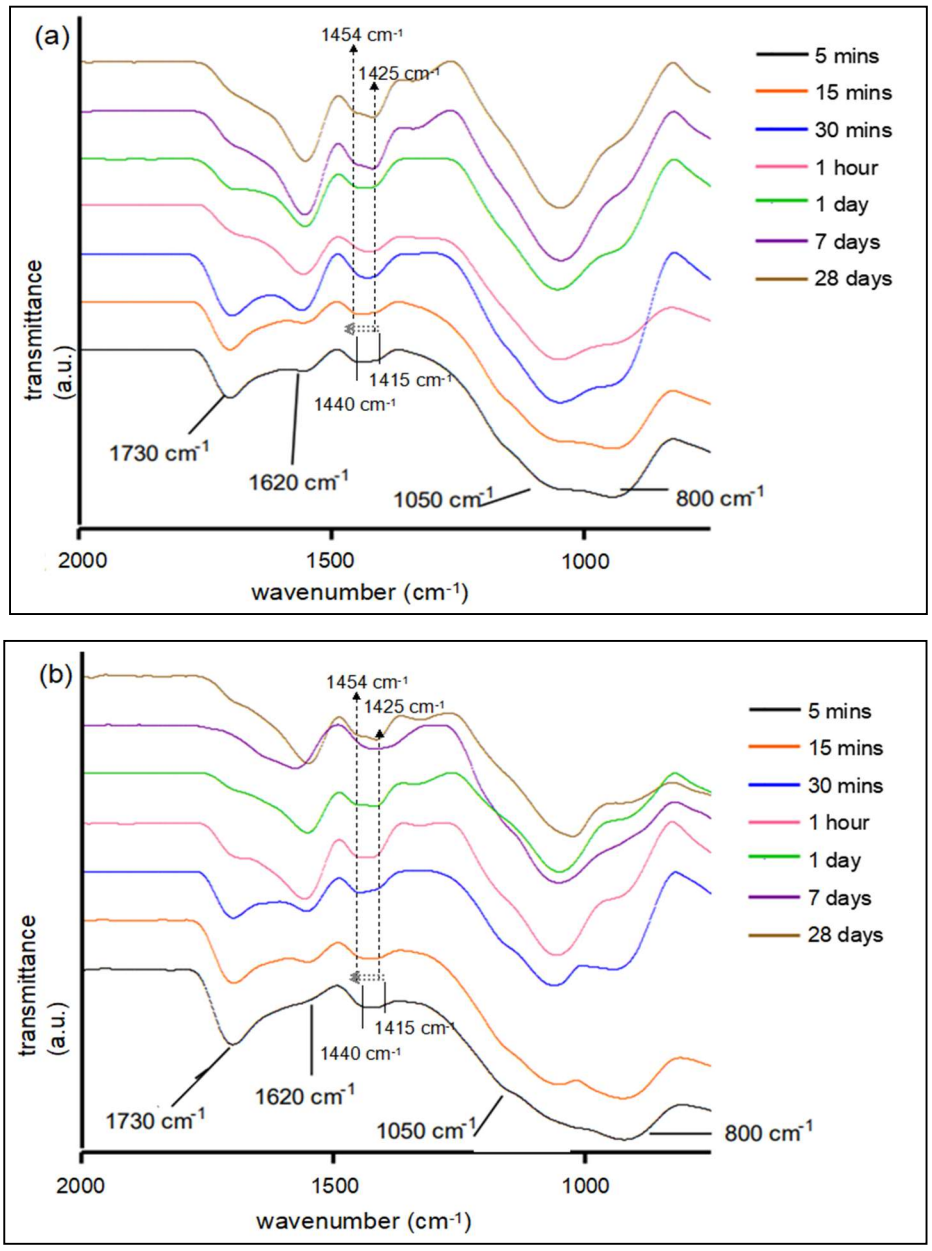

Figure 3. FTIR spectra for (a) GIC-A and (b) GIC-B from 5 minutes to 28 days aging time.

Another reaction in the setting of GIC is repolymerization of silica network of the glass. FT-IR spectra showed changes in the region of 1200 to 800 cm^{-1} which corresponded to the changes from Si-OH (800 cm^{-1}) to Si-O-Si (1050 cm^{-1}). At the early aging time, Si-O-H band from the formation of silica gel was easily observed as compared to Si-O-Si band which remained obscure. This is in line with the setting mechanism which suggests that the proton ionized from COOH group of PAA had displaced metal cations in the silicate network and formed Si-O-H. At a later setting reaction, an absorption band with a shoulder corresponding to Si-O-Si gradually appeared. Meanwhile, the diminishing absorption band of Si-O-H was observed. Next, two weak bands were observed at 1440 cm^{-1} and 1415 cm^{-1} associated with scissors and bending vibrations of $-CH_2$ and -CH-C=O groups respectively. Both bands were slightly shifted to a higher wavenumber from 1440 cm^{-1}

to 1454 cm^{-1} for $-CH_2$ and from 1415 cm^{-1} to 1425 cm^{-1} for CH-C=O. This may be due to the cross-linking reaction where the angle of CH-C=O bonding was altered for calcium ion and aluminum ion to cross-link with the polyacrylic acid on the surface of the glass. This interaction caused the $-CH_2$ bond near the CH-C=O to vibrate and altered the position of $-CH_2$ bending [27]. Due to the higher energy needed to vibrate these species, the absorption bands shifted slightly higher wavenumber in the cement. In conclusion, the study of setting reaction of GICs by using FT-IR spectroscopy indicates that the setting mechanism involves both cross-linking reaction and silica gel repolymerization occur concurrently.

Degree of cross-linking (DCL)

Cross-linking of PAA by metal cations resulted in the formation of cement matrix due to gelation of PAA. The degree of cross-linking (DCL) was calculated according to a previous study by Matsuya et al. [29] using FT-IR spectroscopy. The DCL between polyacids chains was calculated from the formula:

$$\mathrm{DCL} = \frac{Abs(COO^{-}M^{n+})}{Abs(COOH) + Abs(COO^{-}M^{+})} \qquad \text{(eq. 3)}$$

where Abs refer to FTIR absorbance with respect to specific wavenumber.

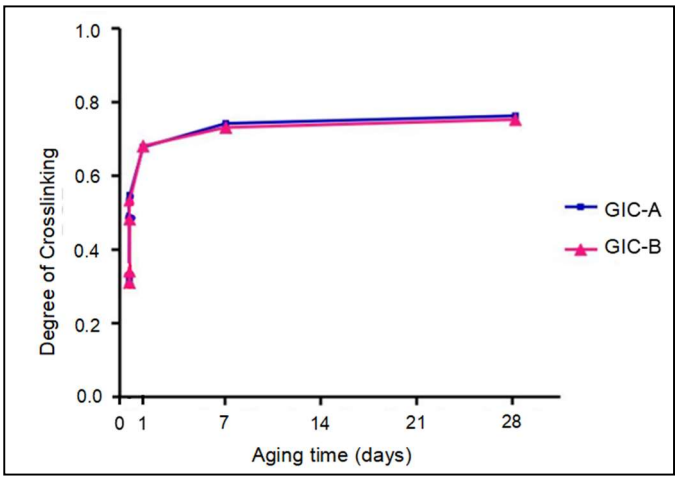

Figure 4. Degree of cross-linking for GIC-A and GIC-B

Figure 4 shows the rapid increment of DCL value within 1 hour followed by gradual increment up to 28 days for both GIC-A and GIC-B. A similar finding was reported previously by Matsuya et al. [29]. The DCL value for GIC-A and GIC-B increased drastically within 1 hour of aging time with DCL values of 0.5473 and 0.5344, respectively. The increase in DCL suggests that a greater extent of the cross-linking reaction occurred between polyacrylate chains and metal cations from the glass. This finding also suggests that there is a high amount of metal cations released during glass degradation where these metal cations then cross-link with the polyacrylate chain. There was only a slight increment in DCL values for longer aging time (7 to 28 days) from 0.7426 to 0.7631 for GIC-A and 0.7316 to 0.7528 for GIC-B. The fact that the DCL still increased up to 28 days suggests that the cross-linking reaction continues with time after the initial setting [30]. This is probably caused by continuous release of ions from the glass and the change in conformation of PAA [31,32]. Change in PAA chain conformation provided accessibility for cross-linking sites at carboxylate group. Previous study by Cattani-

Lorente et al. [33] suggested slow additional cross-linking to be another factor other than the role of silica gel phase which contributed to the strengthening of cement.

In addition, as the setting reaction proceeded, the polyacrylate matrix became rigid and highly viscous which rendered free carboxylic groups from forming ionic bonding with metal cations [27]. Therefore, the intensity of FT-IR absorption bands for COOH and COO^-M^{n+} and DCL values for both cement types were not significantly changed. In conclusion, the setting study of GIC-B which was produced from the *Anadara granosa* shell showed a similar setting mechanism as GIC-A from analytical grade $CaCO_3$.

Compressive strength of GIC

The effect of maturation of cement was examined on compressive strength for GIC-A and GIC-B. Previous studies had reported maturation of cement which involved additional cross-linking between polyacrylate matrices [31, 33]. A minimum aging time of 24 hours is needed as GICs are weak and sensitive to desiccation and moisture contamination at the early setting stage. Loss of water will cause shrinking and crazing of cement surface while hydration will result in the leaching of matrix-forming ions upon disintegration. Figure 5 shows the mean values (MPa) and standard deviations obtained for the compressive strength of GIC-A and GIC-B from 1 day to 28 days of aging time.

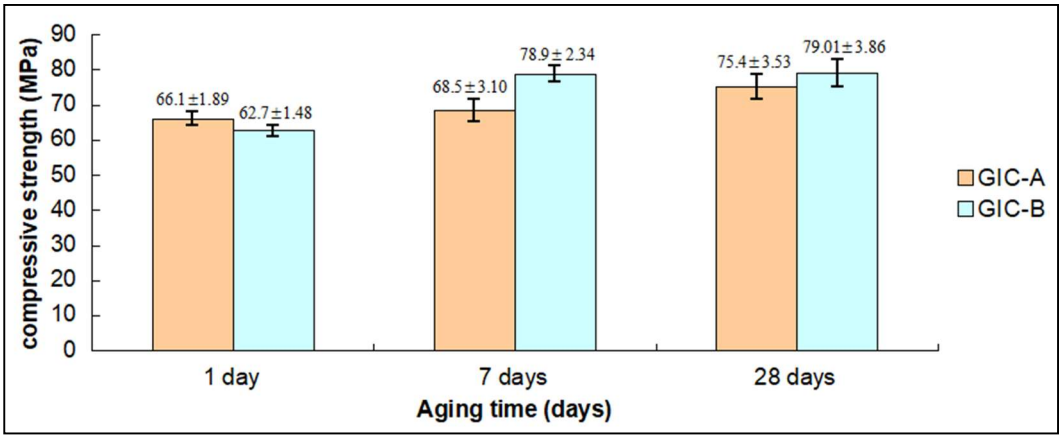

Figure 5. Compressive strength of GIC-A and GIC-B cements at 1 day to 28 days aging time

Figure 5 shows that at 1 day of aging time, GIC-B exhibited slightly lower compressive strength than GIC-A with the value of 62.7 MPa and 66.1 MPa, respectively. The lower compressive strength of GIC-B than GIC-A at 1-day aging time may be due to the presence of sodium in *Anadara granosa* shell in the glass. Lohbauer [34] stated that the incorporation of sodium into glass resulted in an adverse effect on solubility, hydrolytic stability, and mechanical properties of the set cement. The high mobility of sodium in silicate glass increased its tendency to be released from the glass and readily exchanged with protons during the setting reaction [35]. Since sodium was not strongly bound to carboxylate group as COO^-Na^+ hence, it was ionized readily into the aqueous phase.

When aging time increased from 1 day to 7 days, there was an increase in the compressive strength for GIC-B from 62.7 MPa to 78.9 MPa. Previous studies stated that commonly GIC does not reach its maximum strength at 24 hours after setting reaction [36]. For both GICs, the compressive strength increased slightly from 7 days dan 28 days of aging time which is consistent with the findings from FT-IR spectra (Figure 3) as well as DCL (Figure 4). Based on Figure 5, both GICs exhibited almost similar compressive strength at 28 aging time with a value in the range of 75.0 - 79.0 MPa.

Conclusion

In this study, the high percentage of $CaCO_3$ in *Anadara granosa* shells indicates that they can be used as a source of $CaCO_3$ in dental glass. The setting reaction and

compressive strength of GIC made from *Anadara granosa* shells show similar results as GIC from analytical grade $CaCO_3$. Therefore, this study has revealed the potential of *Anadara granosa* shells for dental cement formulation.

Abstract

In this study, molecularly imprinted polymer-oleic acid (MIPOA) was synthesized using oleic acid (OA) as the template via bulk polymerization. The objective of this study was to characterize the MIPOA as an adsorbent for the isolation of OA from palm fatty acid distillate (PFAD) waste, using thermogravimetric analysis (TGA) and Brunauer-Emmett-Teller (BET) analysis. Isolation method of OA from PFAD waste using MIPOA via esterification reaction in methanol and detection of OA by using gas chromatography–mass spectrometry (GC-MS) showed that MIPOA was capable of isolating OA from PFAD waste sample at 99.99% of isolation efficiency. Findings obtained from TGA results showed that MIPOA was less thermally-stable compared to NIP at higher temperature as the percentage weight loss of MIPOA was higher than NIP. At 215 °C, the weight loss of MIPOA (9.36%) was higher compared to NIP (6.55%) as a control due to the less branch of cross-linked polymer was successfully synthesized. Higher surface area in MIPOA compared to NIP was successfully proven in this experiment. In addition, the presence of OA as a template leaves the cavities during MIPOA washing contributes to the increase of the surface contact. Due to its high surface area and ease of degradation by external energy from heating when compared to NIP (which act as control), MIPOA has a high porosity and an abundance of an organic cross-linkage network. From BET analysis, surface area of MIPOA was 390.52 m^2/g and this value was relatively high in isolation efficiency for the isolation of OA methyl ester. MIPOA displays type I isotherms which indicates that the MIPOA was microporous. These results proved that MIPOA can be employed as a potential adsorbent to isolate OA from PFAD waste.

Keywords: molecularly imprinted polymer, oleic acid, palm fatty acid distillate

Abstrak

Dalam kajian ini, polimer tercetak molekul-asid oleik (MIPOA) telah disintesis menggunakan asid oleik (OA) sebagai templat melalui pempolimeran pukal. Objektif kajian ini adalah untuk mencirikan MIPOA sebagai bahan penjerap untuk mengasingkan OA daripada sisa penyulingan asid lemak sawit (PFAD), analisis termogravimetrik (TGA) dan analisis Brunauer-Emmett-Teller (BET). Kaedah pengasingan OA daripada sisa PFAD menggunakan MIPOA melalui tindak balas pengesteran dalam metanol dan pengesanan OA menggunakan kromatografi gas–jisim spektrometer (GC-MS) yang menunjukkan MIPOA mampu mengasingkan

OA daripada sampel sisa PFAD pada 99.99% kecekapan pengasingan. Dapatan diperolehi daripada keputusan TGA menunjukkan MIPOA kurang stabil dari segi haba berbanding NIP pada suhu yang lebih tinggi kerana peratusan kehilangan berat MIPOA adalah lebih tinggi daripada NIP. Pada suhu 215 °C, penurunan berat MIPOA (9.36%) adalah lebih tinggi berbanding NIP (6.55%) kerana kurang bilangan cabang polimer bersilang yang telah berjaya disintesiskan. Luas permukaan yang lebih tinggi dalam MIPOA berbanding NIP telah berjaya dibuktikan dalam eksperimen ini. Di samping itu, kehadiran OA sebagai templat dikeluarkan daripada liang kaviti semasa pencucian MIPOA menyumbang kepada peningkatan permukaan sentuhan. Oleh kerana luas permukaannya yang tinggi dan kemudahan degradasi oleh tenaga luaran daripada pemanasan jika dibandingkan dengan NIP (yang bertindak sebagai kawalan), MIPOA mempunyai keliangan yang tinggi dan kelimpahan rangkaian rantai silang organik. Daripada analisis BET, luas permukaan MIPOA ialah 390.52 m^2/g dan nilai ini agak tinggi dalam kecekapan pengasingan untuk pengasingan OA metil ester. Isoterma jenis paparan MIPOA I yang menunjukkan bahawa MIPOA adalah mikroliang. Keputusan ini membuktikan bahawa MIPOA boleh digunakan sebagai penjerap yang berpotensi untuk mengasingkan OA daripada sisa PFAD.

Kata kunci: Polimer tercetak molekul, asid oleik, sulingan asid lemak sawit

Introduction

Palm Fatty Acid Distillate (PFAD) is a processing residue resulting from the physical refining of crude palm oil (CPO) products. The annual global production of PFAD is estimated at 2.5×10^6 tons, where Malaysia (29%) and Indonesia (58%) are the main contributors [1]. PFAD consists of more than 80% of free fatty acids, primarily palmitic acid, and oleic acid, which can be esterified and added to the biofuel and oleo-chemical industries as feedstock. Free fatty acid (FFA) is an important specification that influences the palm oil quality. According to previous study, PFAD contains roughly 40% of oleic acid (Figure 1), depending on the quality of CPO. Oleic acid (OA) is the most abundant monounsaturated fatty acid in nature which plays important roles in many industries. OA has multiple properties and applications of great value and importance. OA has been used in a variety of industries and sectors that produce many products such as textiles, cosmetics, inks, paints, pharmaceuticals, detergents, and food processing.

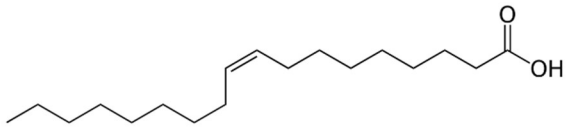

Figure 1. Molecular structure of OA

Throughout the years, different kinds of sorbents were developed to isolate variety of free fatty acids from PFAD waste. Molecularly imprinted polymer (MIP) is one of the sorbents used in research and development which shows great findings. MIP is a synthetic polymer with a predetermined selectivity for a given analyte, or group of structurally related compounds, making them ideal materials to be used in separation processes [2]. For the synthesis of MIP, relevant selection of the template, monomer, crosslinker, and porogen solvent is considered critical to produce high percentage of analyte isolation.

MIPs offer many advantageous features such as simple to synthesize and easy to prepare [3], low cost, and can maintain its performance even if it is stored for several years. They are intrinsically more stable chemically and physically, and robust due to their highly cross-linked polymer nature, which facilitates their application in harsh environments such as in the presence of strong acids or bases, organic solvents, and high temperature and pressures [4]. In this study, the use of MIP as isolation technique of OA from PFAD waste has been proposed to obtain OA from the PFAD waste. The synthesized MIP for oleic acid has been characterized via esterification reaction in methanol with gas chromatography–mass spectrometry (GC-MS), TGA, and BET analysis.

Materials and Methods

Synthesis of MIPOA

The MIP was prepared by following Kugimiya's synthesis method [5]. All ingredients (1.0 mmol oleic acid, 4.0 mmol of allylthiourea, 20 mmol of EGDMA, and 0.12 mmol of AIBN initiators) were dissolved in 4.0 mL of acetonitrile. The solution was then sonicated and purged with nitrogen gas for 5 minutes to remove oxygen gas from the solution. Then, the sealed solution was polymerized at 60 °C in a water bath for 24 hours.

The resulting polymer was washed with methanol/acetic acid (9:1, v/v) using a Soxhlet apparatus to remove oleic acid template. A final washing step using 25 mL of methanol for 3 times washing was carried out and a polymer was centrifuged at 5300 rpm for 3 mins to remove residual of acetic acid. The supernatant methanol was analyzed using a UV spectrophotometer at 280 nm to confirm that there was no OA remains in the cross-linked polymer. Afterwards, the polymer was dried at 60 °C under vacuum overnight and stored at room temperature. Finally, the polymer was ground using mortar and pestle, and sieved to yield particle size between 28 µm and 100 µm. The non-imprinted polymer (NIP) as a control was synthesized using the same procedure described above, with the absence of OA, to evaluate the sorption capacity of the polymer itself and to discriminate from the adsorption of the selective sites of MIP [3].

MIPOA characteristics

Isolation of OA from PFAD waste

The PFAD sample was turned into liquid form at room temperature by esterification process which changed it to fatty acid methyl esters (FAME) [6][7]. Esterification of PFAD was conducted in a flask equipped with reflux condenser and temperature indicator on a hot plate with a magnetic stirrer shown in Figure 2. The mixture of methanol and PFAD was heated to 60ºC under continuous stirring at 500 rpm. The experiment was carried out at around 60ºC-80ºC for a few hours. The volume ratio of methanol to PFAD used was 2:1. The mixture was then separated into six different small jars and left at room temperature. Next, 20 mg of MIPOA and NIP were added and stirred for 1 hour into the mixture solution, respectively (Figure 3). The experiment was carried out in duplicate. After that, the oil-based mixture solution was collected for detection of OA using GC-MS.

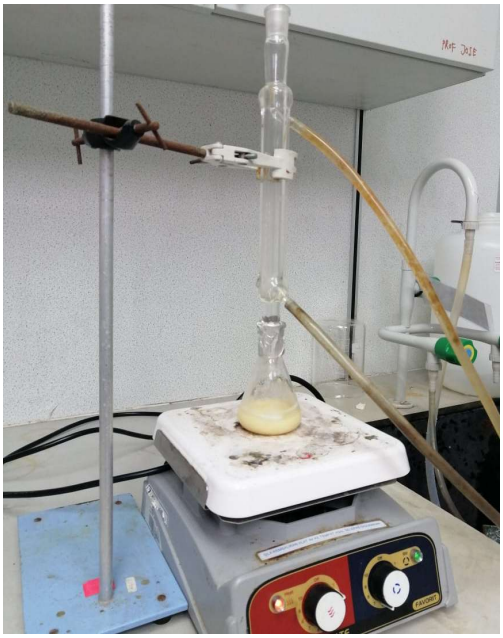

Figure 2. Esterification reaction set-up experiment using PFAD sample

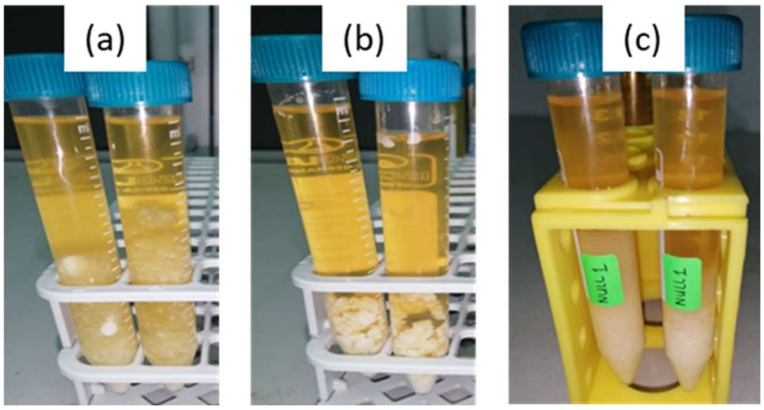

Figure 3. Oil-based mixtures were seen to accumulate solids in different form of yield at room temperature (a) PFAD-methanol after mixed with MIPOA (b) PFAD-methanol after mixed with NIP as a control and (c) PFAD-methanol with absence of any adsorbent.

An Agilent 7890A gas chromatography equipped with a BPX5 capillary column size 30 m × 0.25 mm i.d. (0.25 µm stationary film thickness) was used with helium (purity 99.999%) as carrier gas at a flow rate of 1.2 mL min^{-1}. The initial oven temperature was held at 50 °C for 1 min, and then increased to 280 °C at 20 °C min^{-1}, and held at 280 °C for 1 min. The total analysis run time was 13.5 minutes. The injector temperature was set at 280 °C, and the injection was performed in the splitless mode. The identification of analyte was done by GC retention time (R_t) and by a comparison of the mass spectra of identified substances with those of authentic reference substances.

TGA Analysis of MIPOA

The thermal degradation of different samples for non-isothermal conditions was investigated thermogravimetrically. The calculation of kinetic parameters was carried out under a heating rate of 30 °C min^{-1} in 30-700 °C using a thermogravimetric analyzer (TGA) instrument (model STA7200). In order to minimize the test error, the weight of all the samples in powder form (177 < 210 mm) was identical to be 6 mg to 7 mg. The TGA experiments was carried out in a nitrogen atmosphere (99.99% minimum purity) with a flow rate of 30 mL min^{-1} [8].

BET analysis of MIPOA

In order to determine the MIPOA surface area, an automated gas adsorption analyzer model ASAP2020 (Micromeritics Instrument Corporation, USA) was used with adsorption-desorption isotherms of nitrogen gas temperature sets at -195.89 °C. About 0.05g of sample was used for each analysis. The samples were automatically degassed at 22 °C under nitrogen for at least 24 hours. The specific surface areas of sample were calculated by the BET (Brunauer, Emmett, and Teller) method, while volume of micropore was estimated using the Dubinin Radushkevich (DR) equation. For pore volume, it was directly calculated from the volume of nitrogen held at the highest relative pressure (P/P^o = 0.99).

Results and Discussion

Ability of MIPOA to isolate OA from PFAD waste

Standard solution was Chromatogram of OA standard shows that the R_t for OA occurs at 11.73 mins as a main peak (Figure 4).

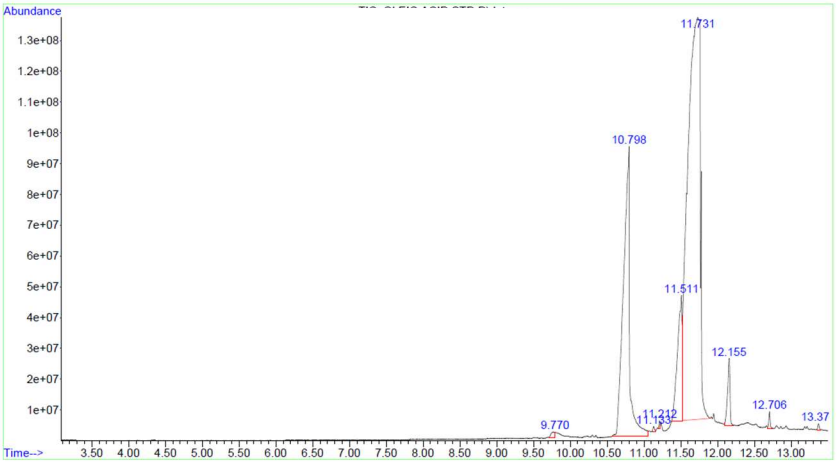

Figure 4. Chromatogram for OA standard using GC-MS

Figure 5 shows the GC-MS chromatogram of the untreated PFAD sample after esterification to produce methyl ester compounds from various free fatty acids. In a PFAD sample with a volume ratio of 1:2 between PFAD and methanol, the composition of certain prominent peaks produced by esterification of free fatty acids is as displayed in Table 1. The fragmentation pattern of the major active compound (R_t = 10.8 mins) was determined as n-Hexadecanoic acid methyl ester or methyl palmitate. OA methyl ester or methyl oleate was

found to be the second higher abundance at the R_t equals to 11.7 mins. Therefore, detection of OA in treated PFAD samples with MIPOA and NIP was observed at R_t around 11.7 mins as mentioned in calibration of OA standard. There was a possibility of peak overlapping occurred at 11.7 mins. However, for the recent findings, it was estimated that OA methyl ester was observed at 11.7 mins by referring to the chromatograms obtained.

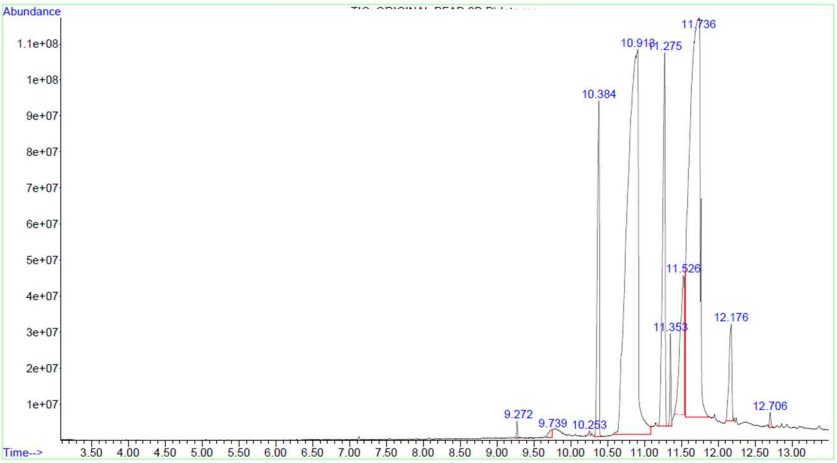

Figure 5. GC-MS chromatogram of PFAD sample in methanol with volume ratio of PFAD to methanol equals to 1:2 with absence of any adsorbent

Table 1. Some major peaks found in untreated PFAD sample

Peak	Retention time, R_t	% Composition	Compound
1	9.2724	0.14	Tridecanoic acid methyl ester
2	9.7389	0.23	Tetradecanoic acid
3	10.2526	0.06	Cyclopentadecanone methyl ester
4	10.9131	38.28	n-Hexadecanoic acid methyl ester/ palmitic acid methyl ester
5	11.2748	8.42	9-Octadecenoic acid methyl ester
6	11.3534	0.83	Octadecanoic acid methyl ester
7	11.7361	38.19	Oleic acid methyl ester

Figure 6 displays the GC-MS chromatogram of treated PFAD sample with MIPOA in methanol. From the results, OA methyl ester was totally isolated with composition left about 0.03% contained in the free oil-based mixture. Palmitic acid methyl ester was not isolated at all as even palmitic acid methyl ester contained about 38.28% in the PFAD samples. The composition of palmitic acid methyl ester was higher after being treated with MIPOA due to the potential of stirring and heating process which caused the increasing in oil viscosity. It was proved that MIPOA was highly selective for the isolation of OA methyl ester. Palmitic acid methyl ester was not isolated at all after being treated with MIPOA. In Table 2, the composition analysis from the chromatogram showed significant peaks of compound present in PFAD samples treated with MIPOA. There was possibility at 11.7 mins that the redundant peaks were determined. However, further study is required to enhance the separation peaks at approximately 11.6 mins until 11.7 mins to identify the ghost peak which was redundant with OA methyl ester peak in the chromatogram.

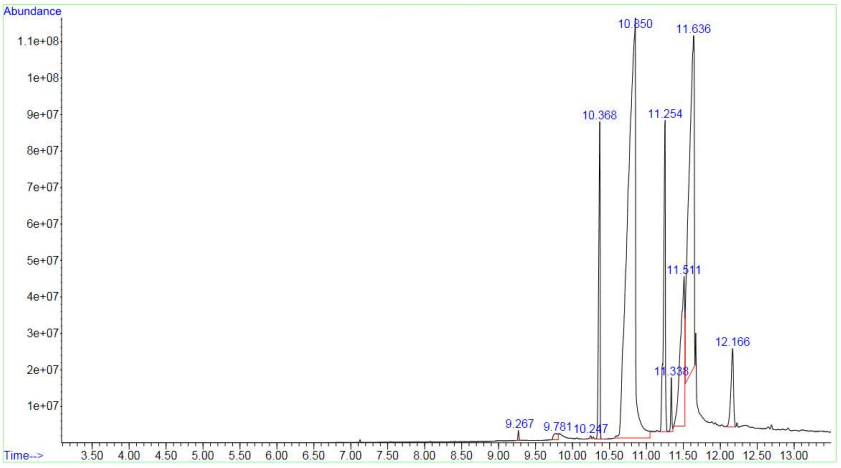

Figure 6. GC-MS chromatogram of PFAD sample after treated with MIPOA as an adsorbent in methanol with volume ratio of PFAD to methanol equals to 1:2.

Table 2. GC-MS analysis in PFAD sample after treated with MIPOA as an adsorbent in methanol

Peak	Retention time, R_t	% Composition	Compound
1	9.2671	0.1361	Tridecanoic acid methyl ester
2	9.7808	0.4017	Tetradecanoic acid
3	10.8502	46.8937	n-Hexadecanoic acid methyl ester
4	11.2538	8.0424	9-Octadecenoic acid methyl ester
5	11.3377	0.7857	Octadecanoic acid methyl ester
6	11.5107	9.2846	Linoleic Acid methyl ester
7	11.7361	0.0300	Oleic acid methyl ester

GC-MS chromatograms of treated PFAD samples with NIP as a control is shown in Figure 7 whereas the significant peaks of compounds present in PFAD samples treated with NIP is shown in Table 3. From the results, at R_t equals to 11.71 mins, the peak for OA methyl ester was presented with composition at 34.53% in free oil-based mixture. The same trend was found when PFAD sample was treated with NIP. The abundance of OA methyl ester was found to be higher compared to the initial condition.

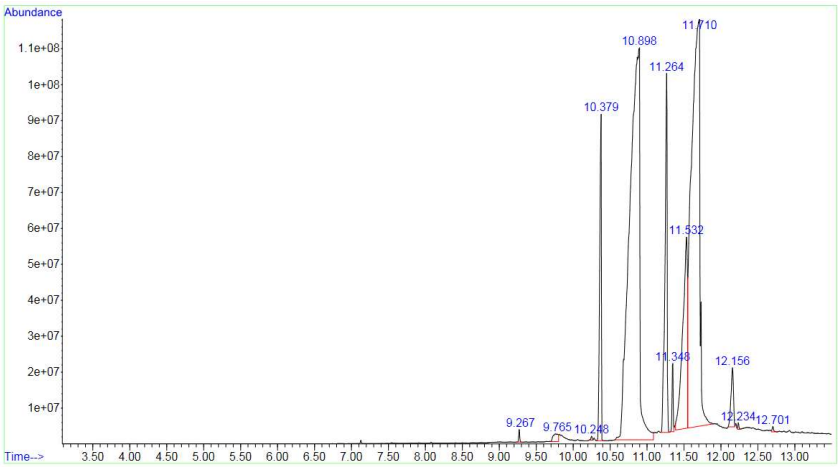

Figure 7. GC-MS chromatogram of PFAD sample after treated with NIP as an adsorbent in methanol with volume ratio of PFAD to methanol equals to 1:2

Table 3. GC-MS analysis in PFAD sample after treated with NIP as an adsorbent in methanol

Peak	Retention time, R_t	% Composition	Compound
1	9.2673	0.128	Tridecanoic acid, 12-methyl-, methyl ester
2	9.7653	0.4011	Tetradecanoic acid
3	10.8975	40.1635	n-Hexadecanoic acid methyl ester
4	11.2645	7.7556	8-Octadecenoic acid, methyl ester
5	11.3483	0.7522	Octadecanoic acid, methyl ester
6	11.7100	34.5268	Oleic Acid methyl ester

The OA methyl ester found at R_t around 11.7 mins in treated sample with MIPOA and NIP respectively are shown in Table 4. The average percentage of oleic acid adsorbed by MIPOA at R_t around 11.7 mins is 99.99%, while the adsorption by NIP samples is 0.88%. This result shows that MIP was capable of isolating oleic acid from PFAD sample. The differences of oleic acid adsorbed by MIPOA and NIP samples are not that high, probably due to some of the template on MIP vanished during crushing and the medium of sample is in oil-based which makes it difficult for MIP to extract because of its high viscosity properties. In addition, using real sample commonly contributes to the unknown compound which is present in the samples due to the matrix effect.

Table 4. % OA methyl ester adsorbed by MIPOA and NIP

Composition of OA methyl ester	MIPOA	NIP
% Initial composition	38.190	38.190
% Final composition	0.002	38.526
% Adsorbed	99.99	0.88

BET analysis

Isotherm linear plot (BET)- N^2 adsorption isotherm in MIPOA

The N^2 adsorption isotherms of the MIPOA is shown in Figure 8. From this figure, MIPOA displays type I isotherms and according to International Union of Pure

and Applied Chemistry (IUPAC) classification, it indicates that the MIPOA is microporous. Usually, Type I isotherm displays a convex curve, and the platform of this type comes out horizontal or virtually horizontal, and the adsorption isotherm directly intersects with the line $P/P^o = 1$ [9]. As seen in the initial stage, the volume adsorbed increased sharply at low relative pressure region ($P/P^o < 0.2$). This means that nitrogen molecules were adsorbed mainly in the microporous structure [9]. Table 5 presents the BET surface area, total pore volume, micropore volume, and average pore diameter of MIPOA that were obtained from N^2 adsorption isotherms. The surface area of MIPOA was 390.52 m^2/g and this value was considered to have potential in adsorbing OA at high isolation efficiency.

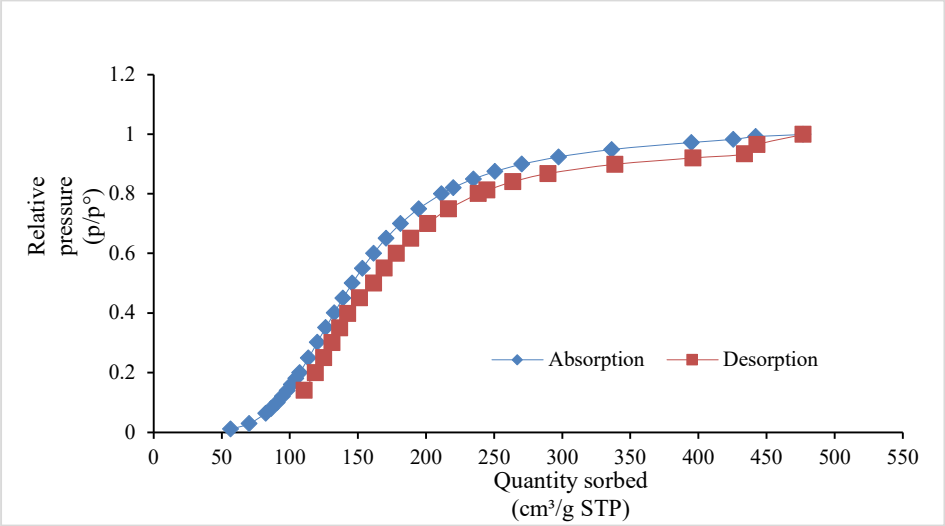

Figure 8. N_2 gas adsorption-desorption isotherms of MIPOA

Table 5. BET surface area, total pore volume, micropore volume and average pore diameter of MIPOA

Sample	BET Surface Area (m^2/g)	Total Pore Volume (cm^3/g)	Micropore Volume (cm^3/g)	Average Pore Diameter (Å)
MIPOA	390.52	0.6106	0.0072	62.55

TGA analysis

During a ramped heating under nitrogen, such as in a TGA experiment, the degradation process usually passes through three stages. In the first and second stage, the less branch cross-linked bonds located at the outer side of the particles were decomposed. Whereas more stable structure polymer which consists of substituted allylthiourea as an active site was degraded in the third stage due to the inner part of the polymer particles contributing to the stability of MIPOA. The final step was the high temperature degradation of these stabilised structures to yield volatile products and a small quantity of carbonaceous char.

The curves for MIPOA display three weight loss stages (DTG maxima at 215 °C, 390 °C and 450 °C) that lead to the formation of a small high temperature residue (9.36 wt.%) (Figure 9). The first DTG peak can be related to the overlapping of less branch of polymer chain (degradation) and char-forming secondary reactions (cross-linking), whereas the second peak corresponds to decomposition of the stabilised allylthiourea structures. The similar temperature range was observed for NIP as a control which led to the formation of a small high temperature residue (6.55 wt.%) (Figure 10).

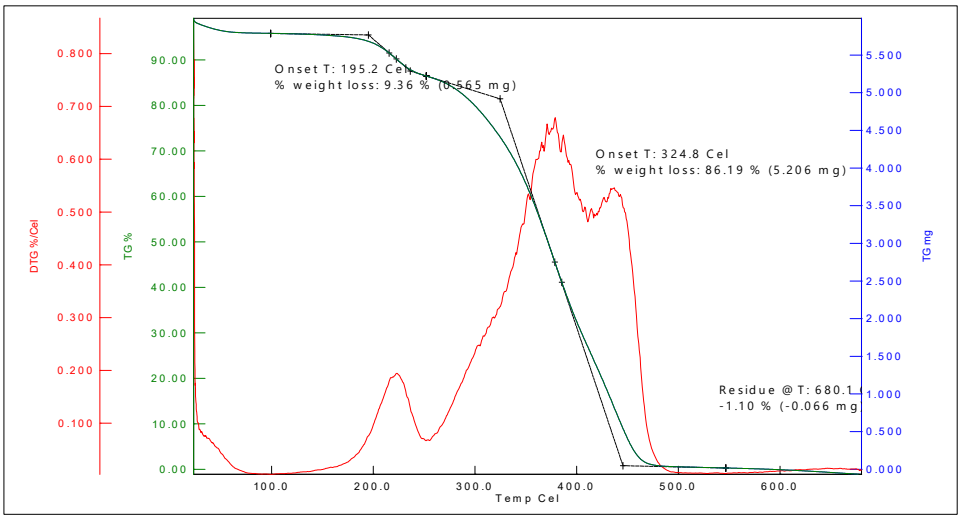

Figure 9. TGA thermogram of MIPOA before isolation

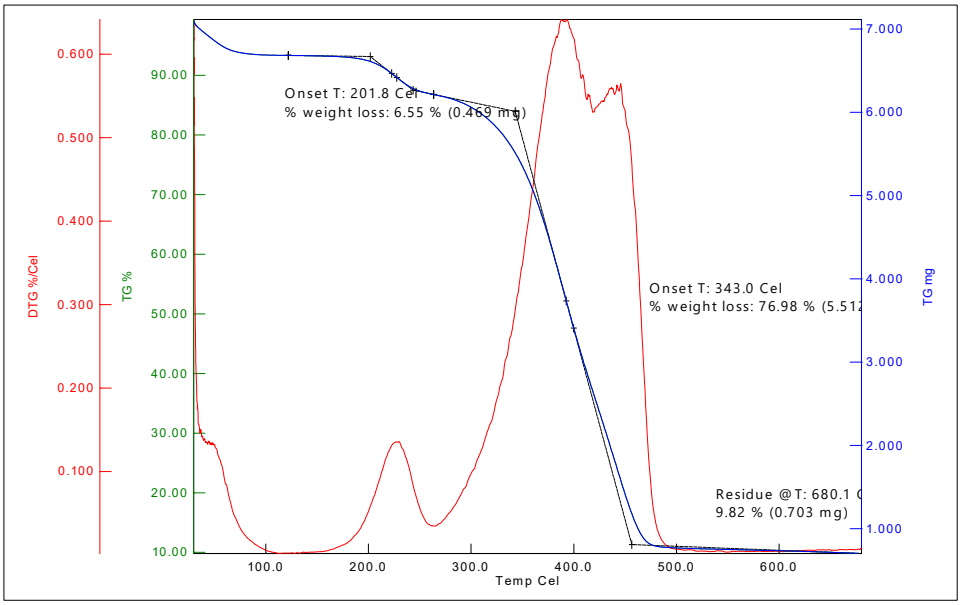

Figure 10. TGA thermogram of NIP as a control

From Table 6, the weight loss due to the degradation was investigated. At 215 °C, the weight loss of MIPOA (9.36%) was higher compared to NIP (6.55%) as a control due to the less branch of cross-linked polymer which was successfully synthesized. Higher surface area in MIPOA compared to NIP was successfully proven in this experiment. In addition, the presence of OA as a template leaves the cavities during MIPOA washing contributes to the increase of the surface contact. At 330 °C, MIPOA (86.19%) also showed higher mass loss compared to NIP (76.98%). In the synthesis of polymer, the cross-linked effect gives benefits in terms of affinity properties as a sorbent and higher surface area of MIPOA.

Table 6. Percentage weight loss of MIPOA and NIP within temperature range of 0 °C to 400 °C

DTG Temperature (°C)	MIPOA (% weight loss)	NIP (% weight loss)
215	9.36	6.55
330	86.19	76.98
680	0.00	9.82

Conclusion

In this research, MIPOA was successfully synthesized using oleic acid as template, acetonitrile as a porogen solvent, allylthiourea as functional monomer, and EGDMA as a cross-linker. Both MIPOA and NIP were synthesized by bulk polymerization technique. The synthesized MIPOA and NIP were successfully characterized by using GC-MS, TGA and BET instruments to understand its sorption ability and thermal properties. Based on GC-MS analysis, the average percentage of oleic acid adsorbed by MIPOA samples at R_t around 11.7 is 99.99%, while by NIP samples is 0.88%. This proves that MIPOA was capable of isolating OA from PFAD sample. BET analysis shows that MIPOA displays type I isotherms and indicates that the MIPOA was microporous. Lastly, TGA data shows that MIPOA was less thermally-stable compared to NIP at higher temperature due to high surface area. The higher % weight loss of MIPOA than NIP ensured the presence of an organic cross-linked network. This study concludes that MIPOA was successfully employed for the effective and selective isolation of oleic acid from PFAD waste.

EVALUATION OF CARRAGEENAN GEL PROPERTIES AT DIFFERENT CONCENTRATIONS OF CALCIUM CHLORIDE DIHYDRATE SALT

(Penilaian Gel Carrageenan Beraroma Pada Variasi Kepekatan Garam Kalsium Klorida Dihidrat)

Abstract

Aromatherapy is an alternative therapy for Complementary and Alternative Medicine (CAM) to relieve mild depression in individuals. This study aimed to evaluate the effect of incorporating calcium chloride dihydrate in carrageenan gel to increase stability property. The gel formulation was produced from a mixture of semi-refined carrageenan, sodium benzoate, alginic acid, polyethene glycol (PEG) and sorbitan monolaurate (Span 20) followed by the inclusion of calcium chloride dehydrate (CCD) at 0%, 0.5%, 1%, 1.5%, and 2% concentrations. The effects of CCD concentration on rheology, gel Bloom strength, morphology, and thermal properties were investigated. The viscosity and shear stress decreased on incorporating of CCD in the carrageenan gel formulation. The highest viscosity of the control gel was 597.84 mPa.s. The intersection of G' and G" at various concentrations of CCD salts in the gel formulation demonstrated that the increment of salt concentration resulted in a faster gelation process in the range 56.6 to 50.43 °C. The gel Bloom strength increased from 830.04 g at 0.5% CCF salt to 1331.39 g at 2% CCD. The highest gel strength of 1324.59 g was achieved with 2% CCD and a melting temperature of 194.4 °C. The weight loss rate for the control gel was 28.88%, the lowest weight loss rate for 2% CCD gel was 11.82%. The residual gel weight was also highest for 2% CCD: 16.74% after 21 days. A high residual gel weight reflects the stability of the carrageenan gel formulation to retain the product and last as aromatherapy gel product. The morphology images showed a highly porous gel structure on addition of CCD salts. In conclusion, CCD salt is capable of forming a strong interaction with the gel matrix to produce a stable gel.

Abstrak

Aromaterapi adalah terapi alternatif untuk Perubatan Pelengkap dan Alternatif (CAM) untuk melegakan kemurungan ringan pada individu. Kajian ini bertujuan untuk menilai kesan penggabungan kalsium klorida dihidrat dalam gel karagenan untuk meningkatkan sifat kestabilan. Formulasi gel dihasilkan daripada campuran karagenan separa halus, natrium benzoat, asid alginik, polietilena glikol (PEG) dan sorbitan monolaurat (Span 20) diikuti dengan kemasukan kalsium klorida dehidrat (CCD) pada 0%, 0.5%, 1%, 1.5%, dan 2% kepekatan. Kesan kepekatan CCD pada reologi, kekuatan Bloom gel, morfologi, dan sifat terma telah disiasat. Kelikatan dan tegasan ricih berkurangan apabila pengambilan CCD dalam formulasi gel karagenan. Kelikatan tertinggi gel kawalan ialah 597.84 mPa.s. Persilangan G' dan G" pada pelbagai kepekatan garam CCD dalam rumusan gel menunjukkan

bahawa pertambahan kepekatan garam menghasilkan proses pemeringkatan yang lebih cepat dalam julat 56.6 hingga 50.43 °C. Kekuatan Bloom gel meningkat daripada 830.04 g pada 0.5 % garam CCF kepada 1331.39 g pada 2% CCD. Kekuatan gel tertinggi sebanyak 1324.59 g dicapai dengan 2% CCD dan suhu lebur 194.4 ° C. Kadar penurunan berat badan untuk gel kawalan ialah 28.88%, kadar penurunan berat badan terendah untuk 2% gel CCD ialah 11.82%. Berat sisa gel juga tertinggi untuk 2% CCD: 16.74% selepas 21 hari. Berat sisa gel yang tinggi mencerminkan kestabilan formulasi gel karagenan untuk mengekalkan produk dan kekal sebagai produk gel aromaterapi Imej morfologi menunjukkan struktur gel yang sangat berliang pada penambahan garam CCD. Kesimpulannya, garam CCD mampu membentuk interaksi yang kuat dengan matriks gel untuk menghasilkan gel yang stabil

Introduction

Aromatherapy is one of the complementary and alternative medicine (CAM) treatments for patients with depressive symptoms. Aromatherapy is defined as the therapeutic application of plant-derived concentrated essences extracted through distillation. It is a low-cost, non-invasive CAM used to improve psychological and mental wellbeing. Ali et al. concluded that aromatherapy is a natural and noninvasive gift of nature because the whole of the human body is rejuvenated on using aroma from essential oil [1]. Essential oils which contain volatile organic compounds that have a pharmacological effect by penetrating the human body through oral, dermal or olfactory administration are commonly used [2]. An electroencephalograph study concluded that fragrances significantly modulate the activity of different brain waves and are responsible for physiological effects of mood, stress, and working capacity [3]. Several marker compounds represent the characteristics of a fragrance, such as patchoulol as the major compound in patchouli oil scent [4]. Olfactory stimulation related to aromatherapy may result in an immediate reduction in pain as well as changes in physiological parameters such as pulse, blood pressure, skin temperature, and brain activity [5]. Application of essential oil aromatherapy gels is particularly used in the home, office, room, and car. This is because most people nowadays spend their time in a room to rest, in an office to work, or in a car to travel. A gel air freshener made from natural polymer gelatin with lavender essential oil and natural banana aroma has been shown to be tolerable for application compared to commercial ones [6].

Most fragrance-scented gel applications use gelatin or gellan gum as the primary material. Both materials are expensive. Gelatin, for example, is derived from animals and would be a source of concern for Muslim consumers if they used the product. Therefore, this research provides an insight into the potential of using carrageenan in the gelling material for scented gel products. Adam et al. developed a carrageenan–gum Arabic and carrageenan–cellulose for application in hard capsules, demonstrating the compatibility of the components [7]. Carrageenan, by itself, can allow the active volatile ingredient of aromatherapy essential oil to evaporate. The objective of this study is the development of carrageenan gel product made from carrageenan. The incorporation of carboxymethyl cellulose (CMC) and microcrystalline cellulose (MCC) can toughen the bioplastic film and harden capsules made from carrageenan [8]. The effect of alginate gel and $CaCl_2$ (calcium chloride) solution made through the external gelation method may contribute to an increase in gel strength with an increment of $CaCl_2$ [9]. The incorporation of cellulose nanofibers (CNF) with α-tocopherol improves the properties of bioplastic film in active packaging [10]. Carrageenan gel produced via crosslinking with calcium ions followed by incorporation of different concentrations of lavender essential oil shows promising mechanical and thermal properties to be applied in the pharmaceutical industry [11]. Pectin, carrageenan, and gelatin are economically valuable hydrophilic polysaccharides that have broad usage in the food, pharmaceutical, cosmetic, and biotechnology industries as gelling, thickening, stabilizing, and emulsifying agents. These polysaccharides have promising potential in many areas and accelerate global technological breakthroughs in this line of work [12].The sol–gel process, which has been used to create silica-based materials doped with flavor and fragrance, is an efficient alternative to previous microencapsulation methods because it prevents the degradation of the delicate compounds included and has the possibility to provide odorant and

flavored components with new and innovative beneficial properties [13]. The purpose of this study was to evaluate the effect of different concentrations of calcium chloride dehydrate salt on carrageenan gel to make a stable gel for potential of aromatherapy carrageenan gel.

Materials and Methods

Chemicals and materials

Carrageenan was purchased from TACARA, Sabah, Malaysia. Sodium benzoate, calcium chloride dehydrates (CCD), sorbitan monolaurate (Span 20), and polyethylene glycol (PEG) were purchased from Merck, Germany.

Preparation of carrageenan gel solution

In 100 mL of deionized water, 3 g of semi-refined carrageenan and 0.5 g of sodium benzoate were mixed for 1 hour at 75 °C. The solution was stirred until homogeneous. After that, 1.5 g of Span 20, 2 ml of PEG, and 0.02 g alginic acid were added. All materials were mixed in a glass beaker and stirred for 2 hours on a hot plate magnetic stirrer at 75°C. After that, the semi-solid gel was molded and left at room temperature. The same method was repeated but with the concentration of calcium chloride dihydrate manipulated at (0, 0.5, 1, 1.5, and 2 wt.%).

Rheology analysis

The viscosity of carrageenan formulation solutions was measured using a cup and bob rotational measuring block Rheometer (Rheo 3000, Brookfield, USA) equipped with LCT 25 4000010 geometry. Approximately 16.5 mL of solution was programmed at speed of 300 rpm, with 100 MPoints at a constant temperature of 40 °C in duplicate. The dynamic rheology measurement was determined using Kinexus Lab+ Rheometer with a controlled stress rheometer using a parallel-plate geometry (gap 1 mm, diameter 40 mm). Within the linear viscoelastic regime, the values of the strain amplitude were set as 4% for all measurements. Before the heating process, the temperature of the loading platform was raised to 60 °C. The prepared fresh samples at 85 °C were put into the loading platform, and then the temperature of the loading platform was reduced to 20 °C and balanced for 1 h. The temperature ramp tests of mixed gels were conducted during heating from 20 to 95 °C and cooling from 95 to 20 °C. Both processes were carried out at a rate of 5 °C/min.

Weight variation analysis

The evaporation of liquid from the formulated gels was tested by weighing the gel each week for 4 weeks. Carrageenan gel weight loss for each week and a total weight reduction after 4 weeks of storage were calculated. Weight reduction of carrageenan gels was obtained by calculating the difference in weight of the gel at the time of weighing (M_n), with weight of gel at initial time (M_0). The difference in weight is the amount of liquid that evaporates. The percentage of total liquid evaporated and residual gel weight were measured by gravimetry and calculated by the formula:

$$Total\ Liquid\ Evaporation\ Percent = \frac{M_n - M_{n-1}}{M_0} \times 100 \quad \text{(eq. 1)}$$

$$Residual\ Gel\ Weight\ Percent = \frac{M_n}{M_0} \times 100\% \quad \text{(eq. 2)}$$

where M_n is the weight of gel at the time of weighing; M_{n-1} is the weight of the gel in the previous week; and M_0 is the weight of gel at the initial time [14].

Gel bloom strength test

Mechanical and Bloom strength test were conducted using a CT3 Texture Analyzer (Rheo 3000, Brookfield, USA). The texture analyzer was loaded with a 50 kg load cell. An average of at least three measurements was taken for each formulation. A flat-end probe (TA-10) with a diameter of 12.7 mm and a Brookfield bloom jar were used for the analysis. Carrageenan gel was placed on the texture analyzer platform and positioned at the center of the probe. The analyzer was programmed to use the 'compression' testing mode and the 'distance' target option was approximately 4.0 mm. At a speed of

1.0 mm/s, the probe was pressed onto the gel and breaking force was recorded.

Thermal properties

Thermogravimetric analysis (TGA) is a precise method for studying the weight loss, decomposition pattern and thermal characterization of carrageenan gel. A TA Instruments Q 500 series instrument with a TGA heating rate of 10 °C/min for a temperature range of up to 800 °C was used. Nitrogen gas was used as the purge gas at a rate of 10 ml/min. Measurements were taken in triplets, with average values recorded.

The thermal properties of the carrageenan gel formulation solution were analyzed by differential scanning calorimetry, DSC, using a TA-Instrument Q1000 calorimeter. Samples of 8 mg were placed on an aluminum pan and nitrogen gas was purged at a flow rate of 10 mL/min and heating rate of 10 °C/min. The heating range was set between 0 to 350 °C.

Morphology analysis

A scanning electron microscope **(**SEM; TM3030 PLUS, Hitachi, Japan) was used to examine the surface morphology of carrageenan gel. SEM was used to examine the surface of the biocomposite obtained. The carrageenan gel was cut into 1 cm × 1 cm rectangles and applied to the specimen stub. The sample was examined and photographed at a magnification of 300×.

Statistical analysis

The confidence level p-value was calculated using ANOVA with the testing null analysis (H_o) and alternative analysis (H_i) for solution viscosity, shear stress, and gel bloom strength of the gel formulation at different CCD concentrations. For the comparison of rejection values, the level of significance was set at $\alpha = 0.05$.

Results and Discussion

Rheology analysis

Sol–gel transitions are common during the process of aqueous gelling systems, resulting in overly complex rheological behaviour. Several factors such as time, temperature, and concentration frequently cause dramatic changes in viscoelastic behaviour [15]. The viscosity of carrageenan gels with different concentrations of CCD is shown in Figure 1. Viscosity and shear stress decreased on increasing the concentration of CCD from 0 to 2 wt.%. ANOVA test results for the viscosity and shear stress have p-values of 0.00012 and 0.000262 at $\alpha = 0.05$, respectively. In previous studies, a solution of carrageenan blended with *Chlorella vulgaris* lipid had a viscosity value of 245.29 mPa.s [16] and that of carrageenan–gum Arabic solution increased to 1058 mPa.s at a 67% w/w ratio of semi-refined carrageenan to gum Arabic [7].

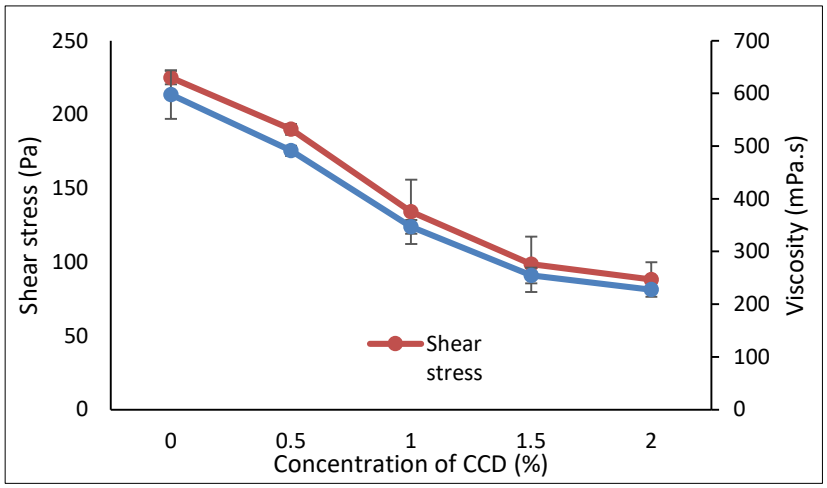

Figure 1. Viscosity and shear stress at different concentrations of CCD

Figure 2 shows the effect of temperature on the sol–gel transition and gel–sol transition for the gel formulations; the analysis is divided into cooling and heating processes. Both G′ and G″ values decreased sharply as temperature increased. During the cooling process, G′ values were always greater than G″ values, and the samples displayed elastic behavior. However, as the temperature increased during the heating process, G′ and G″ values both increased slightly, and G″ gradually surpassed G′, indicating viscous behavior. During the heating process, melting temperature (T_m) was defined as the temperature at which the G′ and G″ values crossed, and the gelling temperature (T_g) was defined likewise for the cooling process. At 0% CCD salt concentration, T_g was 56.66 °C and gradually decreased as the concentration of CCD salt increased, to 50.43 °C at 2% CCD salt. The T_m ranged from 62.17 to 43.88 °C on increasing the concentration of CCD salt. The highest T_m and T_g, 56.66 and 62.17 °C, respectively, were obtained for gels made without 0% CCD salts.

Figure 3 shows the melting and gelling temperature from G' and G'' crossover. The storage modulus of a polymer determines its solid-like properties. The higher the storage modulus, the more difficult it is to degrade the polymer. Loss modulus, which is the inverse of storage modulus, describes a polymer's liquid-like nature. When the storage modulus is large, the loss modulus is small, and vice versa [17]. During the cooling stage, the loss modulus is greater than the storage modulus during the initial cure period. This means that during this stage, the gel's liquid-like (viscous) behavior takes precedence over its solid-like (elastic) character. When G′ = G″, a crossover point is reached, implying that a crosslinking reaction is initiated. This is referred to as the gel point. G′ was much greater than G″ in the final cure stage, meaning that the gel had mostly solidified into an elastic solid. The results for the gelling point, the intersection of G′ and G″, for various concentrations of CCD salts added to the gel formulation demonstrate that increasing the salt concentration resulted in faster gelation (shorter gel point), as shown in Table 1. In a previous study by Cui et al., kappa carrageenan/konjac gum solution with the addition of gellan gum and Ca^{2+}, which remained a gel in the solid state under heating treatment at 85 °C, demonstrated good thermal stability [18], higher than that found in the current study. Here, the highest T_m was 62.17 °C without the addition of CCD salts; this difference is probably due to the addition of gellan gum to the formulation by Cui et al. Gellan gum is insoluble in cold water and must be heated to 90 °C or higher to be completely dissolved [19]. According to Tako et al., in their formulation that consisted of iota-carrageenan and CCD salt, gelation up to 80 °C was observed in the presence of an intermolecular Ca^{2+} bridge with intra- and intermolecular hydrogen bonding and van Der Waals' forces [20]. The higher crossover temperature of iota-carrageenan solution induced with sodium chloride salt indicates a stronger interaction between iota-carrageenan helices and salt ions [21]. The addition of calcium chloride to gelatin extracted from skins of tropical fishes can reduce the G′ and G″ values of the gelatin solution compared to calcium sulphate and magnesium sulphate [22].

Table 1. Gelling point and melting point of gels with different concentration of CCD salts

Sample (%)	$T_{melting}$ (°C)	$T_{gelling}$ (°C)
0	62.17 ± 1.94	56.66 ± 1.48
0.5	50.53 ± 1.62	56.17 ± 1.75
1	43.90 ± 1.11	56.14 ± 0.54
1.5	48.94 ± 0.57	52.73± 2.61
2	43.88 ± 0.14	50.43 ± 5.45

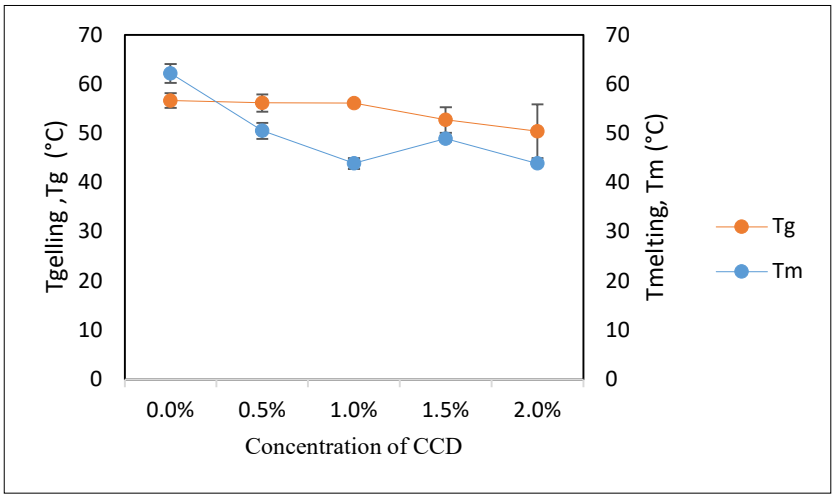

Figure 3. Melting and gelling temperature from G' and G" crossover

Weight variation analysis

Figure 4 (a) and (b) show the weight variation and residual gel weight of the gel air freshener after 4 weeks. The highest residual gel weight percentage was observed for 2% CCD salt concentration, indicating that the formulation solution's ability to prevent evaporation is better for the higher CCD concentration in comparison to lower concentrations. According to Hutagaol, gels made with 3% carrageenan show the ability to maintain the substance to better prevent evaporation [14]. In this study, gels were formulated with 3% carrageenan and different concentrations of CCD salts. Carrageenan gel at 2% shows the ability to maintain its structure at higher concentrations of CCD salts. Figure 4 shows the weight and residual gel weight (%) of the carrageenan gel solution for 45 days. The results obtained in this study support the hypothesis that the greater the resistance of carrageenan gel, the less weight is lost or the greater the weight remaining, meaning less volatile oil and water are evaporated [14].

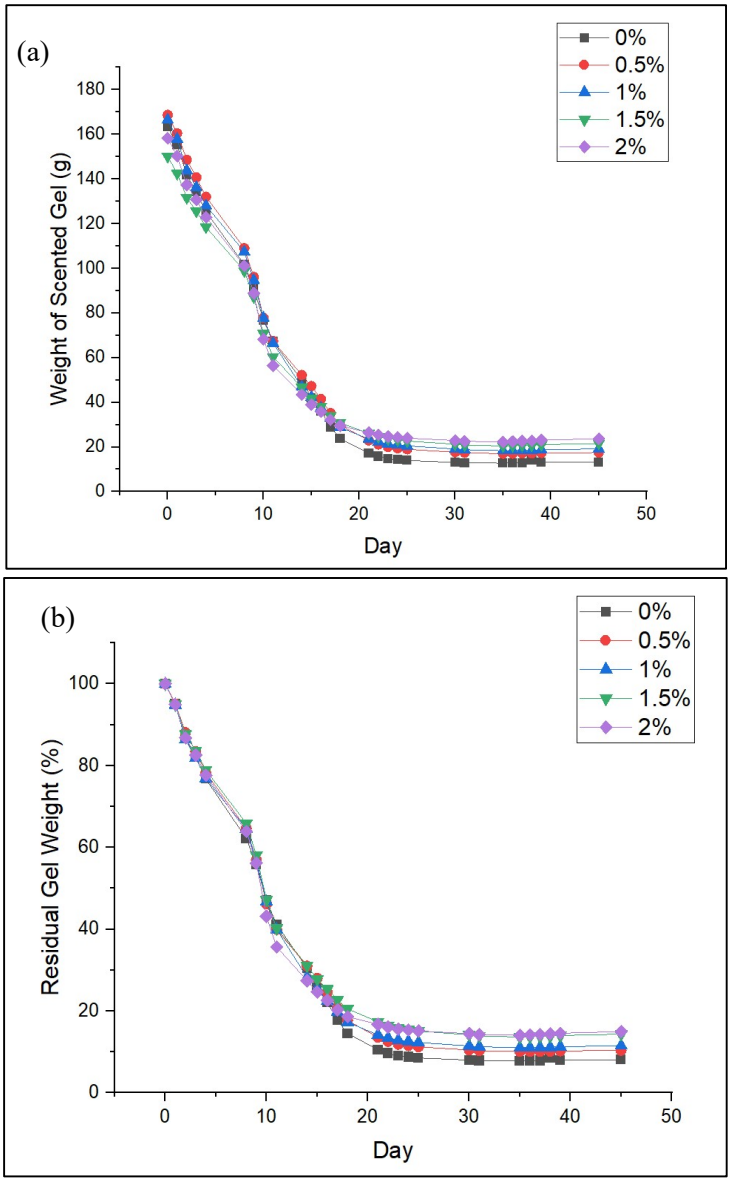

Figure 4. (a) Weight variation (b) residual gel weight

Gel bloom strength test

As shown in Figure 5, the analysis of gel Bloom strength, a commercially important parameter, showed varying values for different samples. The gel formation process is extremely sensitive to the structural and compositional properties of semi-refined carrageenan (SRC). The highest gel Bloom strength, 1331.39 g, was obtained for the carrageenan gel formulation with 2% CCD salt at the lowest viscosity (probability of rejection p-value = 0.00017). The gel Bloom strength has an inverse relationship with viscosity: the higher the gel strength, the lower the viscosity. Formulation solutions containing gellan gum as their gelling agent with the inclusion of calcium ions show decreasing gel strength because of the excessively high concentration of CCD salts. This is because gellan gum molecule relation developed the coagulation state, preventing the stable three-dimensional network structure from being retained [19]. In this study, gel Bloom strength increased with the addition of CCD salts. A better gel strength could also

be attributed to improved carrageenan gelation, as it is believed that chloride salts can improve carrageenan gel strength [23]. In a previous study, the addition of hydroxypropyl methyl cellulose to carrageenan solution increased the viscosity from 172 to 616.5 mPa.s due to the intermolecular interaction between composite chains in the solution which may cause higher mechanical properties [24]. According to Sarbon et al., addition of CCD salts to gelatin solution decreases the gel strength of gelatin but calcium sulphate and magnesium sulphate increase it [22]. This is because of the formulation of a gelatin network in which salt acts as elastic masses for the gelatin. In contrast, in this study, the gel strength increased at higher concentrations of CCD salt. This is probably due to other effects of chemicals such as sodium benzoate and sorbitan monolaurate in the formulation, the effect of which on the gel strength needs to be investigated. Iota-carrageenan hydrogels with various weight percentages of calcium chloride have been successfully developed [25]. Using nanosilica as the carrageenan reinforcement agent increases the mechanical properties of the bioplastic film at a melting temperature of 68 °C [26].

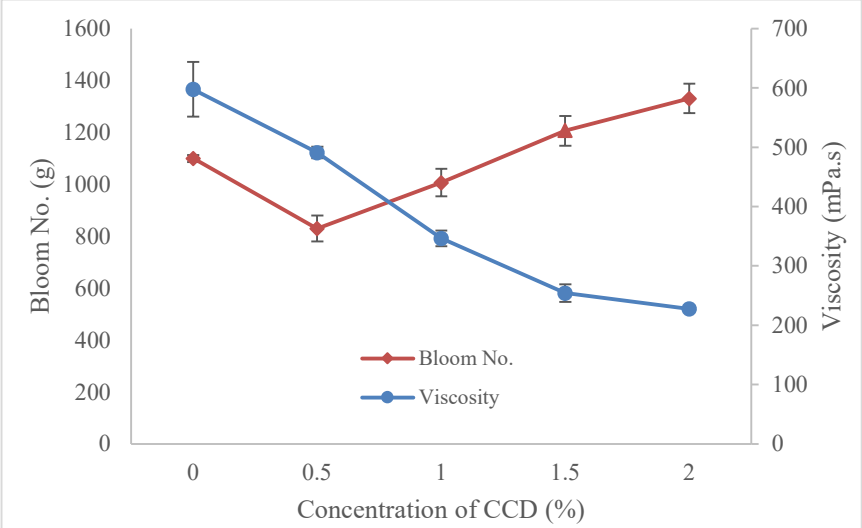

Figure 5. Gel strength test using Bloom gel analysis of carrageenan gel

Thermal properties

TGA was performed to assess the thermal properties of the carrageenan gel formulation. Figure 6(a) and (b) present the relative weight loss from thermogravimetric curves and the weight loss first derivative thermogravimetric (DTG) curves, as functions of temperature in a nitrogen atmosphere, of the carrageenan gels made with various CCD salt concentrations. The results for weight loss obtained from TGA analysis provide an intercorrelation between the variation of CCD salt concentration and weight loss.

Figure 6 (b) shows that the control gel sample had a four-stage weight loss. In the first stage, up to 50 °C, approximately 11.66 % of the weight was lost. This could be attributed to the vaporization of water (absorbed and bound water). The second stage of weight loss began at about 263.4 °C and continued up to 800 °C. At this stage, faster thermal degradation and a weight loss of more than 25% were demonstrated. In the formulation with 2% CCD salts, fewer residues remained at 800 °C and the total weight loss at about 210.2 °C was 11.82%. Carrageenan–poly (vinyl alcohol) composite film heated at 800 °C has shown an increased trend of weight loss with the addition of inorganic ions. This can be explained by the presence of mineral salt produced from the ash [27].

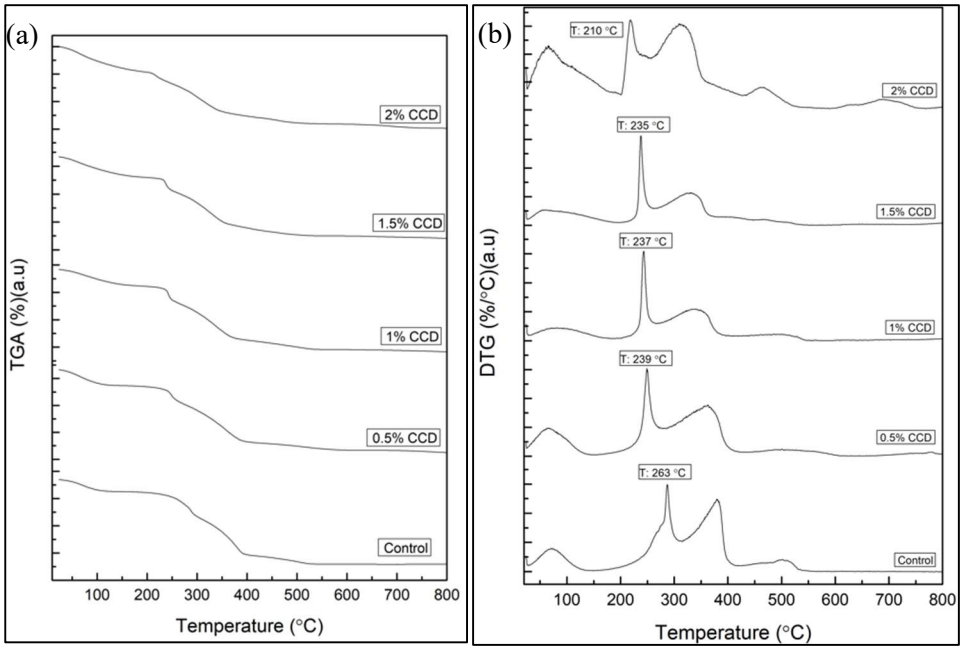

Figure 6. (a) TGA and (b) DTG thermogram for carrageenan gels

Figure 7 and Table 2 shows the DSC analysis on carrageenan gel at different concentrations of CCD salts. The DSC run curve of the control carrageenan gel exhibited an exothermic peak centered at about 185.04 °C corresponding to 323.45 mW of heating. A peak position situated at a higher temperature indicates a stronger interaction with water. Thus, these results suggest that there is an interaction between semi-refined carrageenan and water that may be responsible for the formation of a more stable gel under this condition. According to Figure 7, the DSC results show the enthalpy change during high-temperature heating of samples. In the DSC thermograms, there only one major intense peak was recorded, which was an endothermic transition at temperatures around 185~194 °C. The endothermic transition resulted from the heat absorption for dehydration of water and sample decomposition [28]. Melting temperature decreases with the addition of calcium chloride in bovine gelatin [22].

Table 2. DSC analysis on carrageenan gel at different concentrations of CCD salts

Sample	Sample Mass (mg)	T_m/°C	Heat flow (mW)
0% CCD	7.17	185.04	323.45
0.5% CCD	8.68	184.85	504.06
1% CCD	8.73	188.86	145.78
1.5% CCD	8.39	193.9	154.92
2% CCD	8.89	194.36	415.81

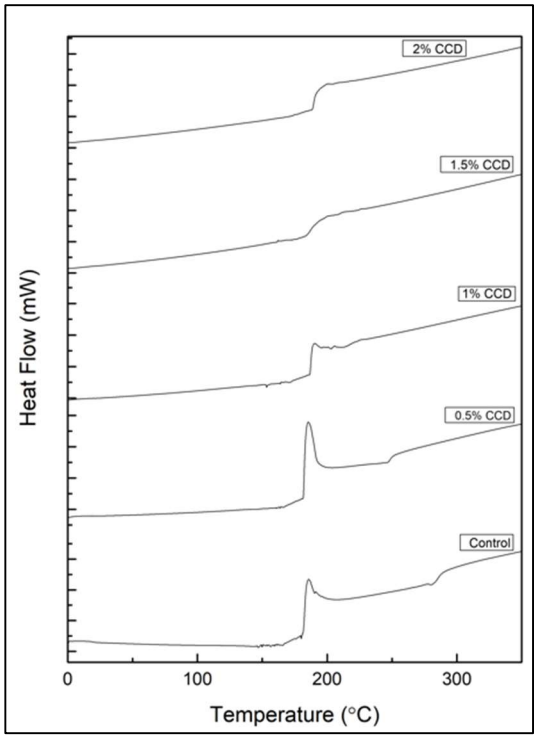

Figure 7. DSC thermograms for carrageenan gels

Morphology analysis

Figure 8 (a) and (b) show SEM images for carrageenan gels from the control sample and 2% CCD salt sample, respectively. Both samples display sponge-like particles with a prominent macroporous structure. In this case, the diameter of the pores seemed to increase at higher calcium chloride concentrations. The images show that the carrageenan gel without salt has a network of smaller and shallow pores. The average diameter of pores at 0% CCD salt was 416.4 μm while at 2% CCD it was 514.1 μm. However, in contrast, the gel produced with the presence of salt displayed larger pores and a higher degree of porosity. The networks became denser by adding CCD salt. This finding is supported by Pan et al., who found that the surface morphology of porcine-myosin–κ-carrageenan mixtures demonstrated large aggregates and cavities at higher calcium chloride concentrations [23]. Adding gellan gum and calcium chloride to surimi gel results in a finer and denser structure compared to surimi gel without the addition of gellan gum and calcium chloride that shows coarser and larger voids due to low breaking force and water-holding capacity [29]. The structure of calcium–ι-carrageenan blended gel has pores that are denser and fragmented; and with addition of glutamic acid, a sheet structure is observed, leading to a weak and open structure [30].

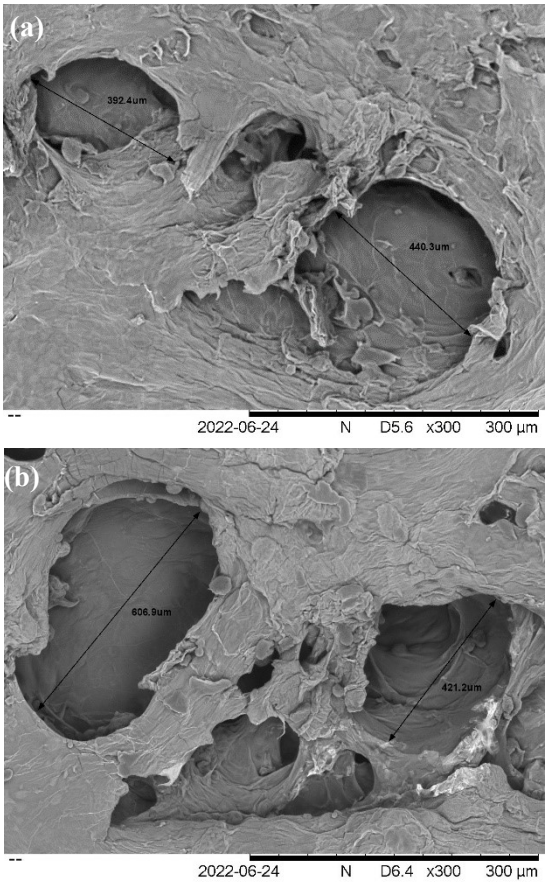

Figure 8. SEM images of surface morphology of carrageenan gel: (a) 0% at 300× and (b) 2% at 300×

Conclusion

In conclusion, the findings in this work provide an important insight into the role of CCD salt to form a strong interaction between gel matrix chemicals to produce stable gel properties. The addition of 2% CCD to the gel formulation manages to increase the residual gel weight from 8% to 15% and improve the mechanical and thermal activities of the gel prepared. This finding suggests the role of CCD salt can be fully utilized in the formulation of a base for aromatherapy scented gel, offering the opportunity to produce a better-quality gel. The mechanical and thermal properties show that the 2% concentration of CCD salts can be used as a base for aromatherapy scented gel, which offers a high gel strength and is expected to enhance the formulation solution of carrageenan scented gel due to the ionic compound of calcium ions.

Abstract

β-Carboline constitutes a tricyclic pyrido[3,4-b] indole ring structure and is widely recognized for its prevalent biological activities. In recent years, numerous studies have reported on its excellent biological activities, particularly anti-cancer, anti-fungal, anti-malarial agents and many more. Thus, a collective of β-carboline derivatives were synthesized to explore its pharmacological properties. The synthetic approach towards β-carboline derivatives has been constructed in a two-step reaction, including Pictet-Spengler condensation reaction and the iodine-mediated oxidative dehydrogenation reaction. Pictet-Spengler was carried out by treating aldehydes bearing different substituents with tryptamine in the presence of trifluoroacetic acid. The synthesized intermediates were then aromatized to give the desired β-carboline derivatives. All these synthesized intermediates and β-carboline derivatives were analyzed and confirmed by NMR and ATR-FTIR spectroscopy. The working foundation established in this study will be applied in future research and development of new broad-spectrum β-carboline based anti-malarial drugs. Compounds **6**, **9** and **12** synthesized in this work could be promising anti-malaria candidates in this future user.

Keywords: β-carboline, oxidative dehydrogenation reaction, pictet-spengler condensation, tetrahydro-β-carboline, trifluoroacetic acid

Abstrak

β-Karbolina membentuk struktur cincin indol pyrido trisiklik [3,4-b] dan diiktiraf secara meluas untuk aktiviti biologinya yang lazim. Dalam beberapa tahun kebelakangan ini, banyak kajian telah dilaporkan mengenai aktiviti biologinya yang sangat baik terutamanya sebagai agen anti-kanser, anti-kulat, anti-malaria dan banyak lagi. Oleh itu, satu kolektif terbitan β-karbolina telah disintesis untuk meneroka lebih lanjut sifat farmakologinya. Pendekatan sintetik terhadap terbitan β-karbolina telah dibina dalam tindak balas dua langkah yang merangkumi tindak balas pemeluwapan Pictet-Spengler dan tindak balas dehidrogenasi oksidatif pengantara iodin. Pictet-Spengler telah dijalankan dengan merawat aldehid yang mengandungi substituen berbeza dengan triptamina dengan kehadiran trifluoroasetik asid. Perantaraan yang disintesis kemudiannya diaromatis untuk memberikan terbitan β-karbolina yang dikehendaki. Semua perantaraan yang disintesis dan terbitan β-karbolina ini dianalisis dan disahkan oleh spektroskopi NMR dan ATR-FTIR. Asas kerja yang ditubuhkan dalam kajian ini akan digunakan dalam penyelidikan dan pembangunan masa depan ubat antimalaria berasaskan β-karbolina spektrum luas baharu. Kompaun **6**, **9** dan **12** yang disintesis dalam kerja ini boleh menjanjikan calon anti-malaria pada pengguna masa hadapan ini.

Kata kunci: terbitan β-karbolina, tindak balas pendehidrogenan oksidatif, pemeluwapan picter-spengler, tetrahydro-β-karbolina, trifluoroasetik asid

Introduction

In the year 2020, WHO estimated 241 million malaria cases leading to 627 000 deaths, globally [1] whilst based on the annual Commonwealth Malaria Report 2022, the increment of malaria incidences and mortality rates has been reported and ever since the outbreaks of COVID-19. This pandemic disrupted all malaria services and progressed.

Malaria is a global disease induced by apicomplexan parasites derived from plasmodium species [2] where plasmodium falciparum and plasmodium vivax were found to be the most dominant genus contributed to the accession of mortality and morbidity rates [3]. These parasites are carried by female *Anopheles* mosquitoes and infect the human bloodstream upon bloodmeals.

Over the years, multiple treatments and approaches like vector control, vaccines and chemotherapy have been used to combat this infectious disease [4]. The most popular malaria treatments are the common artemisinin-based combination (Fig.1) therapies (ACTs). These first-line treatments comprise artemisinin derivatives such as artesunate-mefloquine (AS-MQ), artesunate-sulfadoxine-pyrimethamine (AS+SP) and artesunate-pyronaridine [5]. The absence of a vaccine and the complexity of these plasmodium species lifecycle triggers the resistance of these strains towards the ACTs [6] and other available drugs [7]. Thus, studies on such artemisinin-based molecules will lead to the potential discovery of new and effective anti-malarial drugs.

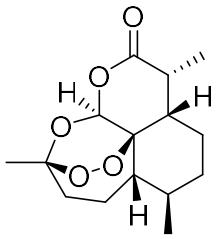

Figure 1. Parent structure of artemisinin

Natural β-carboline alkaloid **1** was found to hold the essential moiety in the exploration of various kinds of drugs due to its excellent biological and pharmacological activities which include anti-plasmodial [8], anti-fungal [9], anti-microbial [10], anti-cancer [11] and more. The scaffolds of β-carboline are extensively distributed in natural products such as plants, insects, marine invertebrates and plant-derived foods [12]. β-Carboline is a part of the indole alkaloid family [13] with a deviating degree of aromaticity [14] of the N-containing six-membered rings. Unsaturated members of β-carboline are known as fully aromatic-β-carbolines (FAβCs). In contrast, the partially saturated and completely saturated rings are known as dihydro-β-carbolines (DHβCs) and tetrahydro-β-carboline (THβCs), respectively (Fig.2).

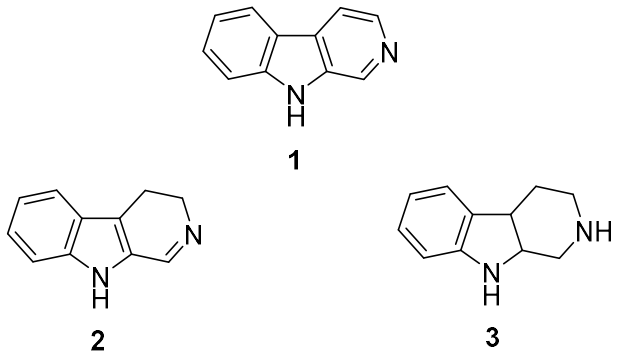

Figure 2. Aromaticity of β-carbolines: (**1**) FAβCs, (**2**) DHβCs, (**3**) THβCs

Yeung et al. (2010) discovered that β-carboline derivatives, spiroindolones or spirotetrahydro β-carbolines possess good anti-malarial activity with in vitro IC_{50} of 90nM. The racemic mixture of spiroazepineindole has been identified to exhibit good efficacy against NF54 and chloroquine-resistant (KI) parasite strains [8]. Additionally, azepineindole (Fig.3) and tetrahydro-β-carboline derivative also (Fig.4) showed a moderate potency towards anti-malarial activity. Tetrahydro-β-carboline (THβCs) and fully aromatic-β-carboline (FAβCs) derivatives such as 5-chloro-tetrahydro-β-carboline [6] exhibit satisfaction activities with low toxicity towards human cells. As for [15], they had reported two guanidine conjugated β-carboline compounds composing excellent activities against malaria strains with IC_{50} values of 0.6 to 1.0 µM.

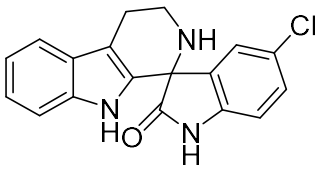

Figure 4. Tetrahydro-*β*-carboline derivative

In line with our interest in finding and developing novel anti-plasmodial agents, we are intrigued to synthesize β-carboline derivatives using tryptamine with various benzaldehyde substituents by applying two facile synthesis reactions. The application of the Pictet-Spengler condensation reaction was the most reported method to synthesize THβCs with the aid of strong Brønsted acids to promote the ring closure of imine. In order to synthesize FAβCs, an oxidative dehydrogenation reaction with iodine was found to be more feasible and convenient [16]. Herein, we report a collection of synthesis results upon applying the Pictet-Spengler reaction catalyzed by trifluoroacetic acid (TFA) and oxidative dehydrogenation reaction.

Materials and Methods

Procedure for the synthesis of compounds 6a-g:
Benzaldehyde (1.0 equiv.) was added to a stirred suspension of tryptamine (1.0 equiv.) and TFA (1.5 equiv.) in DCM. The resulting solution was stirred for 24 hours. The reaction mixture was extracted with EtOAc and dried over anhydrous Na_2SO_4. The combined organic layer was concentrated and purified by silica gel column chromatography with n-hexane, EtOAc (4:1) gradient and 3% triethylamine.

Procedure for the synthesis of compounds 7a-g:
Compound **6(a-g)** (1.0 equiv.) was added to DMSO, iodine, I_2 (0.5 equiv.) and followed by H_2O_2 (1.0 equiv.) and the resulting mixture was stirred at 100˚C for 12 hours. The reaction mixture was poured over cold water extracted with EtOAc and dried over anhydrous Na_2SO_4. The organic layer was evaporated and purified by silica gel column chromatography eluting with a gradient of n-hexane and EtOAc (9:1).

Results and Discussion

4-(2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indol-1-yl)benzonitrile (6a). Yield: 82%, yellow solid. IR *v* cm^{-1}: 3344, 2491, 1659,1449,641cm^{-1}. 1H-NMR (400 MHz, METHANOL-D4) δ 7.86 (dt, J = 8.4, 1.8 Hz, 2H), 7.59-7.54 (m, 3H), 7.29-7.27 (m, 1H), 7.17-7.06 (m, 2H), 6.01 (s, 1H), 3.65-3.53 (m, 2H), 3.23-3.12 (m, 1H). 13C-NMR (101 MHz, METHANOL-D4) δ 139.2, 137.3, 132.9, 130.6, 126.1, 125.8, 122.7, 119.5, 118.0, 117.6, 114.0, 111.2, 108.1, 56.1, 40.8, 18.1.

1-(4-bromophenyl)-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole (6b). Yield: 60%, brown oil. IR *v* cm^{-1}: 3067,2174, 1670, 1455, 722 cm^{-1}. 1H-NMR (400 MHz, METHANOL-D4) δ 7.67-7.65 (m, 2H), 7.53 (d, J = 7.8 Hz, 1H), 7.32-7.26 (m, 3H), 7.14-7.07 (m, 2H), 5.89 (s, 1H), 3.28-3.15 (m, 4H). 13C-NMR (101 MHz, METHANOL-D4) δ 137.2, 133.4, 132.3, 131.4, 126.6, 125.9, 124.4, 122.5, 119.4, 117.9, 111.1, 107.9, 56.2, 40.7, 18.2.

1-(3-bromophenyl)-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole (6c). Yield: 66%, yellow oil. IR *v* cm^{-1}: 3239, 2179, 1675, 1432, 744 cm^{-1}. 1H-NMR (400 MHz, METHANOL-D4) δ 7.61 (dt, J = 7.6, 1.7 Hz, 1H), 7.55-7.50 (m, 2H), 7.39-7.32 (m, 2H), 7.26 (d, J = 8.2 Hz, 1H), 7.14-7.03 (m, 2H), 5.68 (s, 1H), 3.51-3.38 (m, 2H), 3.12-3.05 (m, 2H). 13C-NMR (101 MHz, METHANOL-D4) δ 138.7, 137.1, 132.6, 132.3, 130.7, 128.2, 128.1, 126.1, 122.7, 122.2, 119.2, 117.8, 111.0, 108.3, 56.3, 41.0, 19.1.

1-(3-nitrophenyl)-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole (6d). Yield: 92%, yellow oil. IR *v* cm^{-1}: 3258, 2180,1667, 1135, 667 cm^{-1}. 1H-NMR (400 MHz, METHANOL-D4) δ 8.40-8.37 (m, 1H), 8.32 (t, J = 2.1 Hz, 1H), 7.80-7.73 (m, 2H), 7.56 (d, J = 7.8 Hz, 1H), 7.29 (d, J = 8.2 Hz, 1H), 7.19-7.07 (m, 2H), 6.10 (s, 1H), 3.67-3.58 (m, 2H), 3.24-3.18 (m, 2H). 13C-NMR (101 MHz, METHANOL-D4) δ 148.7, 137.3, 136.2, 135.7, 130.5, 126.1, 125.9, 125.0, 124.5, 122.7, 119.6, 118.1, 111.2, 108.3, 56.0, 41.0, 18.2.

1-(4-(trifluoromethyl)phenyl)-2,3,4,9-tetrahydro-1*H*-pyrido[3,4-*b*]indole (6e). Yield: 90%, yellow solid. IR *v* cm^{-1}: 3055, 1617, 1415, 1321, 742 cm^{-1}. 1H-NMR (400 MHz, METHANOL-D4) δ 7.63 (d, J = 8.2 Hz, 2H), 7.44 (d, J = 8.2 Hz, 3H), 7.20-7.18 (m, 1H), 7.00 (tdd, J = 14.9, 7.0, 1.2 Hz, 2H), 5.23 (s, 1H), 4.07 (q, J = 7.2 Hz, 1H), 3.21 (dt, J = 12.5, 5.4 Hz, 1H), 3.07-3.01 (m, 1H), 2.92-2.78 (m, 2H). 13C-NMR (101 MHz, METHANOL-D4) δ 146.1, 136.7, 132.7, 129.3, 127.0, 125.1, 125.1, 121.1, 118.5, 117.5, 110.7, 109.2, 56.8, 41.2, 21.5.

1-(naphthalen-1-yl)-2,3,4,9-tetrahydro-1*H*-pyridol[3,4-*b*]indole (6f). Yield: 76%, brown oil. IR *v* cm^{-1}: 3055, 1617, 1415, 1321, 742 $cm^{-1.}$ 1H-NMR (400 MHz, CHLOROFORM-D) δ 8.22-8.29 (1H), 7.86-7.93 (1H), 7.80-7.84 (1H), 7.55-7.61 (2H), 7.47-7.53 (1H), 7.33-7.40 (1H), 7.21-7.30 (1H), 7.10-7.18 (2H), 5.85-5.95 (1H), 3.29-3.39 (1H), 3.13-3.22 (1H), 2.84-3.03 (2H). 13C-NMR (101 MHz, METHANOL-D4) δ 147.2, 146.1, 145.7, 138.8, 136.7, 136.7, 132.7, 129.3, 128.3, 127.0, 125.1, 125.1, 121.1, 118.5, 117.5, 110.7, 109.2, 56.8, 41.2, 21.5.

1-(4-isopropylphenyl)-2,3,4,9-tetrahydro-1H-pyrido[3,4-b]indole (6g). Yield: 53%, yellow oil. IR *v* cm^{-1}: 3136, 3057, 1453, 1359, 1710, 744 cm^{-1}. 1H-NMR (400 MHz, CHLOROFORM-D) δ 7.59-7.63 (1H), 7.52-7.55 (1H), 7.18-7.21 (4H), 7.09-7.13 (2H), 5.10-5.15 (1H), 4.08-4.14 (1H), 3.32-3.40 (1H), 3.07-3.15 (1H), 2.86-2.96 (2H), 2.80-2.84 (1H), 1.24-1.25 (3H), 1.22-1.23 (3H). 13C-NMR (101 MHz, CHLOROFORM-D) δ 149.0, 148.7, 141.3, 139.1, 135.9, 134.7, 128.5, 127.5, 126.9, 121.7, 119.4, 118.3, 110.9, 110.2, 57.9, 43.0, 34.0, 24.1, 24.1, 22.6.

4-(9H-pyrido[3,4-b]indol-1-yl)benzonitrile (7a). Yield: 33%, yellow oil. IR *v* cm^{-1}: 3240, 2922, 1670, 1136, 746 cm^{-1}. 1H-NMR (400 MHz, METHANOL-D4) δ 8.42 (dd, J = 5.5, 1.8 Hz, 1H), 8.22 (d, J = 7.8 Hz, 1H), 8.15-8.09 (m, 3H), 7.97-7.93 (m, 2H), 7.61-7.54 (m, 2H), 7.29 (dd, J = 8.2, 6.9 Hz, 1H). 13C-NMR (101 MHz, METHANOL-D4) δ 139.2, 137.3, 132.9, 130.6, 126.1, 125.8, 122.7, 119.5, 118.0, 117.6, 114.0, 111.2, 108.1, 56.1, 40.8, 18.1.

1-(4-bromophenyl)-9H-pyrido[3,4-b]indole (7b). Yield: 71%, yellow solid. IR *v* cm^{-1}: 2983, 1736, 1372, 1233, 1043, 607 cm^{-1}. 1H-NMR (400 MHz,

CHLOROFORM-D) δ 8.54-8.57 (1H), 8.13-8.18 (1H), 7.93-7.97 (1H), 7.81-7.87 (2H), 7.68-7.73 (2H), 7.48-7.59 (2H), 7.29-7.35 (1H). 13C-NMR (101 MHz, METHANOL-D4) δ 137.2, 133.4, 132.3, 131.4, 126.6, 125.9, 124.4, 122.5, 119.4, 117.9, 111.1, 107.9, 56.2, 40.7, 18.2

1-(3-bromophenyl)-9H-pyrido[3,4-b]indole (7c). Yield: 41%, yellow solid. IR *v* cm^{-1}: 3061, 2925, 1231, 742, 673 cm^{-1}. 1H-NMR (400 MHz, ACETONE-D6) δ 8.48 (d, J = 4.8 Hz, 1H), 8.25 (d, J = 7.3 Hz, 1H), 8.20 (t, J = 1.8 Hz, 1H), 8.10-8.05 (m, 2H), 7.64-7.61 (m, 2H), 7.55-7.46 (m, 2H), 7.27 (td, J = 7.5, 0.9 Hz, 1H). 13C-NMR (101 MHz, METHANOL-D4) δ 138.6, 133.1, 132.7, 132.4, 131.6, 126.9, 124.4, 122.5, 117.4, 117.9, 111.3, 104.1, 56.2, 46.7, 19.2

1-(3-nitrophenyl)-9H-pyrido[3,4-b]indole (7d). Yield: 33%, yellow solid. IR *v* cm^{-1}: 3403, 2922, 1348, 729 cm^{-1}. 1H-NMR (400 MHz, ACETONE-D6) δ 8.57-8.47 (m, 3H), 8.41-8.15 (m, 4H), 7.62 (dd, J = 8.2, 0.9 Hz, 1H), 7.57-7.53 (m, 1H), 7.49 (d, J = 8.7 Hz, 0H), 7.29 (td, J = 7.5, 0.9 Hz, 1H). 13C-NMR (101 MHz, METHANOL-D4) δ 148.7, 137.3, 136.2, 135.7, 130.5, 126.1, 125.9, 125.0, 124.5, 122.7, 119.6, 118.1, 111.2, 108.3, 56.0, 41.0, 18.2

1-(4-(trifluoromethyl)phenyl)-9H-pyrido[3,4-b]indole (7e). Yield: 48%, yellow oil. IR *v* cm^{-1}: 3018, 1214, 743, 668 cm^{-1}. 1H-NMR (400 MHz, CHLOROFORM-D) δ 8.58 (d, J = 5.5 Hz, 1H), 8.17 (d, J = 8.2 Hz, 1H), 8.07 (d, J = 7.8 Hz, 2H), 7.98 (d, J = 5.0 Hz, 1H), 7.81 (d, J = 8.2 Hz, 2H), 7.59-7.50 (m, 2H), 7.35-7.31 (m, 1H). 13C-NMR (101 MHz, CHLOROFORM-D) δ 139.8, 136.8, 128.9, 128.6, 128.4, 126.2, 126.2, 125.9, 125.9, 125.6, 125.1, 122.0, 120.8, 120.7, 120.2, 114.6, 112.2, 111.7.

1-(naphthalen-1-yl)-9H-pyrido[3,4-b]indole (7f). Yield: 56%, brown oil. Tryptamine was designated as the model substrate due to its readily synthetic availability. The utilization of benzaldehyde derivatives as the electrophile to undergo condensation with tryptamine commanded most of the initial attention. The Pictet-Spengler reaction was applied to induce the formation of the cyclic ring via C-C bond by the usage of tryptamine as the starting material.

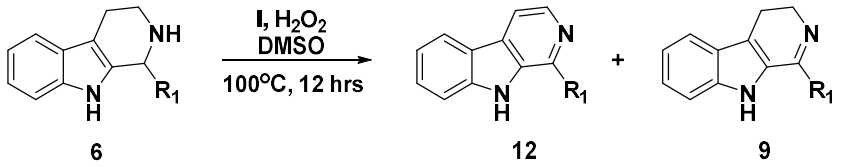
Technically, the Pictet-Spengler reaction expressed the formation of iminium salt upon acid-catalyzed condensation of tryptamine with benzaldehyde derivatives followed by *endo* cyclization between the nucleophilic carbon at the C-2 position and resulting in the intermediate product of N-heterocyclic ring with new C-C bond. Looking at the structure of tryptamine, both carbon-2 and carbon-3 can act as a nucleophile. Spiroindolenine intermediate is produced if the reaction proceeds to attack at carbon-3 before undergoing the 1,2-alkyl shift to yield the tetrahydro-β-carboline (THβCs) intermediates.

In this study, a collective of benzaldehyde derivatives and tryptamine were used to develop a series of tetrahydro-β-carboline (THβCs) and fully aromatic-β-carbolines (FAβCs). Generally, benzaldehyde (**5**) bearing electron-withdrawing group (EWG) provided a higher yield of intermediate THβCs (**6**) compared to those with an electron-donating group (EDG) (Table 1). This can be explained by the inductive and resonance

effects of the substituents. Benzaldehyde with electron-donating groups (EDG) in **6f-g** activated the ring and reduced the electrophilicity of the carbonyl carbon, resulting in weaker reactivity and lower product yields. On the contrary, benzaldehydes bearing electron-withdrawing groups (EWG) in **6a-e** contributed substantially greater yields.

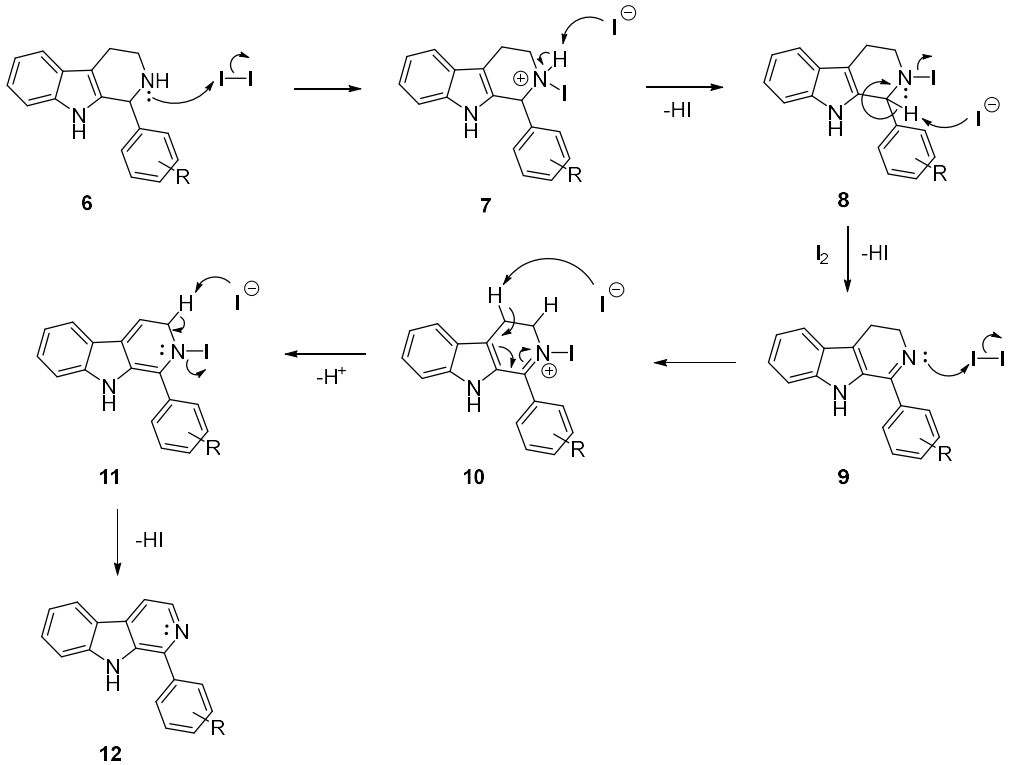
Table 1. Scope of reactions of tryptamine with different substituted benzaldehydes



4 5 6

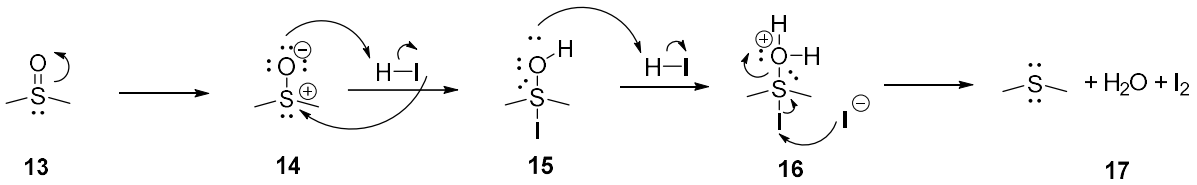
Entry	R_1	Yield (%)
6a	*p*-cyanophenyl	82
6b	*p*-bromophenyl	60
6c	*m*-bromophenyl	66
6d	*m*-nitrophenyl	92
6e	*p*-(trifluoromethyl)phenyl	90
6f	*o*-napthaldehyde	76
6g	*p*-isopropylphenyl	53

Each of the intermediate products, THβCs (**6**) proceeded for aromatization by utilizing the oxidative dehydrogenation reaction with iodine. There are various ways to promote the aromatization and construction of these β-carboline structures. However, a few drawbacks were highlighted. Some procedures such as applying heat with palladium, Pd on carbon, C [17] or sulphur, S [18] or boiling the intermediate THβCs with organic solvents over high temperature with oxidizing agents are not favorable because they require raucous condition. Method utilizing reagents such as chloranil [19], DDQ [20], trichloroisocyanuric acid [21], $PhI(OAc)_2$ [22], N-chlorosuccinimide [23] and IBX [24] could promote aromatization. However, they were reported to suffer from disadvantages of using excess reagents, having massive waste production and affording low yield of target compounds.



According to Table 2, THβCs with both the electron-withdrawing group (EWG) and electron-donating group (EDG) provided moderate product yields since the electronic effect and activation profile of each of the benzaldehyde substituent does not affect the aromatization of the N-heterocyclic ring. The moderate yields of the target products, FAβCs (**12**) can be explained by the formation of DHβCs (**9)** as the minor products. Alternately, complete aromatization of THβCs could also be achieved by increasing the equivalent amount of H_2O_2 [16],[25].

Table 2. Aromatization of tetrahydro-β-carboline (THβCs) intermediates



Entry	R_1	Yield (%)
7a	*p*-cyanophenyl	33
7b	*p*-bromophenyl	71
7c	*m*-bromophenyl	41
7d	*m*-nitrophenyl	33
7e	*p*-(trifluoromethyl)phenyl	48
7f	*o*-napthaldehyde	56
7g	*p*-isopropylphenyl	46

The mechanism of oxidative dehydrogenation reaction can be explained by the initial N-iodination of THβCs intermediate (**6**) where the lone pair of the nitrogen attacks the iodine, followed by the formation of imine intermediate, DHβCs (**9**) *via* dehydroiodination process. Next, DHβCs undergo another N-iodination reaction to yield an ammonium intermediate (**10**). Subsequent deprotonation and dehydroiodination upon this intermediate promote aromatization and give our final target product of FaβCs (Scheme 1).

Scheme 1. Mechanism of iodine-mediated oxidative dehydrogenation

The regeneration of iodine, I_2 is crucial to maintain a continuous cycle for this reaction. Dehydroiodination reaction took at least twice to produce HI where its acidic proton will promote the removal of water, reduction of DMSO to dimethyl sulfate (DSM) and regeneration of iodine, I_2 (Scheme 2). H_2O_2 promotes an atmospheric environment to control the reduction activity by oxidizing the DMS to DMSO and catalyzed the reaction activity [26].

Scheme 2. Mechanism on regeneration of iodine, I_2

Conclusion

In conclusion, a series of tetrahydro-β-carboline intermediates were synthesized via Pictet-Spengler reaction from tryptamine and benzaldehydes with different substituents. Benzaldehydes bearing the electron-withdrawing groups (EWG) provided higher yields compared to those with electron-donating groups (EDG). Application of iodine-mediated oxidative dehydrogenation method promoted the aromatization of N-heterocyclic ring of THβCs intermediates into fully aromatized-β-carbolines (FAβCs) as the major products and dihydro-β-carbolines (DHβCs) as the minor products. Further study on the biological properties of the synthesized products toward anti-malaria activities are currently in progress.

Abstract

It has been reported that the wastewater treatment processes are unable to remove microplastics (MPs) from wastewater completely and often bypass the treatment plants into water resources. Hence, this study tested cobalt (Co) and palladium (Pd) doped tin oxide SnO_2 nanorods as photocatalysts to degrade the MPs. Co and Pd were selected as dopants due to their high oxidation catalytic characteristics. A dosage of 10 mol% dopants was used to prepare the doped SnO_2 nanorods. The SnO_2 was synthesized using a facile hydrothermal route at a relatively lower temperature, 180 °C. To study the photocatalytic performance of MPs, the reaction was executed on polypropylene (PP) for 72 hours under visible light irradiation. While, the effect of pH was tested at different pH conditions (5,7, and 9). The SnO_2 nanorods were analyzed using X-ray diffraction (XRD), field emission scanning electron microscope (FESEM), Fourier transforms infrared (FTIR) spectrometer, and UV-Vis spectrometer. The broadening of XRD peaks in Pd and Co-doped SnO_2 nanorods signifies a decrease in crystalline size, which is supported by FESEM images with ~15 nm diameter. The performance of the photodegradation of PP is verified by using FTIR analysis. The strong vibration peaks of the carbonyl and hydroxyl bands confirmed that the polymer chain broke down via a photo-oxidation reaction. Cracks and cavities have been found on the surface of PP after the photocatalytic reaction. Overall, 10% Pd-doped and Co-doped SnO_2 have exhibited good performance after 72 hours of photocatalytic reaction at pH 9, and it has a high potential as a photocatalyst for the degradation of MPs.

Keywords: tin oxide, palladium doped, cobalt doped, microplastics, photodegradation

Abstrak

Laporan menunjukkan bahawa proses rawatan air sisa tidak dapat membuang mikroplastik (MP) sepenuhnya yang terkandung dalam air sisa malah sering memintas loji rawatan ke sumber air. Oleh yang demikian, dalam kajian ini kobalt (Co) dan paladium (Pd) terdop stanum oksida (SnO_2) telah diselidik sebagai fotokatalis untuk mendegradasi MP. Co dan Pd telah dipilih sebagai logam dopan disebabkan kedua-dua logam tersebut mempunyai ciri-ciri pemangkin oksida yang tinggi. Sukatan sebanyak 10 mol% dopan telah digunakan untuk menyediakan nanorod SnO_2 terdop. SnO_2 telah disintesis menggunakan laluan hidroterma yang mudah pada suhu yang agak rendah, 180 °C. Untuk mengkaji prestasi fotodegradasi MP, proses fotokatalisis telah dijalankan pada polipropilena (PP) selama 72 jam, di bawah penyinaran cahaya nampak. Manakala, kesan pH pada telah dikaji pada pH yang berlainan (5,7 dan 9). Nanorod SnO_2 yang terhasil telah dianalisis menggunakan pembelauan sinar-X (XRD), mikroskop elektron pengimbasan pancaran medan (FESEM), spektrometer Fourier inframerah transfomasi (FTIR) dan spektrometer UV-Vis. Pelebaran puncak XRD bagi sampel nanorod SnO_2 terdop menunjukkan penurunan dalam saiz kristal, yang disokong oleh imej FESEM dengan diameter ~ 15 nm. Prestasi fotodegradasi PP telah disahkan melalui analisis FTIR. Kehadiran puncak getaran kuat karbonil dan hidroksil mengesahkan rantai polimer terputus melalui tindak balas pengoksidaan foto. Keretakan dan rongga telah ditemui pada permukaan PP yang telah dirawat dengan fotokatalisis. Secara keseluruhan, SnO_2 terdop dengan 10 mol% Co and Pd telah menunjukkan prestasi yang baik selepas 72 jam tindak balas fotokatalitik pada pH 9 dan ia mempunyai potensi tinggi sebagai fotomangkin untuk degradasi mikroplastik.

Kata kunci: stanum oksida, dop palladium, dop kobalt, mikroplastik, penguraian foto.

Introduction

The contamination of water by microplastics (MPs) has emerged as a global environmental and public health issue. In contrast to large plastic waste, the removal of MPs is more difficult due to the microscale size, which is often less than 5 mm and hard to detect with the naked eye [1]. Scientists suspect that wastewater treatment plants are the primary source of MPs in rivers and oceans, despite the fact that MPs break down from larger plastics into smaller pieces and eventually enter the water resources. As MPs' concentration in the environment rises, so does the likelihood of ecosystem exposure. Consequently, there is an increased risk of interaction, ingestion, and adverse effects across food webs [2].

Therefore, in recent years, extensive effort has thus been focused on developing ways to minimize the volume of MPs entering the natural aquatic system using various technologies such as electrocoagulation, magnetic extraction, and photodegradation. Electrocoagulation is a method that utilizes metal electrodes to create coagulation for the removal of MPs. Although this method has a higher MP removal efficiency, the characteristics of the electrode and wastewater, such as density, conductivity, and pH, have a significant impact on the process, making consistency difficult to achieve [3]. On the other hand, in magnetic extraction, MPs bind with iron-based nanoparticles before being separated by external magnetic attraction from the wastewater. This technique normally leads to secondary sludge waste. The photodegradation method usually uses UV light to break the polymer chain of MPs. However, the technique's scalability is limited by its high energy consumption and lengthy reaction time [4].

Visible light photocatalysis using semiconductor nanoparticles is regarded as an environmentally friendly process capable of degrading MPs in less time with less energy consumption. Over the years, various semiconductors nanoparticles, especially titanium dioxide (TiO_2) [5, 6] and zinc oxide (ZnO)[7-9] have been extensively studied in the photocatalysis of MPs in water. In spite of the fact that these materials demonstrated degradation of MPs, complete degradation has not yet been reported. Moreover, their applications were often restricted by the limited absorption of visible light and the short lifetime of electron-hole pairs [10]. Tin oxide is an n-type semiconductor, which is well known for its wide band gap (3.6 eV at 300 K), large exciton binding energy (130 meV), and high electron mobility (100-200 $cm^2\ V^{-1}\ S^{-1}$) [11]. Due to its wide band gap, tin oxide itself exhibits a relatively low photocatalytic effect. However, in comparison to SnO_2 to TiO_2 and ZnO, it is known to be a better electron acceptor due to the presence of a more

positive conductive band (CB). Hence, coupling with other metal oxides or doping with transitional metals or noble metals effectively reduces the photogenerated electrons-holes pairs recombination during the photocatalytic reaction [12].

Our previous study reported on the hydrothermal synthesis of metal doped SnO_2 nanorods and their performance as ethanol gas sensors. The results revealed that doping improves the physiochemical properties of SnO_2 [13, 14]. Thus, in the current study, cobalt (Co) and palladium (Pd) doped tin oxide nanorods were synthesized using the hydrothermal method and tested their photocatalytic performance on polypropylene (PP) sample, which is one of the most widely found microplastic pollutants in wastewater.

Materials and Methods

Chemicals

Tin (IV) chloride pentahydrate ($SnCl_4.5H_2O$), cobalt chloride hexahydrate ($CoCl_2.6H_2O$), and palladium chloride ($PdCl_2$) were purchased from Sigma-Aldrich. All chemical reagents were analytical grade without any further purification. Sodium hydroxide (NaOH) was purchased from Qrec Asia Sdn. Bhd, Malaysia, and absolute ethanol (C_2H_5OH) were procured from HmbG Chemicals. All the solutions were prepared using distilled water. MPs sample was prepared from fully aged Polypropylene (PP), which was obtained from a local home storage manufacturer, ASOTV, Kuala Lumpur.

Synthesis of tin oxide nanorods

The synthesis of doped SnO_2 nanorods using the hydrothermal method is described elsewhere [14]. Briefly, tin oxide, 0.32 mol of tin (IV) chloride pentahydrate ($SnCl_4.5H_2O$) was dissolved in 40 ml absolute ethanol - distilled water solvent (1:1 v/v) while stirring continuously. Co and Pd dopants (10 mol%) were added separately in the solution above. Simultaneously the pH of the reaction solution was adjusted to pH 13 by slowly adding an equal volume of 6 M NaOH aqueous solution and absolute ethanol. The pH was monitored throughout the reaction. The final volume of the reaction mixture was completed to 80 mL by adding in absolute ethanol – distilled water solvent (1:1 v/v). A white slurry for undoped SnO_2, a peach color slurry for Co-doped SnO_2, and a grey color slurry for Pd-doped SnO_2 were obtained at the end of the reaction. The samples were then transferred into a 100 mL Teflon -linen stainless-steel autoclave, sealed, and heated at 180 °C for 24 hrs. After being naturally cooled at room temperature, the product was centrifuged and repeatedly washed with distilled water followed by ethanol and then dried in the oven at 60 °C for 24 hrs. The undoped SnO_2 nanorod sample was prepared similarly but without the dopant. Figure 1 shows the final product produced via the hydrothermal process.

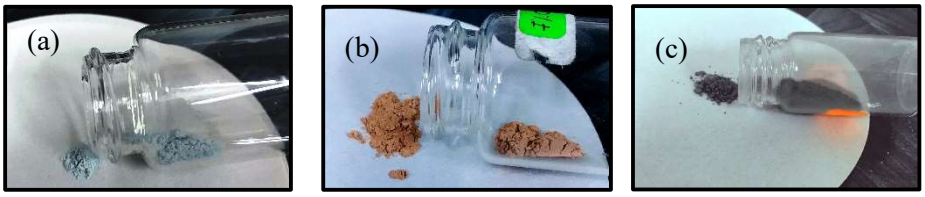

Figure 1. (a) Undoped SnO_2, (b) Co doped SnO_2, and (c) Pd doped SnO_2 powder samples

Photocatalysis reaction setup

The photocatalytic performance of the as-synthesized tin oxide nanorod sample was tested on PP. A known amount of PP microplastics sample (1 g, size particle~125 µm) was suspended in 100 ml distilled water. The photocatalytic reaction was carried out at room temperature under visible light (LED Blu-ray, 18 Watt, λ, 460 -462 nm) irradiation. 0.5 mg of tin oxide nanorods photocatalyst was added to the MPs sample. To obtain a uniform distribution of PP with a photocatalyst, the sample was shaken at the speed of 150 rpm using an orbital shaker for the duration of 72 hrs. To study the effect of pH, doped SnO_2 samples were tested at different pH conditions (5,7, and 9). After the reaction, the PP and photocatalyst were filtered out using a vacuum pump and dried at room

temperature for 24 hours. Figure 2 shows the experimental setup for the photocatalytic reaction.

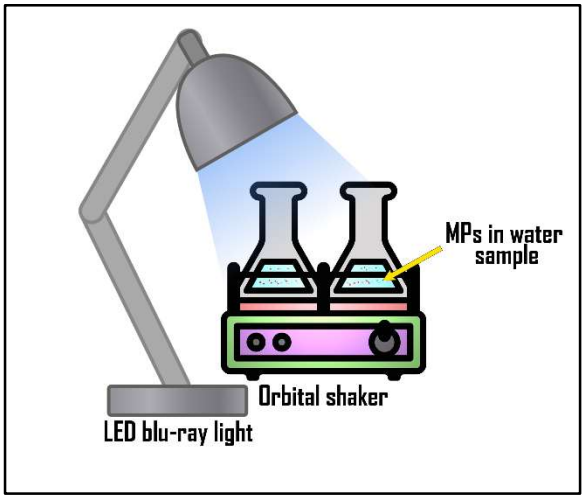

Figure 2. Schematic diagram of photocatalytic reaction under visible light (LED blu-ray) source

Characterization

The morphology and composition of the SnO_2 were determined using HRTEM (high-resolution transmission electron microscopy (HRTEM) (TECNAI G2 20 S-TWIN, FEI, China) and X-ray diffraction technique (PW 3040/60 X'PERT PRO (PANanalytical, Neterland). The X-ray diffraction (XRD) patterns are obtained using Cu Kα radiation (λ=0.1541 nm) in the 2θ range of 20° to 90°. The band gap was calculated using a UV-Vis spectrometer (Perkin Elmer Lambda 35, United States). The photodegradation was verified using Fourier transform Infrared (FTIR) spectrometer (Perkin Elmer's System 2000 FTIR, United States). The infrared spectra were collected in the range of 4000-400 cm^{-1}. For oxidized PP, carbonyl groups were identified in the wide infrared range at 1500-1800 cm^{-1}, with the peak at 2800-2950 cm^{-1} utilized as a reference, which is related to CH bending and CH_3. SEM (HITACHI, TM3030Plus, Japan) was used to observe and determine the morphology of the microplastics with a photocatalyst. The SEM images were taken at a magnification of 600x to 5000x.

Results and Discussion

Figure 3 shows the XRD patterns of undoped SnO_2, Co, and Pd-doped SnO_2 nanorod powder samples. All diffraction peaks could be assigned to the rutile-type tetragonal phase (space group, *P42/mnm*); which was indexed on the basis of ICSD 092552, and no trace of other metallic or metal oxide phases have been detected. The broadening of diffraction peaks shows that the dopants not only reduced the particle size but also lowered the crystallinity of nanoparticles. The prominent reflection of (101), (110), and (211) peaks indicate the preferential crystal planes of the nanostructure [15].

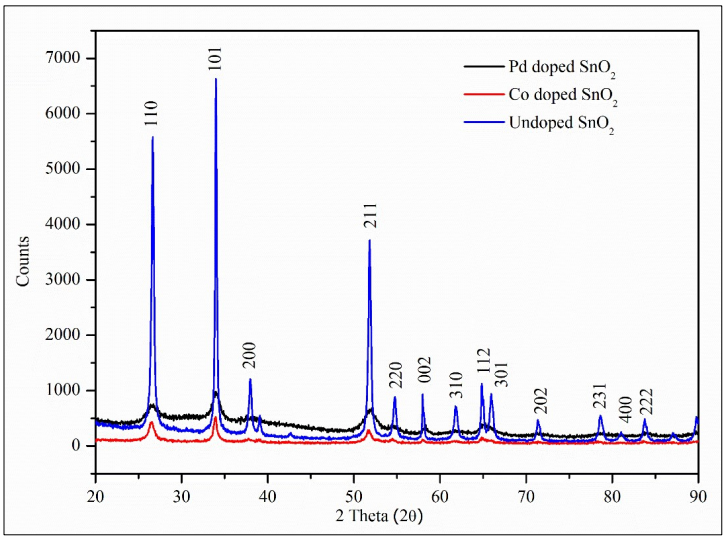

Figure 3. XRD diffraction patterns of undoped and doped SnO_2 nanostructures

The morphology of as-synthesized SnO_2 samples was analyzed by using SEM and HRTEM. Figure 4 exhibits the SEM images of SnO_2 samples. From the SEM images, it can be seen clearly that the SnO_2 are in the form of nanorods. A comparison of the morphology images revealed that the presence of 10% Co and 10% Pd dopants did not affect the shape of the nanorods; However, in comparison to the undoped SnO_2, the size of the nanorods has been significantly reduced. This result suggested that the Co and Pd greatly inhibited SnO_2 grain size, which is in line with XRD data, where the broadening of peaks was observed clearly in doped SnO_2 samples [15].

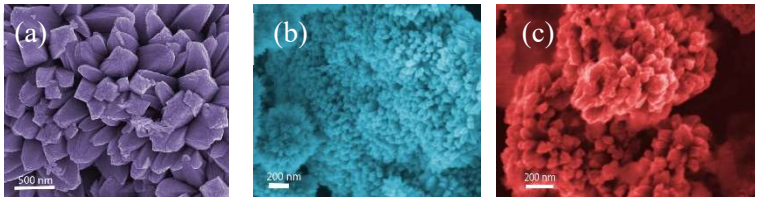

Figure 4. SEM images of (a) undoped SnO_2, (b) Co doped SnO_2 and (c) Pd doped SnO_2 nanorods

Additionally, to study the size and shape of particles, HRTEM analysis was performed on the samples. Figure 5(a) depicts an undoped SnO_2 spear rod-shaped nanorods cluster with an estimated average diameter and length of 23.0 ± 4.2 nm and 152.0 ±7.6 nm, respectively. While Co doped, SnO_2 exhibits needle-like nanorods with an average diameter and length of 14.2± 2.4 nm and 77.2 ± 8.3 nm, respectively (Figure 5 (c)). In contrast, Pd doped SnO_2 formed nanorods with a rounded tip (Figure 5 (c)). The calculated average diameter and length are 8.5 ± 2.9 nm and 43.9 ± 2.7 nm, respectively. The aspect ratio for undoped SnO_2, Co doped SnO_2, and Pd doped SnO_2 changed from 6.6, 5.4 to 5.2, respectively. The result shows that the nanorods formed in the Pd doped SnO_2 sample were the smallest. The drastic decrease in the particle size may be due to the fact that the ionic radii of Co^{2+} (0.72 Å) and Pd^{2+} (0.86 Å) are much bigger than Sn^{4+} (0.69 Å); the introduction of these dopant ions results in lattice strain and a reduction in particle size as well as crystalline size [16].

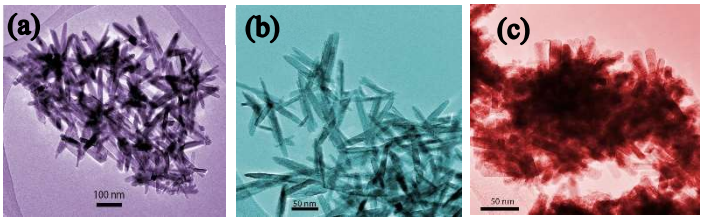

Figure 5. HRTEM images of (a) undoped SnO_2, (b) Co doped SnO_2 and (c) Pd doped SnO_2 nanorods

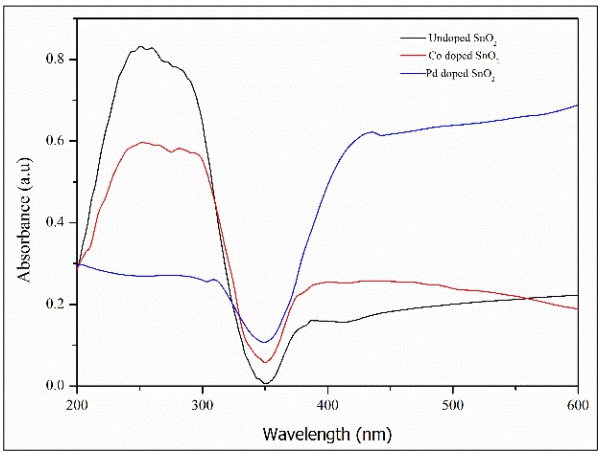

Figure 6: UV-Vis spectra of as-synthesized SnO_2 samples

The UV-Vis absorption spectra of as-synthesized SnO_2 nanorods are shown in Figure 6. The absorption edges of Co-doped SnO_2 and Pd-doped SnO_2 show a redshift (300 -350 nm) which could cause by the high concentration of oxygen vacancies or defects in the SnO_2. The high uptake at the wavelength of 380 nm to 450 nm in Co and Pd doped SnO_2 nanorod samples reveals the sp-d exchange interactions between the band electrons and localized d electrons of dopant ions that replace Sn^{4+} ions in the crystal lattice. Consequently, this finding suggests that the absorption capacity of the Co and Pd doped SnO_2 nanorods is improved from the UV region to the visible region, which is essential for visible light photocatalysis. A similar trend was also obtained in previous studies [17]. The bandgap energy was estimated following Tauc's relation. The bandgap energies of the resulted samples are 3.88 eV, 3.61 eV and 3.55 eV for undoped SnO_2, Co doped SnO_2 and Pd doped SnO_2, respectively, suggest that doping has reduces the bandgap energy [18].

Photodegradation of PP microplastics under visible light

The photocatalytic reactions were conducted for 72 hours under visible light irradiation to test the SnO_2 nanorods as a photocatalyst for degrading the PP MPs in water. The PP residues were filtered and dried before being characterized using an FTIR spectrometer. As can be seen in Figure 7, some chemical reactions occurred during the photocatalytic process. This reaction led to the formation of new functional groups such as carbonyl, hydroperoxide, peroxides, and unsaturated groups, which are assigned to the peaks at 1700-1630 cm^{-1}, 3500-3300 cm^{-1}, 3000-2750 cm^{-1} and 1374 cm^{-1}, respectively. This result is in agreement with previous literature [9]. During the degradation process under visible light, radiation of oxidizing agents, particularly reactive oxygen radical species, would react with PP and eventually produce new functional groups. The combination of visible light irradiation with a chemical attack by reactive oxygen species induced by photocatalysts has

effectively promoted the degradation of PP microplastics [19]. Based on the FTIR spectra, the Co and Pd doped SnO_2 sample exhibit more new peaks than the undoped SnO_2. This may be due to smaller particle size, narrow bandgap, and the presence of oxygen vacancies in Co and Pd-doped SnO_2 nanorods samples.

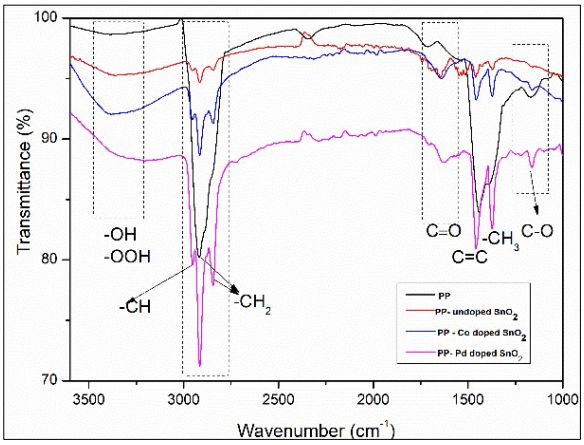

Figure 7. FTIR spectra of PP MPs photodegradation reaction after 72 hours under visible light irradiation

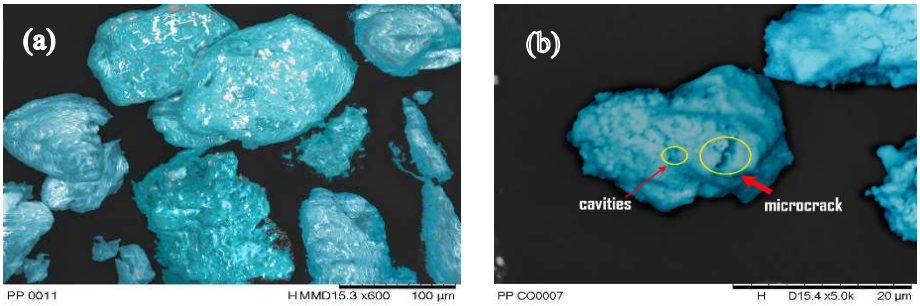

Figure 8. SEM images of PP MPs (a) before the photodegradation reaction (b) after 72 hours of photodegradation under visible light using Pd doped SnO_2 nanorods as the photocatalyst

Further analysis was executed using SEM to investigate the morphology of PP MPs prior to and after photocatalytic reaction; the images are presented in Figure 8. Referring to the figure, the treated PP exhibits surface structural changes such as brittleness, microcracks, and cavities. In conjunction with FTIR findings, the formation of low molecular weight compounds has led to the development of these surface defects, which evidence the degradation process [9]. Generally, in photocatalysis reaction, electron/holes are generated when metal oxide photocatalyst is irradiated by light source that has a higher energy than its bandgap. These pairs migrate to the surface and produce species such as hydroxyl radical (ȮH) and superoxide radical ($\cdot O_2^-$). For SnO_2, it was found that ȮH are the primary active species, this is due to the fact that the conduction band (CB) of SnO_2 (0.2 eV) is more positive than that of ($O_2/\cdot O_2^-$) (-0.05 eV). Hence, when some holes in valence band of SnO_2 reacted with water produced ȮH radicals which subsequently degraded the PP MPs [20, 21] .

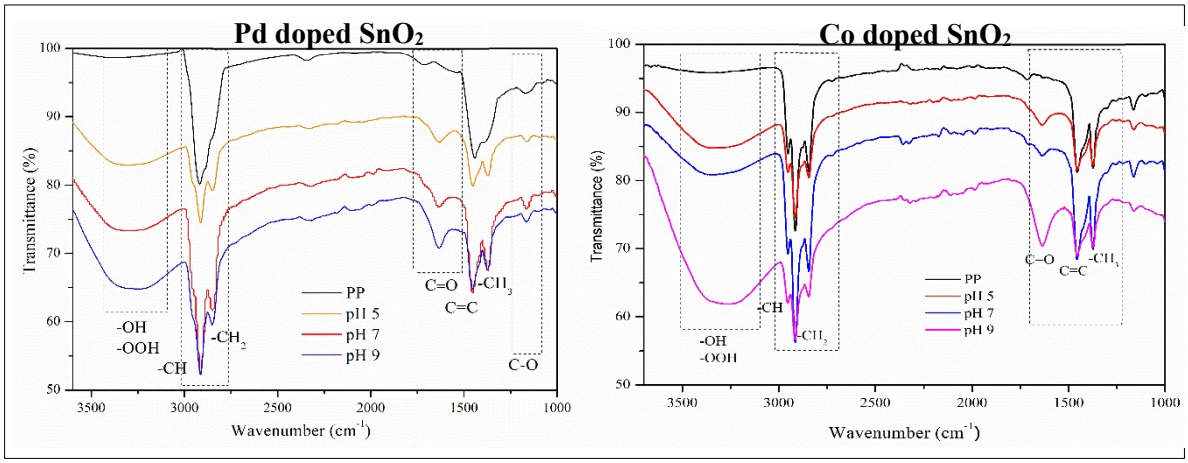

Figure 9. FTIR spectra of PP MPs before and after the 72 hours photodegradation reaction using Pd doped SnO_2 and Co doped SnO_2 as the photocatalysts under different pH conditions.

In order to study the effect of pH, the photocatalytic reaction was performed at different pH (5,7, and 9) using Pd and Co doped SnO_2. Figure 9 depicts the spectra of PP before the treatment and PP MPs residues obtained after 72 hours of photodegradation at various pH under visible light irradiation. The results show for both photocatalysts the intensity of hydroxyl, carbonyl, and peroxide peaks increased when the pH increased. The result suggests that the presence of hydroxide ions increases the degradation of MPs by inducing the formation of more hydroxide radical species [19].

Conclusion

This study successfully demonstrates the degradation of MPs and polypropylene (PP) in water using visible light and hydrothermal synthesized tin oxide nanorods photocatalysts. The photocatalytic reaction led to the formation of low molecular weight compounds such as hydroperoxides, peroxides, carbonyl, and other unsaturated groups, which cause cracks on the surface of PP, and subsequently degrade the MPs. The higher pH of the water sample improves the photodegradation process. In addition, the physical and chemical properties, such as the particle size, bandgap energy, and oxygen vacancies of the photocatalyst, also contribute to enhancing PP degradation. Overall, we conclude that Pd and Co doped SnO_2 nanorods can be applied as an alternative technology to combat global MP pollution.

Abstract

The aim of this study was to develop poly (lactic acid) and chitosan-based films and to examine the effect of cellulose nanocrystal (CNC) as nanofillers on the properties of the films. The biofilms were prepared by solvent casting method. The physical and mechanical properties of the resulting films were examined. SEM analysis showed that the surface of PLA/Cs films smoother when 1% and 2 % of CNC were added. The results for percent of water absorption of the films increased with increasing amount of CNC in PLA/Chitosan matrix. Tensile test results indicated higher TS value by incorporation of 2% of CNC. However, the PLA/Chitosan-CNC films at 3% and 4% CNC concentration exhibited a decreased TS value. PLA/Chitosan films were improved with the addition of a small amount of CNC resulting in PLA nanocomposite, which will be further evaluated for fruit packaging applications. The data obtained through this research could contribute to the establishment of a biofilms with improved the physical and mechanical properties promising significant advantages in term of longer storage life, maintaining safety, and keeping quality of a product especially in fruit packaging.

Keywords: polylactic acid, chitosan, cellulose nanocrystal, films, packaging

Abstrak

Tujuan kajian ini adalah untuk membuat filem berasaskan poli (asid laktik) dan kitosan dan mengkaji kesan kristal nano selulosa (CNC) sebagai pengisi nano pada sifat filem. Biofilm tersebut disiapkan dengan kaedah tuangan pelarut. Sifat fizikal dan mekanikal filem yang dihasilkan diperiksa. Analisis SEM menunjukkan bahawa permukaan filem PLA/Cs lebih licin apabila 1% dan 2 % CNC ditambah.Selanjutnya, peratus penyerapan air filem meningkat dengan peningkatan jumlah CNC dalam matriks PLA/ kitosan. Hasil ujian tegangan menunjukkan nilai TS yang lebih tinggi dengan memasukkan 2% CNC. Walau bagaimanapun, filem PLA / Chitosan-CNC pada kepekatan CNC 3% dan 4% menunjukkan penurunan nilai TS. Filem PLA / kitosan ditambah baik

dengan penambahan sejumlah kecil CNC yang menghasilkan nanokomposit PLA, yang akan dinilai lebih lanjut untuk aplikasi pembungkusan buah. Data yang diperoleh melalui penyelidikan ini dapat menyumbang pada pembentukan biofilm dengan peningkatan sifat sifat fizikal dan mekanikal yang lebih baik yang menjanjikan kelebihan yang ketara dari segi jangka hayat penyimpanan yang lebih lama, mengekalkan keselamatan, dan mengekalkan kualiti produk terutamanya dalam pembungkusan buah-buahan

.

Kata kunci: asid polilaktik, kitosan, selulosa nanokristal, filem, pembungkusan

Introduction

The primary function of food packaging is to preserve the quality and safety of food products during storage and transportation, as well as to extend the shelf-life of food products by preventing undesirable factors such as spoilage microorganisms, chemical contaminants, oxygen, moisture, light, or external force. Many foods packaging currently on the market are made of synthetic polymers that were produced from fossil fuels. This is due to their high mechanical and barrier qualities, as well as their ease of processing and low price. However, there are some disadvantages to this type of material: it requires a lot of energy to recycle, and if it is not properly disposed of, this could pose a risk to the environment because it does not decompose or decomposes slowly in landfills or in the environment, releasing polluting substances. People are currently dealing with rapid climate change as well as the issue of waste disposal that comes with it. As a result, avoiding petroleum-based non-biodegradable polymers such polyethylene (PE), low-density polyethylene (LDPE), and high-density polyethylene (HDPE), as well as polypropylene (PP), which are commonly used in food packaging, is necessary. In recent years, there has been a lot of interest in developing more environmentally acceptable alternatives to the plastics that are currently utilized in the packaging sector. Many natural biopolymer materials, such as chitosan, cellulose, hemicellulose, lignin, pectin, starch, agar, *Eucommia ulmoides* gum, and natural rubbers, have been widely employed to manufacture biodegradable food packaging materials due to their environmentally friendly and biodegradable characteristics.

Chitosan

A chitosan (Cs)-based film has been chosen as an innovative film-forming content. The polysaccharide chitosan is the second most abundant in nature. It has been demonstrated to be biodegradable, non-toxic, biocompatible, and useful [1]. Chitosan is a linear polysaccharide and biodegradable copolymer made up of N-acetyl glucosamine and D-glucosamine. Chitosan is formed by chitin deacetylation, which has the structural element of crustacean exoskeleton, such as crabs and shrimps [2]. Chitosan is a deacetylated product of chitin ß-(1-4)-2-acetamido-2-deoxy-D-glucan. Chitosan has similar characteristics with chitin as the most stable anti-acid and alkali substances, and this portion is also not soluble in ordinary solvents. Most interestingly, it is microbial resistant due to its positively charged amino group, which interacts with negatively charged microbial cell membranes, causing proteinaceous and other intracellular constituents of the microorganisms to leak out [3].

However, the disadvantage of using chitosan-based film is its high cost, which makes it unsuitable for fruit packaging. As a result, it is proposed that chitosan be combined with other biopolymer to form a film in order to produce active fruit packaging [4]. Polylactic acid was chosen to combine with chitosan due to its excellent mechanical properties, which include low flammability, low moisture reversion value, low refraction index, and high UV safety index.

Polylactic acid

Polymers such as polylactic acid (PLA) have attracted the attentions of researchers due to their high strength and modulus. PLA has a proven ability either to substitute traditional petrochemical-based polymers for industrial applications or as a leading biomaterial for a wide range of applications in medicine [5][6]. PLA comes from renewable plant sources, such as starch and sugar. Degradation of PLA can be accomplished by hydrolysis of ester bonds without the need for enzymatic procedure. The use of PLA as food packaging polymer for short shelf-life products with popular applications is growing. In addition, PLA is safe and GRAS is widely

accepted as safe for use in food packages. Indeed, PLA has been known to be ideal for packaging orange juice, yoghurt and dressings [7]. Polylactic acid is a hydrophobic polymer that belongs to a class of biomaterials usually referred to as poly-a-hydroxy acids, poly-a-esters or aliphatic polyesters. It is synthesised from lactic acid (LA; 2 hydroxypropanoic acid) which is a water-soluble monomer with two enantiomeric forms, namely L-(+)-LA and D-(-)-LA. The drawbacks of PLA as it has poor thermal stability, low water vapour or gas barrier properties and inherent brittleness. In order to achieve the films as bioplastics, a filler must be added to improves the mechanical and physical properties of a film.

Cellulose nanocrystal

Cellulose nanocrystal (CNC) has sparked great attention as a potential nano-reinforcement for chitosan films due to its sustainability, abundance, high surface area to volume ratio, lightness, and high mechanical strength among the numerous nanofillers [8]. CNC is a nanometer-sized crystal rod-shaped particle that is formed as a stable aqueous colloidal suspension and is commonly separated from cellulose by acid hydrolysis [9]. Previous researchers have published numerous studies on PLA/ chitosan/CNC bio-composite films [10][11] .There are two ways to obtain nanocellulose. First is mechanical treatment and second is acid hydrolysis. In acid hydrolysis, the separation of cellulose nanocrystals (nanowhiskers) is the product of the difference in solubility between the two regions (amorphous and ordered regions) in the cellulose chain.

Cellulose is a hydrophilic polymer and therefore generally has poor compatibility with hydrophobic synthetic polymers and also poor thermoplastic properties. This constrains the use of nanocellulose, especially cellulose nano crystal, in nanocomposite fabrication [12]. However, according to Sullivan et al. CNC is easily dispersed in water, therefore it can be used as a water-based coating and films for food packaging applications [13].

The use of cellulose nanocrystal as a component in polymeric materials has received a lot of attention. Because of their high crystallinity, good processability, abundance, renewable and biodegradable nature, and outstanding mechanical properties, cellulose-based materials have been the focus of much research. In summary, the combination of cellulose-based fillers to polymer matrices improves material performance in terms of barrier, thermal, and mechanical properties. As reinforcement fillers in polymeric materials, various types of cellulose particles have been used. These cellulose particles can be distinguished by their size, morphology, crystallinity, and crystal structure [14].

Although a number of research efforts aimed at improving the film properties of biopolymer-based packaging films have shown great changes in film properties, their physical & mechanical properties are still not satisfactory and have encountered difficulties in industrial applications [15]. Blending and homogenising cellulose nanocrystals in PLA/Chitosan matrix would result in a new nanocomposite with sufficient mechanical strength suitable for use in food packaging. Therefore, the incorporation of CNC as nanofiller may be useful in improving the mechanical properties of packaging materials. This study evaluates the physical properties and mechanical properties of a new packing material of Poly-lactic acid (PLA)/Chitosan (Cs), Cellulose Nanocrystal (CNC) biopolymer film by using solvent casting technique.

Materials and Methods

Materials

Polylactic acid (PLA) resin of 4032D type used in this study was supplied by Nature Works LLC (USA) with a specific gravity of 1.24, high molecular weight and melt mass flow rate (MFR) of 7 g/10 min at 210°C/2.16 kg. Chitosan (Cs) powder with a degree of deacetylation of 90.5%, molecular weight of >700 kDa, a viscosity of 62 cPs, was purchased from Cleo International Trading (Shanghai)

Isolation of CNC

Microcrystalline cellulose (MCC) is often derived from wood pulp and purified cotton linters. 1g of Micro Crystalline Cellulose was hydrolysed by 10 g of 64% w/w sulphuric acid at 45 °C for 45 min under constant mechanical stirring. The suspension was then diluted with cold deionised water and centrifuged at 4300xg for

15 min. Sodium hydroxide was used in the washing process to neutralize the pH value. After completion of process, the acid was moved by washing with deionized water and centrifuged first, then, 0.5 N of NaOH was applied to neutralizing the suspension followed by washing again by deionised water. The supernatant was removed, and the solid phase was diluted again with deionised water until the milky substance was form and can start to collect (Lim et al., 2021).

Films preparation

Preparation materials Polylactic acid (PLA) and chitosan (Cs) were pre-treated by drying in a vacuum oven at 50 °C for 24 h to eliminate possible absorbed water on the surface of the particles. The PLA and chitosan were dissolved separately in different solvents before blending. PLA (1% by weight) (0.3 g) was dissolved in 30 ml of chloroform and 1 g chitosan in 100 ml of 1% (v/v) acetic acid. Then chitosan solution (1% by weight) was added to the PLA solution and stir until homogenized. After stirring, the solution was modified with glycerol (1% by weight) as plasticizers and stirred for 30 minutes. Then, 1, 2, 3 and 4 wt % of CNC solution were added in PLA/CS solution and stirred until homogenized. Then the solutions were poured on a petri dish, and the solvent used was evaporated at room temperature in fume chamber for 24 h to volatilize the residual solvent. To control film thickness, the quantity of each film-forming solution poured onto a plate was calculated. After that time, films were peeled from the plates and cut to specimens of appropriate sizes for subsequent testing.[9]

Tensile properties

The tensile strength and elongation at break were assessed according to American Society for Testing and Materials (ASTM) method D882 [17]. Specimens were prepared from rectangular film strips (1 cm × 10 cm), dimensions. A universal testing machine, Instron (Model 5569) with 1kN load cell was operated at a crosshead speed of 2 mm/ min. The average value of at least three samples for each composition was reported.

Scanning electron microscopy

The microstructural analysis of the cross-sections of the films was carried out by means of a scanning electron microscope (JEOL JSM-5410, Japan). Film pieces, 0.5 x 0.5 cm^2 in size, were cryofractures from films and fixed on copper stubs, gold coated, and observed using an accelerating voltage of 10 kV. Observations were taken in duplicate for each formulation. [18]

Water absorption

Water absorption was measured using the following procedure. Films with dimensions 2cm x 2cm were placed in a desiccator for 24 h, followed by weighing to measure the dry mass. The films were then immersed entirely in the distilled water in a sealed beaker. The weight gained was monitored until equilibrium was obtained as described by previous findings [19], the percent of water absorption was calculated as follows:

$$\text{Water absorption } \% = \frac{(Ww - Wd)}{Wd} \times 100 \qquad \text{(eq. 1)}$$

Fourier transform infrared spectroscopy

The samples were dried in a desiccator for at least 1 week before analysis. A Nicolet iS10 Fourier transform infrared spectroscopy, with a spectral resolution of 1 $cm^{-1}$was used to recorded infrared spectra of samples. FTIR spectra were collected from 400 cm^{-1} to 4000 cm^{-1}[18].

Statical analysis

All data are shown as a mean ± standard deviation. Analysis of variance (one-way ANOVA; Microsoft Excel 2010) was conducted, utilising a probability level less than 5% ($p < 0.05$). A value of $p < 0.05$ was represented to be statistically significant.

Results and Discussion

Scanning electron microscopy

The results of SEM of the pure PLA/Cs films with (0% - 4%) of CNC are presented in Figure 1. SEM images showed that the surface of PLA/Cs films changed when the concentration of CNC increased. For the pure PLA /Cs film, the surface was seen to be rough and rigid, while the surface of films with CNC content up to 2% was relatively smoother than the pure PLA. For the films containing 1% and 2% of CNC, there is no agglomerations of CNC in the surface of the polymer matrix, which indicated that filler substances were homogeneously dispersed. This might have occurred

because of the processing route of films' preparation [13]. However, for the nanocomposite films with high CNC content (3% & 4%), the presence of agglomerations of CNC in the surface of the PLA matrix was observed. These agglomerations on the surface of the PLA matrix are caused by the hydrophilic nature of cellulose, which encourages strong interactions between the cellulose nanocrystals via hydrogen bonds, resulting in agglomerations on the polymer surface [14].

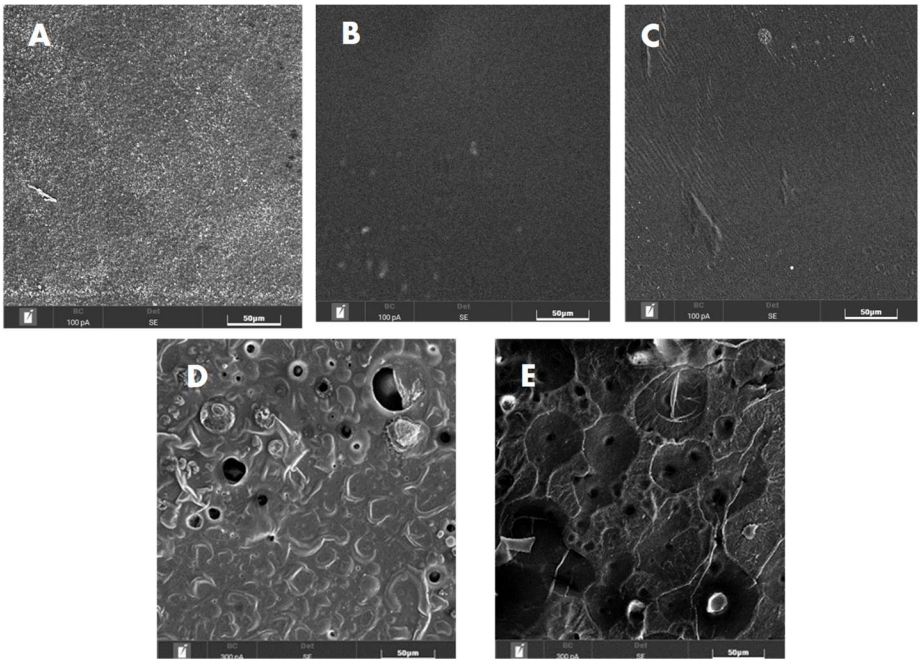

Figure 1. SEM image of the surface of (A) PLA/Cs film, (B) PLA/Cs/CNC 1% film (C) PLA/Cs/CNC 2% film, (D) PLA/Cs/CNC 3% film, (E) PLA/Cs/CNC 4% film

Tensile properties

The obtained results of tensile strength test, elongation at break and young modulus were conducted on the pure PLA/Chitosan film and the nanocomposite films with different content of CNC (0%- 4%). The comparison of the ultimate strength point of the films are presented in Figure 2, Figure 3 and Figure 4. For the pure PLA/Chitosan film without CNC, the yielded TS value (ultimate strength point) was 5.4 MPa. In the case of the film containing 2% of CNC, the TS increased significantly to 13.8 MPa in comparison with the pure PLA/Chitosan film value.

The PLA/Cs films at 3% and 4% CNC concentration exhibited a decreased TS value. The PLA/Cs films at 4% CNC load were more brittle which may be the cause for higher elastic modulus as shown in Figure 4 which is the highest value of young modulus is the films with 4% CNC [20]. The decrease in toughness in nanocomposites has been attributed to large agglomerations of nanofillers has been discussed on the SEM analysis above, the films with high CNC content (3% & 4%) showed the presence of agglomerations of CNC in the surface of the PLA/Cs matrix. Zeyad and Sullivan et al. reported similar results of the tensile strength of their cellulose nanocomposites [13, 21]. These agglomerations can act as stress concentrators, which facilitate the spreading of defects generated at the interface. These defects can grow larger than the critical crack size, resulting in film failure as can be seen on films with 3% and 4% CNC. This suggested that the film containing 2% of CNC was more ductile than the other films since the tensile strength and the elongation break is the highest compared to others [21]. Generally, the

improvement of the mechanical performance of nanocomposite films results from different factors: compatibility between the polymer matrix and the filler, aspect ratios of the filler, and the orientations of the filler. However, in this work, we can hypothesize that the improvement of the tensile strength of the nanocomposite films caused by the stiffness effect of CNC that homogeneously dispersed in the PLA matrix [22].

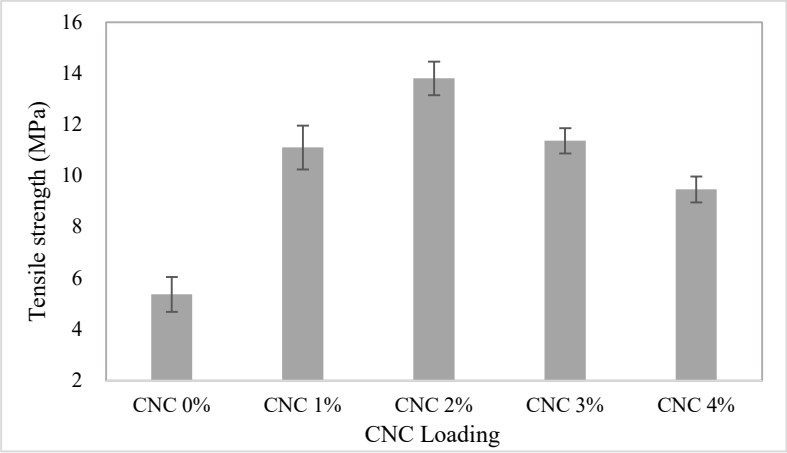

Figure 2. Effect of CNC loading on tensile strength of the film. Values in the figure were significantly different ($p < 0.05$)

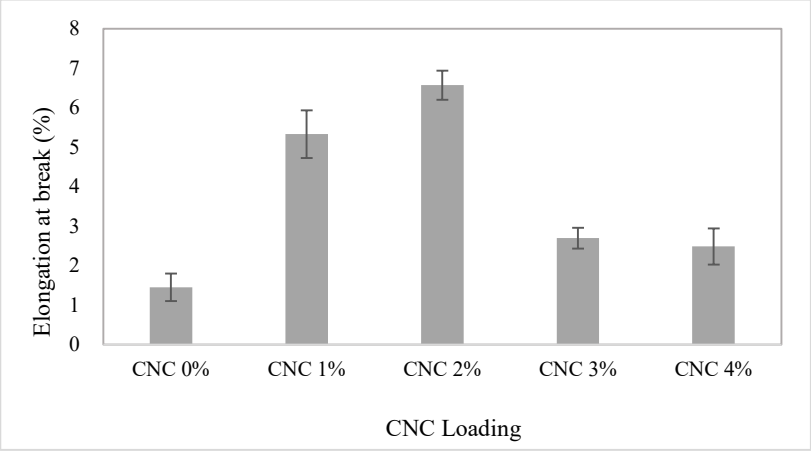

Figure 3. Effect of CNC loading on elongation break of the film. Values in the figure were significantly different ($p < 0.05$)

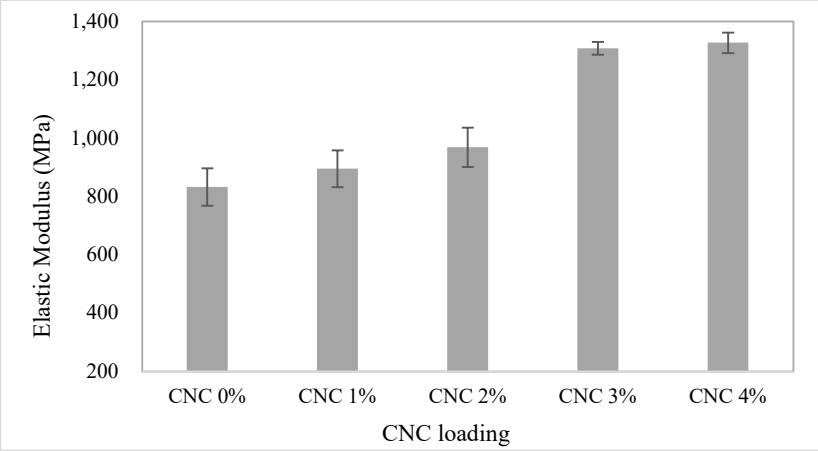

Figure 4. Effect of CNC loading on young modulus of the film. Values in the figure were significantly different ($p < 0.05$)

Water absorption

Water absorption test of pure PLA/Chitosan and PLA/chitosan/CNC films were carried out to investigate water absorption properties by calculating the percentage of water absorption. The water absorption value is shown in Table 2. It can be seen from Figure 5 that the percent of water absorption of the films increased with increasing amount of CNC in PLA/Chitosan matrix. The water absorption of all PLA/Cs/CNC films containing 0, 1, 2, 3 and 4 wt.% CNC increased to 3.02%, 3.77%, 9.82%, and 16.18% after 180 minutes of immersion, respectively. Since PLA is strongly hydrophobic [17] and CNC has hydrophilic nature [21], where hydrogen bonds easily form in water thus increased water absorption [23]. The water absorption of the films is mainly due to the CNC which affect the ability of the film to retain water. The increased water absorption of the film with CNC corresponds to the FT-IR curve, which shows a stronger intensity of the hydrophilic functional group band at 1750 cm^{-1} (reflecting C=O stretching).

Table 1. The initial weight of a films and water absorption of films containing different amount of CNCs

CNC Concentration (%)	Initial Weight (g)	Water Absorption (%)
0	± 0.0218	1.90 ± 0.50
1	± 0.0229	3.02 ± 0.39
2	± 0.0246	3.77 ± 0.29
3	± 0.0136	9.82 ± 0.45
4	± 0.0188	16.18 ± 0.36

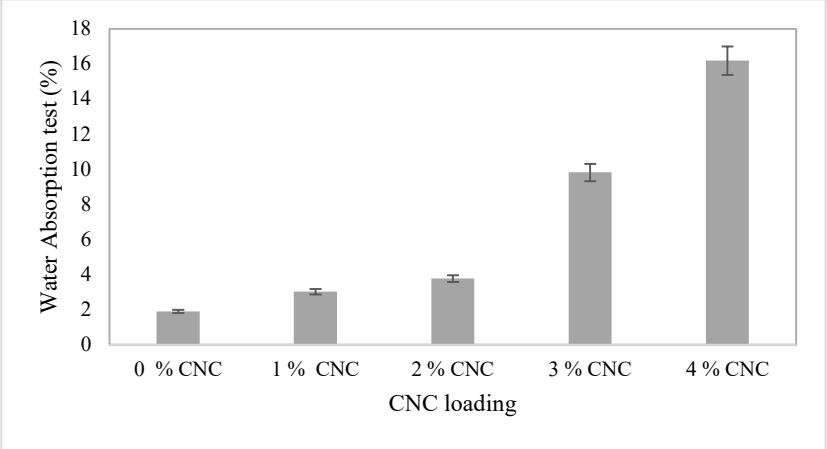

Figure 5. Water absorption test on Films with different concentration of CNC Values in the figure were significantly different ($p < 0.05$)

Fourier transform infrared spectroscopy

FT-IR spectroscopy analysis spectra were recorded to study the differences in the identifying signals of PLA/Cs/CNC films. The infrared spectra of the film with CNC as shown in Figure.6. The absorption peaks of the PLA/Cs/CNC film spectrum are mainly due to the –CH3 stretching vibration at 2,991 cm^{-1}. A strong absorption band was observed at 1,750 cm^{-1} due to the C=O stretching from keto esters [9] According to previously published research, the bending vibrations at 1,452 and 1,382 cm^{-1} are connected to symmetric and antisymmetric deformations of the CH_3 group by [24]. The band at 1261 cm^{-1} are from the antisymmetric and symmetric stretching of C–O–C in esters. The peak at 1,181 cm^{-1} can be attributed to C–O–C stretching of PLA as mentioned in previous studies [9, 12]. The peaks of the chitosan can be found at 1542 cm^{-1} (N-H bending in amide and protonated amino group) which in the agreement of previous study [25]). The peaks at 876 cm^{-1} (β-glycosidic linkage of the cellulose) were observed, associated with typical structures of cellulose [26, 27].

Conclusion

Packaging materials based on PLA and chitosan containing different amount crystal nanocellulose (CNC) were developed to improve the mechanical and physical properties of the films. Cellulose nanocrystal improved the physical properties, tensile strength, percentage elongation breaks and the water absorption. SEM images showed that the surface of PLA/Cs films smoother when 1% and 2% of CNC were added. The addition of 2% CNC enhanced the interactions (e.g., hydrogen bonds and electrostatic interactions) between the PLA/chitosan chains to perform a well-disperse film. FTIR analysis allowed characterizing the molecular interactions occurring after incorporation of Cellulose nanocrystal The set of results indicates that the films with 2% CNC were promising as a filler for PLA/Chitosan based film. However, more work is required in this area of research to maximize the effectiveness of the fillers and also bioactive incorporated agents.

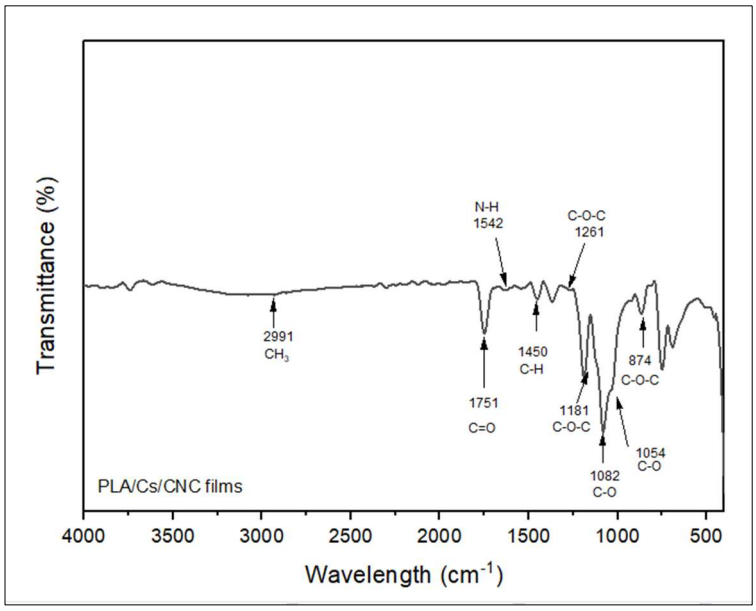

Figure 6. Fourier-transform infrared spectroscopy analysis PLA/Cs//CNC film. Scanning range from 400 to 4000 cm^{-1} is shown.

Abstract

Emulsified oil in wastewater is a severe problem and requires extensive treatment before it can be disposed of in a manner that meets environmental regulation standards. One strategy to remove emulsified oil is by utilizing the adsorption process. The goal of this study is to synthesis magnetic eggshell membrane (ESM) functionalized with waste palm fatty acid, (MNP@ESM-WPFA) for the adsorption of oils (lubricating oil). The synthesis procedure involves three steps including preparation of ESM, functionalization of ESM with waste palm fatty acid (WPFA) and magnetization of eggshell membrane (ESM) functionalized with waste palm fatty acid (ESM-WPFA) through co-precipitation method to obtain MNP@ESM-WPFA. The novel adsorbent was characterized using SEM, FTIR, and EDX analyses. SEM analysis revealed the magnetic nanoparticles scattered throughout the porous and fibrous network structure of ESM-WPFA, confirming the successful synthesis of the MNP@ESM-WPFA. Further FTIR analysis on MNP@ESM-WPFA adsorbent revealed the appearance of peaks at 2933 cm^{-1} and 2852 cm^{-1} and 630 cm^{-1}, thus

confirming the presence of the alkyl chain of the waste palm fatty acid (WPFA) and Fe-O band on the surface of MNP@ESM-WPFA. The oil adsorption performance of MNP@ESM-WPFA was optimal at pH 7, treatment time of 50 minutes, and adsorbent dosage of 50 mg. The MNP@ESM-WPFA showed the highest oil adsorption capacity (K) for lubricating oil (4.61 mg/mg), followed by olive oil (2.72 mg/mg), and corn oil (2.00 mg/mg). The MNP@ESM-WPFA adsorbent was also reusable, with a sorption capacity that was maintained after five usage-regeneration cycles.

Key words: Eggshell membrane, waste palm fatty acids, magnetic nanoparticles, adsorbents, oil removal

Abstrak

Minyak teremulsi dalam air sisa merupakan satu cabaran yang serius dan memerlukan rawatan yang meluas sebelum ia boleh dilupuskan dengan cara yang memenuhi piawaian peraturan alam sekitar. Salah satu strategi untuk mengeluarkan minyak emulsi adalah dengan menggunakan proses penjerapan. Kajian ini bermatlamat untuk sintesis membran kulit telur (ESM) magnetik berfungsikan dengan sisa asid lemak sawit, (MNP@ESM-WPFA) untuk penjerapan minyak (minyak pelincir). Prosedur sintesis merangkumi tiga langkah termasuk penyediaan ESM, perfungsian ESM dengan sisa asid lemak sawit dan permagnetan membran kulit telur (ESM) berfungsikan dengan sisa asid lemak sawit (ESM-WPFA) melalui kaedah kopresipitasi untuk mendapatkan MNP@ESM-WPFA. Penjerap novel ini telah dicirikan menggunakan analisis SEM, FTIR, dan EDX. Analisis SEM mendedahkan nanopartikel magnetik yang bertaburan di seluruh struktur rangkaian berliang dan berserabut ESM-WPFA, mengesahkan kejayaan sintesis MNP@ESM-WPFA. Selanjutnya, analisis FTIR pada penjerap MNP@ESM-WPFA mendedahkan kemunculan puncak-puncak pada 2933 cm^{-1} and 2852 cm^{-1} and 630 cm^{-1} mengesahkan kehadiran rantai alkil WPFA dan Fe-O pada permukaan MNP@ESM-WPFA. Prestasi penjerapan minyak MNP@ESM-WPFA adalah optimum pada pH 7, masa rawatan 50 minit, dan dos penjerap 50 mg. MNP@ESM-WPFA menunjukkan kapasiti penjerapan minyak (K) tertinggi untuk minyak pelincir (4.61 mg/mg), diikuti minyak zaitun (2.72 mg/mg), dan minyak jagung (2.00 mg/mg). Penjerap MNP@ESM-WPFA juga boleh digunasemula, dengan kapasiti penyerapan yang dikekalkan selepas lima kitaran penjanaan semula penggunaan.

Kata kunci: membran kulit telur, sisa asid lemak sawit, zarah nano magnetik, penjerap, penyingkiran minyak

Introduction

Emulsified oil wastewater is regarded as a widespread pollutant around the world. Large volumes of wastewater containing oil and grease are increasingly produced due to population growth and fast urbanization. The release of oil-containing wastewater into water bodies causes public concern due to toxicological and aesthetic reasons [1]. Oil effluents come from various sources, including petroleum refineries, rolling mills, chemical processing, manufacturing plants, industrial processing, and municipal wastewaters [2-4]. Oily wastewater can contain fats, oil, cutting fluids, lubricants, edible oil, grease, crude oils, diesel oils, and other hydrocarbons [5]. Emulsified oils are difficult to handle and pose a real problem for treatment because of steric interaction or structural barriers and electrostatic repulsion between oil droplets [6]. Oil emulsions can produce an impermeable layer on the water's surface, decreasing oxygen content in the water and retard the photosynthesis process of aquatic plants [7-9].

The removal of residual oil remains a difficult technological challenge. Gravity separation, flotation, coagulation, ultracentrifugation, and membrane filtration are traditional methods for removing oil from industrial oily wastewater [10, 11]. In recent years, several techniques for handling emulsified oil have been developed, including bacterial degradation [12], electrocoagulation [13], emulsion destabilization [14], filtration [15], and adsorption [16-19]. An ideal adsorbent should have a high adsorption capacity, a fast adsorption rate, high selectivity, and be relatively inexpensive. Although the adsorption process is not extensively employed in treating emulsions, it has several benefits, and it does not always necessitate the use of extra chemicals [20]. Even though most commercially available oil sorbents are made of synthetic polymers with high sorption capacities such as polypropylene and polyurethane, their use releases massive amounts of hard to recover, non-biodegradable plastic into the environment [21].

There are three main types of adsorbents commonly used to remove oily pollutants: organic sorbents

(activated carbon, sawdust, straw, butyl rubber, carbon-based product), inorganic sorbents (kieselguhr, organoclay, bentonite, vermiculite), and synthetic sorbents (polyvinyl chloride, polyurethane, nylon fibres) [17]. Recently, biomaterials have attracted a great deal of attention as a prospective adsorbent material due to their abundance, environmental friendliness, and ability to be manufactured from renewable sources [22]. Various studies have been carried out to evaluate the preparation of bio-sorbents (sugarcane bagasse, coffee grounds, eggshell membranes, lignocellulosic material) as well as their properties and efficacy in removing various organic contaminants [22]. One of which, the eggshell membrane (ESM), comprises of a porous network of insoluble fibrous proteins with a high surface area that could be exploited as a sorbent for various types of pollutants in wastewater [23, 24]. ESM contains disulfide bonds, causing it to be impermeable to water, thus giving it an advantage in specific applications [25].However, ESM consists of hydrophilic functional groups such as hydroxyl, amine, and carboxylic acid that limits its use as adsorbent for hydphobic pollutants, especially oil contaminants [26, 27]. To overcome this problem, the surface of ESM can be coated with a hydrophobizing agent.

Waste palm fatty acid can be a potential hydrophobic modifier on the surface of ESM. High amounts of free fatty acids can be produced in waste palm cooking oil through a hydrolytic process that occurs in the presence of oil and water from food. The chemical structure of free fatty acids, which consists of long alkyl chains, makes them an excellent hydrophobizing agent to tune the hydrophilic surface of ESM for selective adsorption of oil from aqueous. Waste palm cooking oil was selected because it is easily available and economically viable.In this study, a novel magnetic eggshell membrane (ESM) functionalized waste palm fatty acid, (MNP@ESM-WPFA) was synthesized for the removal of lubricating oil. Magnetic Fe_3O_4 nanoparticles dispersed onto ESM functionalized with waste palm fatty acid can facilitate the rapid separation of oil from water while boosting the adsorption capability of ESM-WPFA. As the utilization of MNP@ESM-WPFA has not been reported yet for environmental applications, therefore, it is a good idea to explore its potential as adsobent for treatment and decontamination of organic pollutants, particularly oil. Therefore, this work focuses on analyzing the performance of MNP@ESM-WPFA in removing lubricating oil. The influence of adsorbent dosage, pH of the solution and contact time on the removal process was thoroughly investigated. Subsequently, the adsorption capacity and reusability of MNP@ESM-WPFA were evaluated.

Materials and methods

Chemicals

Sulphuric acid was purchased from Fischer Scientific (New Hampshire, USA). Sodium sulphate (anhydrous), while *n*-hexane, ethanol, ammonium iron(II) sulphate and iron trichloride hexahydrate were obtained from Merck (Darmstadt, Germany). All solvents used for the synthesis were of analytical grade. Deionized water was used throughout the study.

Instrumentation

Surface morphological analysis of MNP@ESM-WPFA was carried out using Hitachi SU8220 Scanning Electron Microscopy (Oxford Instrument, Oxford shire, UK) that is equipped with x-ray energy dispersion (Carl-Zeiss, Germany). FTIR spectra were recorded on Perkin Elmer FTIR spectrophotometer (Massachusetts, USA) with a crystal diamond universal ATR sampling accessory at room temperature. All spectra were recorded in the wavenumber range of 4000 to 450 cm^{-1}. Wettability analyses were performed using the Theta Lite 100 and Theta Lite 101 contact angle measurement instruments (Attension, Espoo, Finland).

Preparation of magnetic eggshell membrane functionalized with waste palm fatty acid:

Preparation of ESM

Raw eggshells were collected from a local shop and rinsed with deionized water to minimize the deterioration of the eggshell membrane (ESM). The ESM were then carefully removed from the eggshells and rinsed with deionized water again. This is followed by a drying process for 1 hour at 70 °C in the oven, after which the ESM were crushed and sifted using a 30 nm sieve to produce consistently sized powder particles.

Preparation of ESM-WPFA

The ESM-WPFA was prepared in accordance with a previously reported work by Sathasivam and Haris [28] but with minor modifications. Briefly, 2.00 g of ESM powder was mixed with 8.00 g of free fatty acid from waste palm cooking oil (WPCO) and three drops of concentrated sulphuric acid was used as a catalyst. This mixture was dispersed in 20 mL of *n*-hexane for 15 minutes at 60 °C. The obtained ESM-WPFA was then washed with excess *n*-hexane and air-dried.

Preparation of MNP@ESM-WPFA

The MNP@ESM-WPFA preparation was also slightly modified from the reported work by Rozi et al. [29]. In summary, 2.00 g ESM-WPFA, 3.17 g $FeCl_2.4H_2O$, and 7.57 g $FeCl_3.6H_2O$ were mixed in 320 mL deionized water. The mixed solution was agitated for 1 hour at 80 °C. The reaction mixture was then rapidly infused with 40 mL of aqueous ammonia. The resulting mixture was stirred for another hour before allowed to cool to room temperature. The precipitated MNP@ESM-WPFA was washed five times with hot water until the filtrate becomes neutral, after which it was separated using magnetic decantation.

Batch adsorption studies

A certain amount of MNP@ESM-WPFA was mixed with 3 mL lubricating oil in 20 mL water at room temperature for 30 minutes according to the method of Rozi et al. [29]. Using an external magnet, the MNP@ESM-WPFA was separated from the water surface after several minutes. The procedure is illustrated in Figure 1. The adsorption capacity was determined by weighing the sample before and after introducing it to the lubricating oil. Oil adsorption capacity K was calculated using Equation 1.

$$K = \frac{m_2 - m_1}{m_1} \quad \text{(eq. 1)}$$

Where m_1 represents the weight before adsorption and m_2 represents the weight after adsorption.

In this experiment, several parameters such as contact time, adsorbent dosage, and pH of the solution were investigated for their influence in the removal of lubricating oil. Adsorption experiments were carried out in batches, with different conditions of the parameters which includes adsorbent dosage (10, 20, 30, 40, 50, and 60 mg), contact time (10, 20, 30, 40, 50, and 60 minute), and pH of the solutions (pH 2, 4, 7, 8, and 10). This is to determine the best conditions for the removal of lubricating oil using MNP@ESM-WPFA. The optimum conditions obtained from adsorption of lubricating oil were adopted to examine the performance of MNP@ESM-WPFA for removal of several oils including olive and corn oil. Experiments were performed in triplicate for each parameter. After adsorption, the MNP@ESM-WPFA adsorbent was rinsed with *n*-hexane to desorb the lubricating oil and then dried for 24 hours at 90 °C. The regenerated MNP@ESM-WPFA adsorbent was reused up to 5 times. The oil adsorption capacity of the regenerated adsorbent towards the removal of lubricating oil was again measured to determine its reusability.

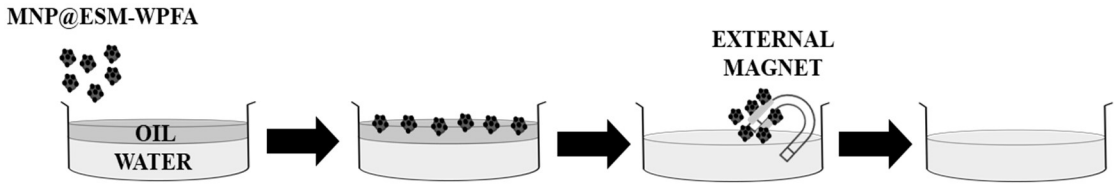

Figure 1. The schematic illustration of oil adsorption using magnetic adsorbent

Results and Discussion

Characterization

The FTIR spectra of ESM, ESM-WPFA, and MNP@ESM-WPFA are illustrated in Figure 2(A-C). Figure 2(A) shows the most significant peaks for ESM at 3429 cm^{-1}, 2933 cm^{-1}, 2852 cm^{-1} and 1647 cm^{-1}. The broad peak at 3429 cm^{-1} can be assigned to the N-H and O-H stretching vibrations. The peaks at 2922 cm^{-1} and 2852 cm^{-1} are attributed to asymmetric and symmetric stretching of a methylene group ($=CH_2$) respectively, while the band at 1647 cm^{-1} represents the stretching of the carbonyl group (C=O). In Figure 2(B), the high intensity of infrared bands at 2925 cm^{-1} and 2855 cm^{-1}

for ESM-WPFA correspond to an alkane stretching, proving that the alkyl chain of the WPFA has been successfully functionalized onto the ESM surface. In Figure 2(C), a new prominent band appears at 630 cm^{-1} due to the Fe-O group confirming the presence of Fe_3O_4 particles in MNP@ESM-WPFA.

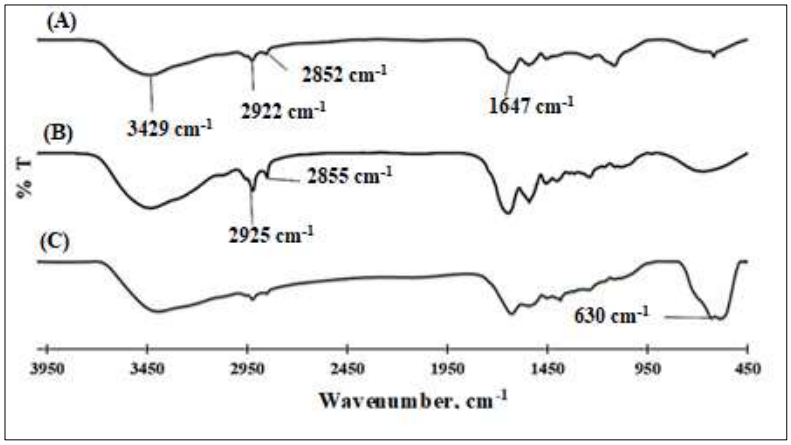

Figure 2. FT-IR spectra of (A) ESM (B) ESM-WPFA and (C) MNP@ESM-WPFA

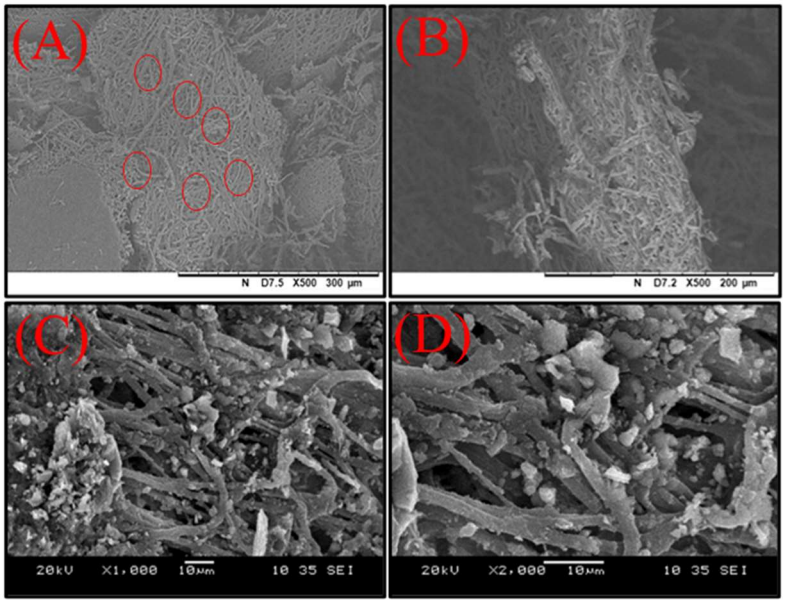
The morphologies of ESM, ESM-WPFA and MNP@ESM-WPFA (Figure 3(A-C)) was examined by using scanning electron microscopy. The image of ESM shows that the virgin ESM has porous and fibrous surface (as circled in Figure 3(A)). The porous and fibrous structure of ESM-WPFA (Figure 3(B)) was found to be smoother after functionalization of waste palm fatty acid (WPFA). Small particles scattered throughout the structure of ESM-WPFA (Figure 3 (C-D)) are the magnetic nanoparticles proving the successful synthesis of MNP@ESM-WPFA.



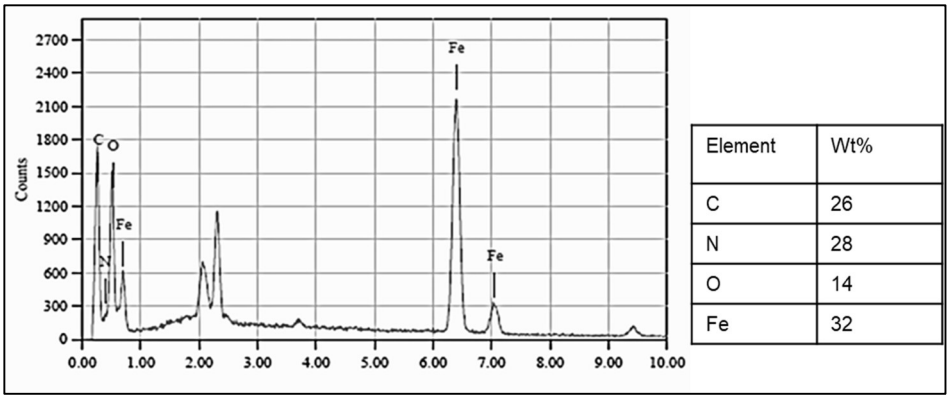


Figure 3. Morphological surface structure of (A) ESM (B) ESM-WPFA under 500× and MNP@ESM-WPFA under magnification of (C) 1000× (D) 2000×

The elemental composition of MNP@ESM-WPFA was examined using energy-dispersive X-ray spectroscopy (EDX) analysis. Figure 4 shows that MNP@ESM-WPFA have an iron (Fe) content of 32%, carbon (C) content of 26%, nitrogen (N) content of 28%, and oxygen (O) content of 14%.

Element	Wt%
C	26
N	28
O	14
Fe	32

Figure 4. EDX spectrum of MNP@ESM-WPFA

The buoyancy of the synthesized nanosorbent was checked by placing it on a surface of water for 24 hours. Remarkably, the MNP@ESM-WPFA was found to float on water (Figure S1 (A) and (B)) , suggesting the fabricated adsorbents possess high buoyancy. In addition, The contact angle (CA) of MNP@ESM-WPFA was measured to be 123.6º (Figure S1 (C)) showing this adsorbent exhibits higly hydrophobic, which may be exploited for the adsorption of oil pollutants on the surface of water.

The optimization of the parameter for efficient oil removal:

Effect of treatment time

The effect of treatment time on oil adsorption using MNP@ESM-WPFA was studied within the range of 10 to 60 minutes. Figure 5(A) shows that the K value increase significantly until 50 minutes, after which it reaches a plateau (at time >50 min). As the treatment time increases, so does the mixing cycle; as the oil droplets have more time to break up and shrink in diameter (emulsification), resulting in a larger interfacial area for adsorption on the MNP@ESM-WPFA [30]. The curve shows that the maximum adsorption capacity was reached at 50 minutes of treatment. The highest K value obtained at 50 minutes of treatment is due to greater existence of interfacial surface of MNP@ESM-WPFA for adsorption, while the K value plateau after 50 minutes is due to the saturation of the surface of MNP@ESM-WPFA. Thus, 50 minutes was chosen as optimum treatment time for subsequent studies.

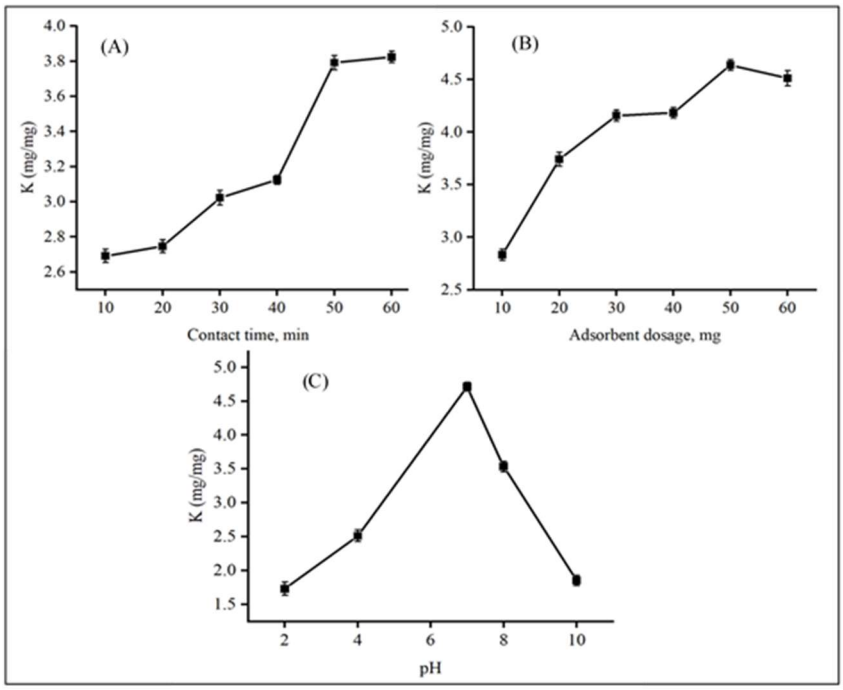

Figure 5. The effect of (A) contact time (B) adsorbent dosage (C) pH on oil adsorption capacity. The error bar represents the relative standard deviations of 3 measurements

Effect of adsorbent dosage

A batch experiment was carried out to determine the effect of adsorbent dosage (10 to 60 mg) on adsorption capacity. Figure 5(B) shows the relationship between adsorption capacity and the MNP@ESM-WPFA adsorbent dosage. Initially, the adsorption capacity increases together with increase of adsorbent dosage from 10 to 50 mg. The maximum adsorption capacity was reached when the dosage was 50 mg. After 50 mg, the adsorption capacity value decreased slightly, likely due to self-aggregation of the adsorbent which reduces the available sites for oil adsorption [31]. The optimum dosage for oil uptake using MNP@ESM-WPFA was thus set at 50 mg.

Effect of pH

The effect of the treatment pH on the oil adsorption process is presented in Figure 5(C). The adsorption process of oil on MNP@ESM-WPFA was found to be highly pH-dependent. The adsorption capacity rapidly increased from 1.73 to 4.71 mg/mg when the solution pH was increased from 2 to 7. However, at pH above7 (pH 8-10), the adsorption capacity slowly decreased until it reaches 1.86 mg/mg at pH 10. This phenomenon can be explained by the changes in the number of free protons in the solution and the stability of the oil emulsion [6]. In acidic conditions, the residual amine, carboxyl, and hydroxyl groups on the surface of MNP@ESM-WPFA becomes protonated, increasing the surface's cationic property and thus improving the adsorbent's hydrophilicity [29]. Additionally, in acidic conditions, as the acidity increased (from pH 7 to pH 2), the oil emulsion began to destabilize, causing clusters to form and larger oil droplets to form [30]. As a result, the interfacial area available for adsorption on MNP@ESM-WPFA decreases. On the other hand, the deprotonation of residual amine, carboxyl, and hydroxyl from ESM-WPFA in alkaline solution causes the adsorbent surface to become more anionic, reducing the oleophilic property of MNP@ESM-WPFA [29] and thus its oil adsorption capability. Thus pH 7 was selected as the optimum pH for oil uptake using MNP@ESM-WPFA.

The adsorption capacity of various oils

The adsorption capacities (K) of MNP@ESM-WPFA for lubricating oil, olive oil and corn oil were also

determined, and the results are shown in Table 1. MNP@ESM-WPFA was found to have the highest K value for lubricating oil, at 4.6 mg/mg, followed by olive oil (2.7 mg/mg) and corn oil (2.0 mg/mg). The difference in oil adsorption capacity is attributed to the difference in the viscosity of the oils [32]. The adsorption capacity increases with oil viscosity due to improved oil adhesion onto the adsorbent surface [33-35].

Table 1. Adsorption capacities and viscosity values for studied oils. (Amount of MNP@ESM-WPFA = 50 mg, contact time = 50 min, and pH = 7)

Type of Oils	K, (mg/mg)	Viscosity, (mm^2/s)	Density, (kg/m^3)	Surface Tension, (mN/m)
Lubricating Oil	4.6	157.7	767.0	30.3
Corn oil	2.0	34.9	918.5	31.6
Olive oil	2.7	43.2	916.0	31.9

Reusability of MNP@ESM-WPFA

For practical application purposes, reusability is a crucial feature of any adsorbent. Here, the reusability study was carried out by repeating the lubricating oil adsorption experiment five times using the same adsorbent. Between each repeated runs, the adsorbent was cleaned with *n*-hexane and dried in an oven at 70 °C for one hour. Each experiment run used 50 mg MNP@ESM-WPFA, pH 7, and 50 min treatment time. The performance for five successive cycles is shown in Figure 6. Evidently, the regenerated MNP@ESM-WPFA can be recycled many times as it can adsorb oil 4.18 times its own weight even after five cycles. Therefore, the synthesized adsorbent MNP@ESM-WPFA can be considered recyclable and stable. The high hydrophobic/oleophilic property also contributes to the excellent recyclability of the adsorbent. This is because when hydrophobicity and oleophilicity are introduced to a sorbent, it tends to concentrate and interact with the oil phase medium, hence, transforming it to a semisolid phase via Van der waals forces [36]. This makes it easier for desorption. This characteristic suggests that as-prepared MNP@ESM-WPFA shows a great potential application in multifunctional wastewater purification.

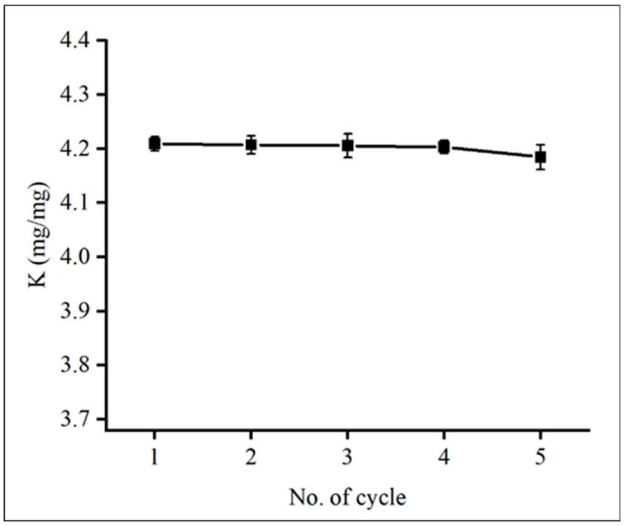

Figure 6. Oil-adsorption capacity of MNP@ESM-WPFA at different cycles. The error bar length accounts for the relative standard deviations for 3 measurements

Analysis of Oil-Loaded MNP@ESM-WPFA

The surface of lubricating oil loaded MNP@ESM-WPFA was evaluated using FTIR, SEM and EDX analyses. Figure 7 depicts the FTIR analysis of MNP@ESM-WPFA with and without oil loading (A-B). When comparing the original MNP@ESM-WPFA (Figure 7(A)) spectrum to the oil loaded MNP@ESM-WPFA spectrum (Figure 7(B)), it is observed that the intensity of -CH_2- group bands at 2853 cm^{-1} and 2923 cm^{-1} are substantially higher for oil loaded MNP@ESM-WPFA. This result proves that a significant amount of oil adsorption occurred at the hydrophobic tails of waste palm fatty acid on the surface of MNP@ESM-WPFA.

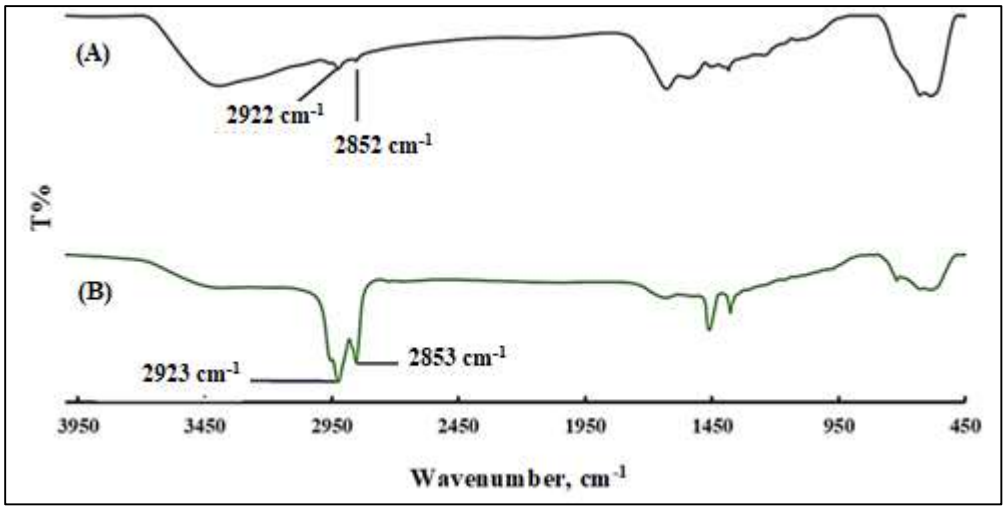

Figure 7. FTIR spectra of (A) MNP@ESM-WPFA and (B) lubricating oil loaded MNP@ESM-WPFA

Figure 8 shows the SEM images of MNP@ESM-WPFA before and after the lubricating oil adsorption process. The SEM images of oil-loaded MNP@ESM-WPFA (Figure 8(C-D)) show substantial differences from the unloaded MNP@ESM-WPFA (Figure 8(A-B)). The oil loaded MNP@ESM-WPFA surface was covered with a layer of oily mud-like material, which is the adsorbed oil molecules.

Elemental analysis reveals that the mass content of C (33%) in the oil-loaded MNP@ESM-PFA (Figure 9(B)) is notably higher than the percentage of C discovered in the unloaded MNP@ESM-WPFA (26%) (Figure 9(A)). These results align with that obtained from the FTIR analysis for oil loaded MNP@ESM-WPFA (Figure 7(B)) indicating that a higher carbon content causes a stronger band intensity for the alkane group in oil-loaded MNP@ESM-WPFA.

Comparison of MNP@ESM-WPFA with other adsorbents

Table 2 summarizes and compares this work with previous works reported in literature. MNP@ESM-WPFA shows the highest adsorption capacity among the published works reported in the table, suggesting the potential of MNP@ESM-WPFA usage in water remediation. Furthermore, the proposed approach offers numerous other benefits, such as simplicity, ease of removal, and operation.

Table 2. Comparison to oil adsorbents from the literature

Adsorbent	Emulsified Oil Studied	Sorption Capacity (mg/mg)	References
MNP-FA	Lubricating oil	3.50	[29]
ACF-PO	Lubricating oil	3.03	[37]

Conclusion

This present study shows that the synthesized MNP@ESM-WPFA can be potentially used for the removal of oil from an oil-water system. SEM, FTIR, and EDX analyses confirmed the successful synthesis of MNP@ESM-WPFA. The oil adsorption performance of MNP@ESM-WPFA was optimum at pH 7, 50 minutes treatment time, and 50 mg adsorbent dosage. MNP@ESM-WPFA is versatile as it can adsorb several types of oil, which are, for this study, lubricating oil, corn oil and olive oil. The MNP@ESM-WPFA has an adsorption capacity of 4.6 mg/mg for lubricating oil, 2.0 mg/mg for corn oil, and 2.7 mg/mg for olive oil. The MNP@ESM-WPFA can also be reused up to 5 times without losing efficiency. FTIR, SEM, and EDX analyses proved that the oil was adsorbed by MNP@ESM-WPFA, as evidenced by the intense peaks attributed to the oil in the FTIR spectrum, the mud-like covering seen in the SEM images, and the increase in C content during the EDX analysis. It is suggested that the oil droplets adsorbed on MNP@ESM-WPFA interacts with the hydrophobic tails of waste palm fatty acid via hydrophobic interaction. This study opens new possibilities for developing high-efficiency, recyclable demulsifiers for emulsified oil wastewater.

Abstract

This study aimed to determine the active substance levels in L-Carnitine and Coenzyme Q_{10} in dietary supplements using the High-Performance Liquid Chromatography (HPLC)-UV method. They are often found in dietary supplements because these ingredients can be used to maintain heart health. L-Carnitine is an active ingredient belonging to amino acids, while Coenzyme Q_{10} is one of the most significant lipid antioxidants, which prevents the formation of free radicals and modification of proteins, lipids, and DNA. The method used in this study is HPLC-UV because the method has good sensitivity, can use the column and solvent developer many times, the detector varies, the analysis time is generally short, easy to operate, and has relatively high accuracy and precision. The HPLC procedure for determining L-Carnitine used a UV detector with a wavelength of 225 nm using an L1 (4.6 mm x 15 cm; 5 m) column with a flow rate of 0.7 mL/min. Meanwhile, the determination of Coenzyme Q10 using the HPLC procedure used a UV detector with a wavelength of 280 nm using a C_{18} (4.6 mm x 15 cm, 5µm) column with a flow rate of 1.5 mL/minute. This study also reports differences in L-Carnitine and Coenzyme Q10 in dietary supplements (in capsule form) during the mixing and encapsulation processes. The results show the suitability test for the HPLC-UV system in good condition; seen from the %RSD value below 2%. In testing the active substance Coenzyme Q_{10} in the mixing process is 101.07% and encapsulation is 96.77%. While the active substance L-Carnitine in the mixing process is 105.05% and encapsulation is 93.03%. The overall test results fall into the range of requirements, meaning that the product quality is in a good category.

Keywords: l-carnitine, coenzyme Q_{10}, high-performance liquid chromatography, mixing, encapsulation

Abstrak

Penelitian ini untuk mengetahui kadar zat aktif L-Carnitine dan Ko-enzim Q_{10} pada suplemen makanan menggunakan kaedah kromatografi cecair prestasi tinggi (HPLC)-UV. Zat aktif ini sering ditemukan dalam suplemen makanan kerana bahan-bahan ini dapat digunakan untuk menjaga kesihatan jantung. L-Carnitine merupakan bahan aktif yang tergolong ke dalam asid amino, sedangkan Ko-enzim Q_{10} adalah salah satu antioksidan lipid yang paling signifikan, yang mencegah pembentukan radikal bebas dan modifikasi protein, lipid, dan DNA. Kaedah yang digunakan dalam penelitian ini adalah HPLC-UV karena memiliki sensitiviti yang baik, dapat menggunakan turus dan pelarut berkali-kali, pengesan pelbagai, memiliki waktu analisis yang singkat, mudah dioperasikan, dan memiliki ketepatan dan kejituan yang relatif tinggi. Prosedur HPLC untuk penentuan L-Carnitine menggunakan pengesan UV dengan panjang gelombang 225 nm menggunakan turus L1 (4.6 mm x 15 cm; 5 m) dengan kadar aliran 0.7 mL/minit. Sedangkan penentuan Ko-enzim Q_{10} menggunakan prosedur HPLC menggunakan pengesan UV dengan panjang gelombang 280 nm menggunakan turus C_{18} (4.6 mm x 15 cm, 5µm) dengan kadar aliran 1.5 mL/minit. Dalam penelitian ini, kami juga melaporkan perbezaan kadar L-Carnitine dan Koenzim Q_{10} dalam suplemen makanan (dalam bentuk kapsul) selama proses pencampuran dan pengkapsulan. Hasil pengujian menunjukkan bahwa uji kesesuaian sistem HPLC-UV dalam keadaan baik dilihat dari nilai %RSD dibawah 2%. Pada pengujian zat aktif Ko-enzim Q_{10} pada proses pencampuran adalah 101.07% dan pengkapsulan adalah 96.77%. Sedangkan zat aktif L-Carnitine pada proses pencampuran adalah 105.05% dan pengkapsulan adalah 93.03%. Hasil pengujian secara keseluruhan menepati piawaian, memberi maksud produk berada pada kategori baik.

Kata kunci: L-carnitine, ko-enzim Q_{10}, kromatografi cecair prestasi tinggi, pencampuran, pengkapsulan

Introduction

This study aimed to determine the active substance levels in L-Carnitine and Coenzyme Q_{10} in dietary supplements using the High-Performance Liquid Chromatography method. L-Carnitine is a component that is needed by the human body. Where L-Carnitine is an amino acid derivative such as a vitamin, which is an important factor in fatty acid metabolism as an acyltransferase cofactor and in energy production processes, such as interconversion in the regulatory mechanisms of ketogenesis and thermogenesis, and is also used in the treatment of primary and secondary deficiencies, as well as in other diseases [1–3]. L-Carnitine is a zwitterion at pH 3.8. L-Carnitine has a molecular weight of 161.2 g/mol with a solubility of >2500 g/L at a temperature of 20 ºC with the chemical formula $C_7H_{15}NO_3$. The structural formula of L-Carnitine is presented in Figure 1 [4].

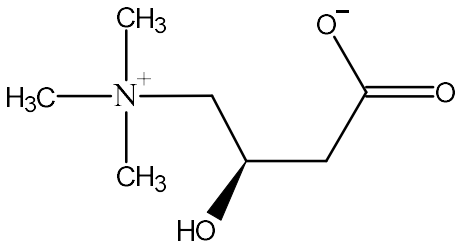

Figure 1. Chemical structure of L-Carnitine [4]

In particular, L-Carnitine among the various forms of Carnitine is also called vitamin B and Carnitine used for food generally means L-Carnitine. L-Carnitine plays a role in helping the breakdown of fat in the human body. Therefore, if it is insufficient, the energy produced in the decomposition of fatty acids is not generated, because the fatty acids do not decompose properly. For this reason, Carnitine is widely used as a drug or food additive to aid diet [5]. L-Carnitine deficiency leads to the accumulation of lipids in the cytosol and impaired energy production of long-chain fatty acids, especially during periods of fasting or stress. L-Carnitine can be found in various foods or medicines such as injections, syrups, tablets, and capsules, which can be used in treating primary and secondary Carnitine deficiency in other diseases such as dyslipoproteinemia and Alzheimer's [6]. Several oral formulations (tablets, capsules, solutions) are commercially available from a wide various of products [7].

The content of L-carnitine in various types of food has been published. Contents vary widely and the highest amounts of L-carnitine are found in meat and dairy products, and a wide variety of fruits and vegetables. In addition to biosynthetic ingredients, L-carnitine can also be found in dietary supplements. Various methods that are sensitive, reliable, relatively simple, inexpensive, and powerful for assessing L-carnitine content are needed to determine the amount of L-carnitine in

various materials [8–10]. Various methods to determine the L-carnitine content in food or other materials have been developed including using high-performance liquid chromatography (HPLC) or gas chromatography (GC), Mass Spectrometric (MS), capillary electrophoresis (CE), TLC-densitometry technique [11–14]. Because L-Carnitine is a polar compound, amphoteric and non-volatile, and does not have a chromophore group [3, 5]. Based on AOAC, the HPLC method can be used to determine L-Carnitine quantitatively [3].

Coenzyme Q_{10} is one of the most significant lipid antioxidants, which prevents forming free radicals and the modifying proteins, lipids, and DNA [15]. Coenzyme Q_{10} is a lipophilic compound consisting of a benzoquinone ring and ten isoprenoid side chain units. [16, 17]. Coenzyme Q_{10} also has poor stability to light and very poor solubility in water. This poor solubility stems from the isoprenoid chain, which is very long in its chemical structure and has a relatively high molecular weight (MW: 864 g/mol) (Figure 2) [18].

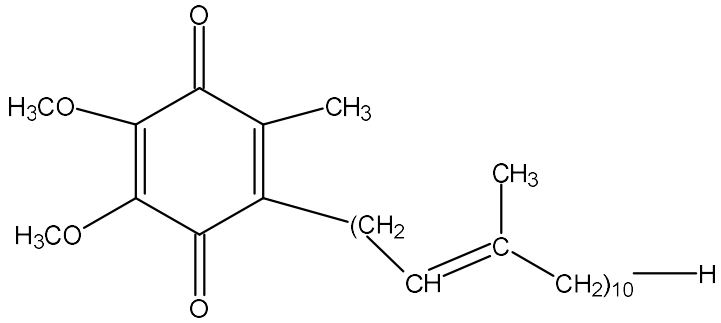

Figure 2. Chemical structure of Coenzyme Q10 [18]

The name Coenzyme Q_{10} comes from its chemical structure, a benzoquinone ring with a side chain of 10 isoprene units. These natural compounds are ubiquitous in nature; thus, it is also known as ubiquinone. There are three types of Coenzyme Q_{10} in the oxidized state the fully reduced form of ubiquinol (CoQ_{10} H_2), the semiquinone radical intermediate (CoQ_{10} H), and the fully oxidized form of ubiquinone (CoQ_{10}) [19–21]. Coenzyme Q_{10} (ubiquinone and its reduced form ubiquinol) can be found in most dairy products, vegetables, fruits, and cereals [22].

Methods of determining Coenzyme Q_{10} in various samples have been carried out such as FT-NIR spectroscopy [23], UPLC/MS-MS [24], ^{1}H NMR Spectroscopy [25], HPLC-ESI-MS/MS [26], HPLC-ECD [27], HPLC with coulometric detection [28], HPLC-UV[17]. Thus, this study discusses the determination of Coenzyme Q_{10} in dietary supplements using HPLC-UV. The HPLC-UV method is an excellent method in all validation parameters (sensitivity, bias, repeatability, intermediate precision, and accuracy profiles) for the determination of Coenzyme Q_{10}. In addition, it allows its widespread use in QC in the pharmaceutical industry [29].

This study reports the determination of L-Carnitine and Coenzyme Q10 in capsules of dietary supplement samples in two manufacturing processes: mixing and filling (encapsulation); the determination will see the levels of L-Carnitine and Coenzyme Q10 from each process. In addition, this test also looks at the precision of the method used which is expressed as Percent Relative Standard Deviation (%RSD).

Materials and Methods

Tools and materials

The tools used in this study include Analytical Balance (Sartorius type B 124 S), Analytical Balance (Shimadzu type ATY124), Disintegrator Tester (Flight type BJ-3), High-Performance Liquid Chromatography (Shimadzu), pH meter (Lovibond type 150), Karl Ficher (Mitsubishi), Spatula, Pro pipette (D&N), Syringe (one road), 0.20 m filter (Phenomenex), 0.4 m filter

(Meissner), Vacuum filter (Duran), Sonification (Elma type S 30 H), Stopwatch (Toto). In contrast the materials used in this research are Acetonitrile 99.9% (JT Backer), phosphoric acid 85%-87% (JT Backer), water for HPLC (JT Backer), Potassium Dihydrogen Phosphate 99% (KH_2PO_4) (JT Backer), 99.5% tetrahydrofuran (JT Backer), 95% N-Hexane (JT Backer), 99.9% Ethanol (JT Backer), L-Carnitine standard, and Coenzyme Q_{10} standard.

Procedure

The research includes two processes: mixing (mixing the capsule's contents) and encapsulation (combining the capsule's contents with the capsule shell, which then becomes a complete capsule. The test is carried out by determining the level of the active substance contained in the supplement, namely L-Carnitine which is a derivative of the active substance L-Carnitine, and also Coenzyme Q_{10} using the high-performance liquid chromatography (HPLC) method.

Instrumentation and optimization of HPLC

The HPLC instrument before being used for the analysis of L-Carnitine and Coenzyme Q_{10} must be optimized first with the specifications in Table 1.

Table 1. Instrumentation and Optimization of HPLC

Description	Condition of HPLC	
	L-Carnitine	**Coenzyme Q_{10}**
Detector	225 nm (UV)	280 nm (UV)
Column	L1 (4.6 mm x 15 cm; 5 µm)	C18 (4.6 mm x 15 cm, 5µm)
Flow rate	0.7 mL/minute	1.5 mL/minute
Injection volume	20 µL	20 L

Preparation of standard solutions of L-Carnitine and Coenzyme Q_{10}

Standard L-Carnitine weighed as much as 100 mg, put into a 50 mL volumetric flask, added solvent to fill 30 mL, sonicated for 5 minutes, then calibrated with solvent to the meniscus mark and homogenized. The standard solution was pipetted as much as 1 mL, put into a 10 mL volumetric flask, diluted with a solvent to the meniscus mark, and homogenized. The standard solution was filtered using a syringe equipped with a 0.20 L filter and inserted into the vial. Then the standard solution was measured using HPLC at a wavelength of 225 nm. The same method was also carried out to determine the Coenzyme standard solution by changing the type of standard used and measuring using an appropriate wavelength of 280 nm for the Coenzyme standard solution.

Determination of the active substance of L-Carnitine by HPLC-UV:

Mobile phase preparation

The mobile phase was made with a mixture of 0.05 M KH_2PO_4 and acetonitrile (4:6), and the pH of the solution was adjusted using phosphoric acid to pH 4.2. The mixture was filtered using a vacuum equipped with a 0.4 L filter and then sonicated for 15 minutes.

L-carnitine analysis using HPLC

The sample was weighed (capsule contents) equivalent to 20 mg of standard, put into a 100 mL volumetric flask, added solvent to fill 50 mL, sonicated for 15 minutes, then calibrated using a solvent to the meniscus mark and homogenized. The sample solution was filtered using a syringe equipped with a 0.20 µL filter and inserted into the vial. Standard solutions were measured using HPLC at a wavelength of 225 nm. This test is repeated in triples.

Determination of the active substance of Coenzyme Q_{10} with HPLC:

Mobile phase preparation

The mobile phase was made with a mixture of acetonitrile: tetrahydrofuran: water (55:40:5). The mixture was filtered using a vacuum equipped with a 0.4 L filter, then sonicated for 10 minutes.

Coenzyme Q_{10} analysis using HPLC

The sample was weighed (capsule contents) equivalent to 100 mg, put into a 50 mL volumetric flask, added solvent to fill 30 mL, sonicated for 5 minutes, and then calibrated with solvent to the meniscus mark and homogenized. 5 mL of the solution was pipetted, put into a 25 mL volumetric flask, diluted with a solvent to the meniscus mark, and homogenized. The sample solution was filtered using a syringe equipped with a 0.20 L filter and inserted into the vial. Standard solutions of Coenzyme Q_{10} were measured using HPLC at a wavelength of 280 nm

Results and Discussion

HPLC system suitability Analysis on L-Carnitine and Coenzyme Q_{10} samples

The system suitability test was carried out using a single standard for six repeated injections, where the %RSD result obtained had to be less than 2%. This value is acceptable because it is below 2% and can be used for quality control of pharmaceutical preparations [6, 30, 31]. Table 2 shows the results of the suitability test for the Coenzyme Q_{10} active substance system.

Table 2. HPLC system suitability test on samples of L-Carnitine and Coenzyme Q_{10}

Description	L-Carnitine				Coenzyme Q_{10}			
	Retention time		Area		Retention time		Area	
	Mixing	Encapsulation	Mixing	Encapsulation	Mixing	Encapsulation	Mixing	Encapsulation
	(minute)		(uAU)		(minute)		(uAU)	
Average test results	1.933	1.995	4378568	4516281	7.827	7.827	3571486	3571486
SD	0.005	0.001	7630	1933	0.0238	0.024	16721	16721
RSD (%)	0.283	0.055	0.174	0.043	0.304	0.304	0.468	0.468

Table 2 shows that the HPLC system suitability test results for L-Carnitine and Coenzyme Q10 standards can be categorized as good. It can be seen from the value of %RSD below 2%. Therefore, this test is feasible for sample analysis in dietary supplements.

Determination of active substance levels in Coenzyme Q_{10} samples

Table 3 shows that the retention time of the sample in the mixing process is longer than the retention time in the encapsulation process. However, this does not affect the results in the separation process using HPLC. Moreover, Table 4 shows that the measurement results are still within the predetermined limits.

Table 3. The retention time of Coenzyme Q_{10}

Description	Retention Time (minute)	
	Mixing	Encapsulation
Sample 1	7.859	7.541
Sample 2	7.827	7.492
Sample 3	7.771	7.457
Average	7.819	7.497

Table 4. Results of the active substance Coenzyme Q_{10}

Process	Description	Area of Sample (uAU)	Area of Standard (uAU)	Standard Concentration %w/v	Content %w/v
Mixing	Sample 1	3635588	3571486	99.62	101.41
	Sample 2	3520627	3571486	99.62	98.20
	Sample 3	3714669	3571486	99.62	103.61
				Average	101.07
				%RSD	2.69
				CV Horwitz	1.9968

	Sample 3	3411998	3571486	99.62	95.17
				Average	96.77
				%RSD	2.39
				CV Horwitz	2.0099

% w/v is percent weight/volume

Determination of Coenzyme Q_{10} levels using the HPLC method with a UV detector at a wavelength of 280 nm. The use of a UV detector is because the Coenzyme Q_{10} compound has a chromophore group that can absorb wavelengths in the UV region. In addition, the use of the HPLC method uses an inverted phase where the stationary phase in the form of a C18 column is non-polar and the mobile phase used is polar.

Table 4 shows that the results of testing the Coenzyme Q_{10} level in the sample of dietary supplements fall into the required category; the value must be between 90%-115% [32]. Based on the repetition of the sample 3 times, it shows that the precision value seen based on the %RSD shows more than 2%, meaning that the value does not meet the requirements that have been set. Then, the %RSD value was compared with Horwitz's CV value. Because the %RSD value is good if the %RSD obtained is within the acceptable limit, i.e. %RSD is less than 2/3 CV Horwitz [33]. The determination results indicate that the %RSD value is above the CV Horwitz value. Although the %RSD value is greater than the CV Horwitz value, this does not affect the test. The levels obtained in the HPLC test are still within the required range.

Determination of active substance levels in L-Carnitine samples

The results of the retention time of the active ingredient L-Carnitine in Table 5 show that the sample in the mixing process is shorter (1.927 minutes) than the encapsulation process (1.990 minutes). It occurs in HPLC conditions, especially during the test's mobile and stationary phases. The stationary phase is used repeatedly which causes its performance to decrease over time so that it can affect the retention time of the tests performed.

Table 5. The retention time of L-Carnitine levels

Description	Retention Time (minute)	
	Mixing	Encapsulation
Sample 1	1.927	1.989
Sample 2	1.927	1.986
Sample 3	1.928	1.996
Average	1.927	1.990

Table 6. Results of levels of the active substance L-Carnitine

Process	Description	Area of Sample	Area of Standard	Standard Concentration	Content
		(uAU)	(uAU)	%w/v	%w/v
Mixing	Sample 1	4572792	4378568	100	104.44
	Sample 2	4611470	4378568	100	105.32
	Sample 3	4615174	4378568	100	105.40
				Average	105.05
				%RSD	0.51
				CV Horwitz	1.9852
Encapsulation	Sample 1	4175852	4516281	100	92.46
	Sample 2	4185019	4516281	100	92.67
	Sample 3	4243936	4516281	100	93.97
				Average	93.03
				%RSD	0.88
				CV Horwitz	2.0219

%w/v is percent weight/volume

Table 6 shows that the measurement results of L-Carnitine in the sample using the HPLC method in the mixing or encapsulation process have met the specified requirements; the results are in the range of 90%-115%, i.e. 105.05% w/v in the mixing process, and 93, 03 %w/v on the encapsulation process. The sample's precision is determined by repeatability, measuring three times repetition in each process, either in the mixing or encapsulation process. The measurement results obtained that the %RSD value was below the CV Horwitz value. That is, the results of sample precision in each process are in a good category.

Conclusions

The results of the active substance levels in the mixing process of Coenzyme Q_{10} were 103.61% and L-Carnitine was 105.05%, then in the encapsulation process, the results were Coenzyme Q_{10} of 96.77% and L-Carnitine of 93.03%. The internal specifications of the two active substances that have been determined are the same 90%-115%. Based on the comparison of the results obtained with the specifications, the two active substances contained in the supplement meet the range of requirements, meaning that the quality of the chemical test of the product is in a good category.

Abstract

In past years, the π-conjugated system has attracted much attention as a promising material for developing and manufacturing the next generation of organic electronics made of synthesised organic compounds. Chalcone, having the π-conjugated systems in their molecular structures and the unique α, β-unsaturated ketone structural, have gained much attraction due to their potential use in optoelectronics applications like organic light emitting diode (OLED). By altering the molecular structure, the physical and chemical properties of chalcone derivatives can be tailored to the application needed. In recent years, chemists have produced many types of π-conjugated molecules to acquire excellent luminescence characteristics from organic compounds, and such structures typically lead to intense colour and excellent photoluminescence. In this study, a disubstituted chalcone derivative featuring terephthalaldehyde (**N1A**) as a π-linker with anthracene as donating group substitution has been synthesised through the Claisen-Schmidt condensation reaction. The synthesised compound has been characterised using Fourier Transform Infrared spectroscopy (FTIR) and UV-Visible analysis. Density functional theory (DFT) computations are executed to evaluate the effect of anthracene as an electron donating substitution on NLO properties of disubstituted chalcone derivative. NLO responses of this disubstituted chalcone derivative disclose that the chalcone molecular framework exhibit an important characteristic for further application as OLED emitting material.

Keywords: chalcone, density functional theory, non-linear optical, spectroscopic

Abstrak

Pada tahun-tahun lepas, sistem π-konjugasi telah menarik banyak perhatian sebagai bahan yang berpotensi untuk dibangunkan dan dikeluarkan sebagai generasi seterusnya elektronik organik, yang dibuat daripada sintesis sebatian organik. Kalkon, yang mempunyai sistem terkonjugasi-π dalam struktur molekulnya serta struktur keton α, β-tak tepu yang unik, telah mendapat banyak tarikan kerana potensi penggunaannya dalam aplikasi optoelektronik seperti diod pemancar cahaya organik (OLED). Dengan mengubah struktur molekul, sifat fizikal dan kimia, terbitan kalkon boleh disesuaikan dengan aplikasi yang diperlukan. Dalam tahun-tahun kebelakangan ini, ahli kimia telah menghasilkan banyak jenis molekul terkonjugasi-π untuk memperoleh ciri kependarkilauan yang sangat baik daripada sebatian organik, dan struktur sedemikian biasanya membawa kepada warna yang terang dan foto pendarcahaya yang sangat baik. Dalam kajian ini, terbitan kalkon tergantian yang menampilkan terephthalaldehid (**N1A**) sebagai penghubung-π dengan antrasena sebagai penggantian kumpulan penderma, telah disintesis melalui tindak balas pemeluwapan Claisen-Schmidt. Sebatian yang disintesis telah dicirikan menggunakan spektroskopi Lembayung Inframerah (FTIR) dan analisa Ultra Lembayung sinar nampak. Pengiraan teori fungsi ketumpatan (DFT) dilaksanakan untuk menilai kesan antrasena sebagai penggantian pendermaan elektron ke atas sifat NLO bagi terbitan kalkon tersubstitusi. Dapatan NLO bagi terbitan dualgantian ini menunjukkan kerangka molekul kalkon mempunyai ciri penting untuk aplikasi seterusnya sebagai bahan pemancar OLED.

Introduction

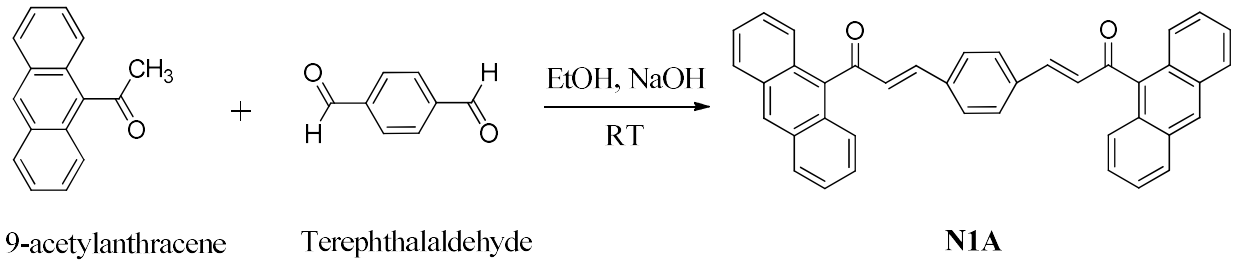
Light emitting diode (LED) represents a little solid-state semiconductor device that produces light when current flows through it [1]. The current produced is due to the movement of electrons through a semiconductor. An inorganic semiconductor is commonly used in LED. Haque et al. reported that using inorganic semiconductors in LED has several problems in terms of efficiency, heat management, colour rendering, lifetime, and probably the most significant one is the high cost [2]. In contrast, LED that uses an organic semiconductor is called organic light emitting diode (OLED), which was first revealed by Pope, Kallmann, and Magnante in 1963 [2]. Organic semiconductors are polymers or π-bonded molecules and can conduct electricity when charge carriers are injected into them [3]. Organic semiconductor devices now form the basis of an ongoing revolution in electronics in the twenty-first century. One of the materials used in organic electronics is organic materials that are made up of carbon-based materials. The widely used inorganic materials in semiconductors have caused some disadvantages as it needs high purity and accurate processing under extremely demanding conditions. The problems arising when using inorganic semiconductors have led to extensive semiconductor technology development. Hence, the organic semiconductors are wished for the potential solutions, especially on how the organic compound in these organic semiconductors will affect the OLED performance. Some benefits of using organic semiconductors are infinite variety and tuneable properties by changing the chemical structure, easy shaping, and manufacturing. These benefits came from the great properties of organic materials [4].

Organic materials such as chalcone having π-conjugated materials have become a major interest in OLED applications due to their low cost, tuning ability, structural diversity, favourable chemical modification, flexibility, and ease of fabrication. Chalcone derivatives occur naturally in plants and can also be synthesised using a synthetic approach to produce fluorescent materials. The characteristics of chalcone, particularly having benefits of chemical structure modification, have raised a question on how the modified structure can change the effect chalcone derivatives have on that particularly applied field. Organic materials having well-defined electrical properties are being deployed for optoelectronic devices such as OLED, and these devices are now replacing the use of liquid crystal displays (LCD) in consumer electronics such as cell phones, tablets, and televisions [5]. In past years, the π-conjugated system has attracted much attention as a promising material for developing and manufacturing the next generation of electronics, such as organic electronics. Organic semiconductors possess structural plasticity that allows the molecular design to incorporate functionality [6]. Aside from that, π-conjugated systems in molecular structures have received much attention due to their use in optoelectronics like OLEDs. The

conjugated organic molecules are used in organic electronics. Furthermore, by altering the molecular structure, the physical and chemical properties of organic molecules can be customised to the application's needs. For example, the colour of organic molecules' emission can be changed by increasing or lowering the π-electron conjugation [7]. Over the last 150 years, chemists have produced many types of π-conjugated molecules to acquire excellent luminescence characteristics from organic compounds, and such structures typically lead to intense colour and excellent photoluminescence [8]. In addition, Cho et al. stated that it has recently been discovered that even minor chemical changes can significantly impact luminescence characteristics [9].

It is worth noting that chalcones have a unique structure with an α, β - unsaturated carbonyl framework that helps with structural alterations [10]. By modifying the polarity of aprotic solvents, heteroaryl chalcones containing both electron donor and acceptor groups have been studied, which improves quantum yields and fluorescence intensity via intermolecular charge transfer (ICT) [11]. As a result, the researchers are working on chalcone structural alteration in developing new and unique materials with a wide range of uses. This structural modification also includes the electron donating-withdrawing substituents that will affect the luminescent properties of chalcone derivatives. According to Prabhu et al., it is clear that the electron-donating group significantly influences the optical properties of the chalcones [12]. Therefore, a comprehensive understanding of the relationship between conjugated π-linker and molecular design is a crucial concern for developing efficient luminescent materials in chalcone derivatives for high OLED performance.

In this study, a new disubstituted chalcone derivative; ((2E,2'E)-3,3'-(1,4-phenylene) bis(1-(anthracen-9-yl) prop-2-en-1-one) (**N1A**) has been successfully synthesised. This study aims to characterise and elucidate the disubstituted chalcone derivative using Fourier Transform Infrared spectroscopy (FTIR) and Ultraviolet-Visible (UV-vis) spectroscopy. The nonlinear optical (NLO) properties such as nonlinear refractive (μ), nonlinear absorption (β) and third-order nonlinear susceptibility (χ^3) of the disubstituted chalcone derivative are evaluated through the Z-scan method. Moreover, the density functional theory (DFT) method is computed using B3LYP/6-31G (d, p) basic set to obtain the optimised geometric molecular structure before analysing the NLO response.



Materials and Methods

Chemical and reagents

All starting chemicals, reagents, and solvents were purchased and used as received from Sigma-Aldrich and Merck which are 9-acetylphenanthrene, terephthalaldehyde, ethanol, sodium hydroxide, acetonitrile, and dichloromethane. All of the chemicals, reagents, and solvents were used as received without further purification.

Experimental details

Disubstituted chalcone is prepared using the Claisen-Schmidt condensation reaction method because it is affordable, simple to use, and not sensitive to oxygen or water, making it simple to operate at room temperature and readily applicable in laboratories [13]. 9-Acetylanthracene (7.5 mmol, 1.6 g) and terepthalaldehyde (3.7 mmol, 0.5 g) were each dissolved in ethanol (10 mL). Both mixtures are mixed before adding ethanol (50-60 mL) until the mixture is completely dissolved. While stirring, a catalytic amount of 20% NaOH was added to the solution dropwise. The reaction mixture was stirred for 5 hours at room temperature. Once adjudged completed, the reaction mixture was poured into cold iced water and left for precipitation. The resultant crude product was filtered. The obtained crude product of **N1A** was recrystallised from acetonitrile by a slow evaporation process to afford the corresponding disubstituted chalcone derivative (**N1A**). Scheme 1 illustrates the synthetic pathway to the synthesis of **N1A**.

9-acetylanthracene Terephthalaldehyde **N1A**

Scheme 1. Synthesis of disubstituted chalcone derivative (**N1A**)

Instrumentation and characterisation

The chemical structure of the **N1A** chalcone is confirmed by recording its FTIR spectra. KBr pellet is used on Perkin Elmer Spectrum Version 10.03.06 to obtain FTIR spectra in the wavenumber range at 4000-650 cm^{-1}, and the infrared values are listed in $\bar{\upsilon}$ units. The UV–Vis absorption spectrum was observed in acetonitrile (CH_3CN) solutions at room temperature respectively on Perkin Elmer Lambda 365 UV–Vis Spectrophotometer in the range of 200-700 nm at a concentration of 10^{-5} mol L^{-1} in 1 cm cuvette.

The third-order NLO properties of **N1A** chalcone are evaluated using the Z-scan technique. The transmittance of a nonlinear medium is measured with this method as a function of the sample position using a single polarised Gaussian laser beam in a tight focus geometry. This single beam, which is propagating in the Z direction, is narrowly concentrated. The sample is moved in the Z direction, and a finite aperture in the far field is used to measure the transmitted intensity as a function of the sample's Z position, measured with reference to the focal plane. Self-focusing or self-defocusing changes the wavefront phase when the sample passes through the beam focus (at Z = 0), changing the observed beam intensity [13]. A continuous wave from a diode-pumped solid-state laser operating at 532 nm is used to analyse the NLO response in the **N1A** chalcone. The sample was kept in a quartz cuvette with a path length of 1 mm, and the beam was sharply focussed with a 20 cm focusing lens. A laser beam profiler measured the beam waist at the focal point [14]. A powdered sample weighing 0.002 g was used for the analysis in 1 mL acetone. The experiments were conducted at room temperature. The sample used in this experiment is $4x10^{-3}$ M of acetone solution of **N1A**. The Z-scan technique measures nonlinear absorption (NLA) and nonlinear reflection (NLR). This technique was used to explore third-order susceptibility (χ^3), nonlinear refractive index (n_2), and nonlinear absorption coefficient (β).

The basic single-beam Z-scan setup is shown in Figure 1 [15]. The normalised transmittance was plotted by Levenberg–Marquardt algorithm to estimate the effective nonlinear absorption β_{eff} value. From the value of nonlinear absorption (β) and nonlinear refractive (n_2), the imaginary and real part of third-order nonlinear susceptibility, $\chi^{(3)}$, can be obtained from the following equation (Eq. 1 – Eq. 3):

$$Re\,\chi^{(3)}\,(\text{esu}) = [10^{-4}(\varepsilon_0 C^2 n_0^2 n_2]/\pi \quad \text{(Eq. 1)}$$

$$Im\,\chi^{(3)}\,(\text{esu}) = [10^{-2}(\varepsilon_0 C^2 \beta\lambda]/\pi \quad \text{(Eq. 2)}$$

$$\chi^{(3)} = [(Re\,\chi^{(3)})^2 + (Im\,\chi^{(3)})^2]^{1/2} \quad \text{(Eq. 3)}$$

where C is the velocity of the light in a vacuum, ε_0 is the permittivity of the free space, and n_0 is the linear refractive index of the sample solution.

The optimisation of the molecular geometries leading to energy minima was achieved using the DFT method with a basic set of B3LYP/6-31G (d, p) level of theory as implemented in the GAUSSIAN 09 program

package. The optimised structural parameters were used to calculate the vibrational wavenumbers [16]. The nonlinear optical properties such as static dipole moments (μ_{tot}), mean polarizability ($<\alpha_{tot}>$), anisotropic polarizability ($\Delta\alpha$) and first hyperpolarizability index (β-V), were computed via B3LYP/6-31G (d, p) level of theory under finite field scheme at $\omega = 0$, and the values obtained were calculated using the following equations (Eq. 4 – Eq. 7):.

$$\mu_{tot} = \left(\mu_x^2 + \mu_y^2 + \mu_z^2\right)^{1/2} \quad \text{(Eq. 4)}$$

$$< \alpha_{tot} > = \frac{1}{3}\left(\alpha_{xx} + \alpha_{yy} + \alpha_{zz}\right) \quad \text{(Eq. 5)}$$

$$\Delta\alpha = \frac{1}{\sqrt{2}}\left[\left(\alpha_{xx} - \alpha_{yy}\right)^2 + \left(\alpha_{yy} - \alpha_{zz}\right)^2 + \left(\alpha_{zz} - \alpha_{xx}\right)^2 + 6\left(\alpha_{xy}^2 + \alpha_{xz}^2 + \alpha_{yz}^2\right)\right] \quad \text{(Eq. 6)}$$

$$\beta - V = \left(\beta_x^2 + \beta_y^2 + \beta_z^2\right)^{1/2} \quad \text{(Eq. 7)}$$

Result and Discussion

Vibrational analysis

The FTIR spectrum of **N1A** is shown in Figure 2. The stretching frequency of α, β-unsaturated carbonyl compounds usually lie in the range of 1660-1685 cm^{-1}. The stretching frequency of **N1A** gives away characteristics -C=O stretching at 1645 cm^{-1} and -C=C- stretching at 1586 cm^{-1}. The carbonyl group mostly depends on the bond strength, which depends on steric effects, inductive effects, conjugative effects, and oxygen lone pair electrons. This might be the reason for the difference in wavelength in the **N1A** chalcone. However, the wavelength still agrees with the literature value of 1600 cm^{-1}. The C=C stretching vibration is probably around 1667-1640 cm^{-1}. However, C=C is expected around 1600 cm^{-1} when conjugated with C=O. Additional -C=C- stretching and the aromatic C-H in-plane and out-of-plane bending bands of aromatics C-H at 1108 cm^{-1} and 734 cm^{-1}, respectively [17], had established due to the frequent occurrence of aromatic rings in all compounds, especially in **N1A** chalcones. The typical ranges for the C-H in-plane and out-of-plane bending vibrations are 1300-1000 cm^{-1} and 1000-700 cm^{-1}, respectively. The type of substituents has no impact on the bands in this region. Due to the inductive effect that increases the substituent's chain length, all C-H stretching is weak [18]. The vibrational modes for the **N1A** chalcone are presented in Table 1.

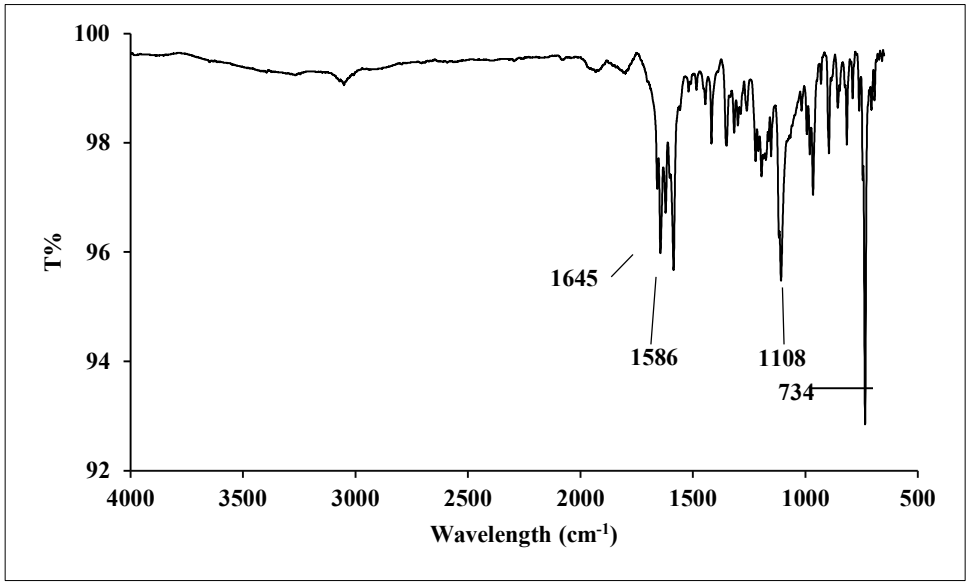

Figure 2. The FTIR spectrum of **N1A**

Table 1. Vibrational Mode for **N1A** chalcone.

Vibrational Mode	N1A
	Wavelength (cm^{-1})
C=O stretch	1645
C=C-C aromatic ring stretch	1586
C-H in-plane band	1108
C-H out-of-plane band	734

Electronic transition analysis

The UV-vis absorption spectrum of **N1A** is shown in Figure 3. It is clear that **N1A** chalones are transparent in the entire visible region and the absorption takes place in the UV region. The absence of absorption in the visible region is a key factor if any compound is to be exploited for NLO applications at room temperature [19]. Most organic compound absorption spectroscopy is based on transitions of n or π-electrons to the π* excited state. As a result, the transition absorption peaks occur within 200–700 nm suitable for experimental investigation. In order to supply the electrons for these transitions, the molecule must have an unsaturated group. α, β-unsaturated carbonyl compounds usually show two absorption bands of the n→π* and π→π* transitions [20]. The absorption and transmission spectra help us to identify the nature of the molecule by analysing the transition of electrons in σ and π orbitals between the ground state and higher excited states with the energy absorbed [21]. The UV-Vis absorption spectra of **N1A** exhibit one absorbance maximum, as shown in Figure 3, at 252 nm. The maximum absorption of **N1A** chalcone at 252 nm is due to the increased conjugation and greater resonance stabilisation. This peak might attribute to π→π* transition since the wavelength is below 300 nm, indicating the presence of a carbonyl group in the compound. The other absorbance bands observed are 341 nm, 367 nm and 384 nm. The absorbance bands observed have an absorption tail stretching to ± 454 nm. The peaks may be attributed to the mixture transition of n→π* and π→π* interband transition and are due to the excitation in the aromatic

rings for wavelengths more than 300 nm. N1A chalcone exhibits a higher maximum wavelength due to its greater amount of benzene rings. The absorption corresponds to the transition from the highest occupied molecular orbital (HOMO) in the ground state to the lowest unoccupied molecular orbital (LUMO) in the excited state [21]. As the molecule is conjugated, the HOMO-LUMO transition implies the transfer of electron charge density throughout the aromatic rings [22].

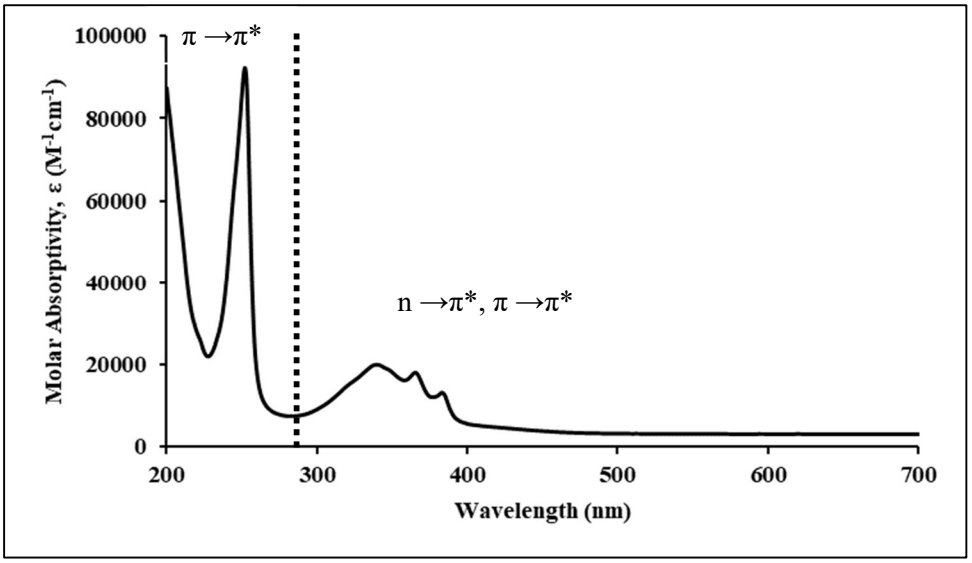

Figure 3. UV-Vis spectrum and electronic transition of **N1A** chalcone

Table 2. electronic transition of **N1A** chalcones

Compound	λ (nm), ε (M^{-1} cm^{-1})	Electronic transition
N1A	252, 92134	π→π*
	341, 19810	n→π*, π→π*
	367, 17381	n→π*, π→π*
	384, 12889	n→π*, π→π*

Optical energy band gap (E_g) analysis

The strongest absorption and smaller energy gap, particularly in the visible region, are important features in the suitability for optoelectronic applications [23]. The purpose of evaluating the energy band gap (E_g) is to calculate the difference in orbital energy between the highest occupied molecular orbital (HOMO) (the top of the valence band) and its lowest unoccupied molecular orbital (LUMO) (the bottom of the conduction band). Since they have a greater capability for electron mobility in the π-conjugated system, compounds with shorter HOMO-LUMO energy gaps are highly preferred because they produce an enlarged energy distribution [24]. The optical band gap was calculated via Tauc's approach (Figure 4) by analysing the UV-vis spectra to determine the absorption coefficient (α) and photon energy ($h\nu$). This technique entails extrapolating the linear stretch of the tail of the lower energy band $(\alpha h\nu)^2$ up to the cut-off value with the abscissa axis, which corresponds to the photon (hν) energy. The absorption coefficient (α) is calculated from the absorbance data, and frequency (ν) is the reciprocal of wavelength, with h being Planck's constant [25]. The optical bandgap for the **N1A** chalcone is 3.16 eV. The optical bandgap plays

an essential role in the enhancement of the NLO properties of the compound. The narrowed bandgap is due to the intermolecular charge transfer (ICT) transition, leading to the high performance of NLO response [26]. Anthracene as donating group substituent, has a greater π-conjugation system, leading to lower optical bandgap energy in the **N1A** chalcone. The optical bandgap was evaluated using the following equation (Eq. 8 – Eq. 10):

$$(\alpha h\nu)^2 = A(h\nu - E_g) \quad \text{(Eq. 8)}$$

$$h\nu = \frac{1240}{\lambda} \quad \text{(Eq. 9)}$$

$$\alpha = 2.303\frac{A}{L} \quad \text{(Eq. 10)}$$

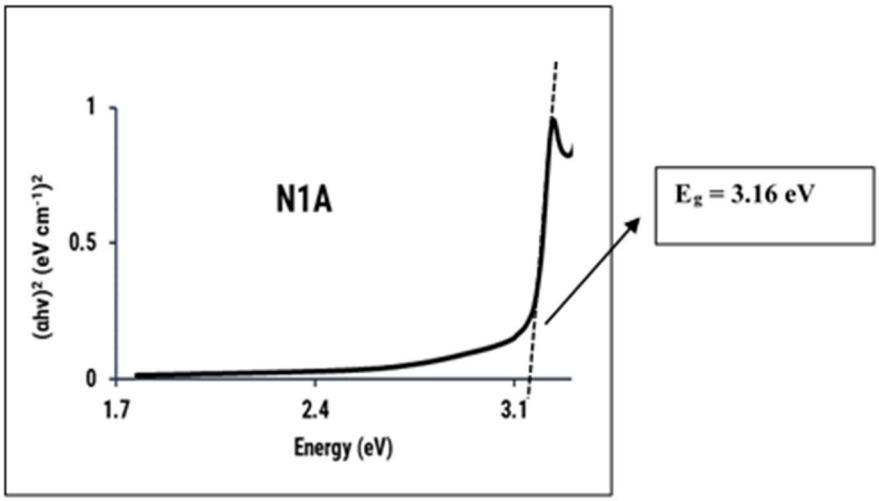

Figure 4. The Tauc's plot for optical energy band gap analysis of **N1A**

Non-linear optical characterisation

The NLO properties were investigated using the Z-scan technique. From Figure 3, the absorption is absent in the region between 500-700 nm which is a key requirement for materials having NLO properties. The linear absorption coefficient, α, of the compound for the 4 x 10^{-3} M was measured to be 0.4604/cm. Figure 5 shows the open (left) and closed aperture (right) transmittance spectra for the **N1A** chalcone. **N1A** chalcone shows a symmetric valley in the open aperture Z-scan spectrum about the focus, indicating positive non-linear absorption in the compound. Maximum absorption typically occurs when the sample is at the focal point of the lens since the on-axial peak irradiance I_0 of the beam is the maximum. The reduction in the transmittance measured with an open aperture is independent of non-linear refraction (NLR) and thus can be used to determine the value of the two-photon absorption (TPA) coefficient (β) by the depth of the valley. By fitting experimental normalised transmission data to the equation described in the literature [27], the value of nonlinear absorption (β) was found to be 2.5 x 10^{-4} cm W^{-1} for **N1A** chalcone. The strong reverse saturable absorption (RSA), which is responsible for the NLO material properties [28], is visible in the sample transmittance profile shown in Figure 5 (right), where the excited state absorption is greater than that for the ground state. This might be due to the effect of the delocalisation of π-electrons in the anthracene group and strong ICT in the compound.

Nonlinear refraction coefficient (n_2) is obtained from the transmittance measurements during close aperture by placing an aperture in front of the detector (closed aperture). The division method is applied to obtain pure nonlinear refraction. The Z-scan spectrum in close aperture is shown in Figure 5. The finding shows a negative nonlinear refraction property in the **N1A** chalcone (defocusing). However, the calculation shows a positive value of nonlinear refraction. The experimental data were fitted with the equation described in the literature, which yields nonlinear refraction, 1.2 x10^{-15} esu. From the value of the imaginary part (Im χ^3) and real part (Re χ^3), the third-order nonlinear susceptibility, $|\chi^3|$, was evaluated to be 2.8 x 10^{-6} esu, which indicates that the material possesses good NLO properties. However, the value is lower due to the donor-pi-donor system compared to the previously reported chalcone derivatives of the D-p-A system [15, 16]. The calculated NLO parameters extracted from Z-Scan curves are shown in Table 3.

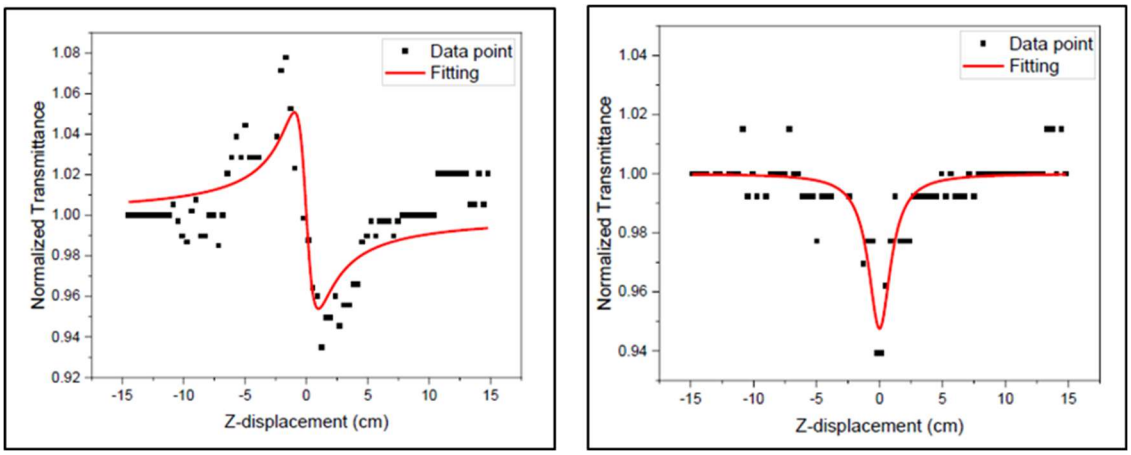

Figure 5. Close (left) and open (right) aperture of Z-scan analysis

Table 3. The calculated NLO parameters extracted from Z-Scan curves

Parameter	Value
Nonlinear absorption [β]	2.5 x10^{-4} cm/W
Nonlinear refraction [n_2]	1.2 x10^{-15} cm^2/W
Imaginary part of third susceptibility [Im $\chi^{(3)}$]	2.8 x10^{-6} esu
Real part of third susceptibility [Re $\chi^{(3)}$]	8.5 x10^{-15} esu
Third-order nonlinear susceptibility [$\chi^{(3)}$]	2.8 x10^{-6} esu

Quantum chemical calculation using density functional theory (DFT)

The nonlinear optical response of a material is strongly correlated with its electric properties, such as its dipole moments, polarizability, and hyperpolarizabilities [29]. When an external field is applied, molecules experience an induced electric dipole moment. This dipole moment is then approximated as the origin to examine microscopic polarizabilities. Additionally, the dipole moment directly affects the hyperpolarizability [30]. In this study, the static dipole moment and polarizability, anisotropic polarizability and hyperpolarizability were computed for the **N1A** chalcone under B3LYP / 6-31G (d, p) method, and the values obtained are presented in Table 4. A higher dipole moment will induce greater polarisation in the field direction. The total dipole moment (μ), mean polarizability (<α>), anisotropy of polarizability (Δα) and hyperpolarizability (β) are found to be 4.49 D, 3.45 x 10^{-23} esu, 3.96 x 10^{-24} esu and 3.53 x 10^{-30} esu, respectively for **N1A** chalcone. The value of

the dipole moment of **N1A** chalcone is higher than the chalcone derivative with anthracene studied by [31] which is 3.18 D. NLO properties can be related to the HOMO-LUMO energy gap and the dipole moment of the molecules. When E_g decreases, NLO properties increase. Smaller E_g allows a higher charge transfer within the electron delocalisation system. Based on Table 4, **N1A** chalcone shows good NLO properties and has the potential in related NLO devices application. DFT study provides a valuable tool for the in-depth examination of new disubstituted chalcone derivative compounds and the electronic property prediction for possible applications.

Table 4. Calculated static dipole moment, polarizability, anisotropic polarizability and hyperpolarizability from DFT data

Compound	Electric dipole moment, μ (debye)	Polarizability, <α> (e.s.u) (x10^{-23})	Anisotropic polarizability, Δα (e.s.u) (x10^{-24})	Hyperpolarizability, β (e.s.u) (x10^{-30})
N1A	4.49	3.45	3.96	3.53

Conclusion

A new chalcone derivative ((2E,2'E)-3,3'-(1,4-phenylene) bis(1-(anthracen-9-yl) prop-2-en-1-one) (**N1A**) was successfully synthesised and characterised for its NLO properties. The functional groups of the C=O carbonyl group, C=C-C aromatic ring, and aromatic C-H of the FTIR spectrum confirmed the structure of chalcone in **N1A** chalcone. The UV-visible study shows that the material is transparent in the visible region with the energy band gap of 3.16 eV and the electron transition analysis revealed the n→π* and π→π* transition of the carbonyl group and the presence of aromatic rings. The NLO response has been explored using a single-beam Z-scan and DFT method. The value of nonlinear absorption (β) and nonlinear susceptibility (χ3) are 2.5 x10^{-4} cmW^{-1} and 2.8 x10^{-6} esu, respectively, while for dipole moment (μ), polarizability (α) and hyperpolarizability (β), the values are found to be 4.49 D, 3.45 x10^{-23} esu and 3.5 x10^{-30} esu, respectively. **N1A** chalcone represents a promising NLO material due to the good NLO response. This NLO characteristic and strong band gap stability of this material are very intriguing for potential use in nonlinear optical devices. In a nutshell, molecular arrangement, the role of donor substituent, and the narrow energy gap may all contribute to the NLO performances.

Abstract

Heavy metal contamination has a more significant impact than microbial and organic contaminations as the elements could remain in the aqueous and particulate phases for an extended period. Setiu River, Terengganu, is one of the crucial rivers utilised as sites for aquaculture by the local communities. Generally, the concentrations of lead (Pb), zinc (Zn), copper (Cu), and arsenic (As) were influenced by human activities around river systems. Consequently, the present study investigated the seasonal concentration variations of Pb, Zn, Cu, and As in the surficial sediment of the river. The sediment samples were collected between January and July 2017, corresponding to the wet and dry seasons, from 60 different sampling locations along the river. The samples were subjected to Teflon bomb closed digestion procedures with mixed acid before the concentrations of the metals were determined with inductively coupled plasma mass spectrometry (ICP-MS). Resultantly, the mean concentrations of Pb, Zn, Cu, and As were 19.9 ± 9.89, 68.4 ± 31.8, 1.30 ± 0.66, and 3.05 ± 0.53 µg/g dry weight (wt.), respectively, in the samples gathered in the wet season (January). Alternatively, the samples collected during the dry season (July) contained 16.7 ± 15.1, 68.9 ± 48.5, 14.7 ± 16.9, and 2.46 ± 2.78 µg/g dry wt. mean concentrations of Pb, Zn, Cu, and As, respectively. The sample sediment quality was assessed based on the geoaccumulation index (I_{geo}). Based on the I_{geo}, the area was considered uncontaminated to moderately contaminated as the average values acquired were within Classes 0 and 2. Nevertheless, the pollution load index (PLI) revealed elevated concentrations of the metals, thus indicating anthropogenic sources, particularly in the aquaculture area. Accordingly, the Setiu river was assumed to be slightly polluted as the PLI values were 1.25 ± 0.34 (wet season) and 1.00 ± 1.00 (dry season).

Abstrak

Pencemaran logam logam berat mempunyai kesan yang lebih signifikan berbanding dengan pencemaran mikrob atau organik

kerana unsur–unsur ini dapat dikitar dalam fasa berair dan partikulat untuk jangka masa yang panjang. Sungai Setiu di Terengganu adalah salah satu sungai yang penting sebagai tempat akuakultur bagi masyarakat setempat. Secara amnya, kepekatan plumbum (Pb), zink (Zn), kuprum (Cu), dan arsenic (As) dipengaruhi oleh aktiviti manusia di sekitar system sungai. Oleh itu, kajian ini dilakukan untuk menyelidik variasi bermusim dalam kepekatan logam Pb, Zn, Cu dan As dalam sedimen permukaan sungai. Sampel sedimen dikumpulkan dari 60 lokasi persampelan yang berlainan di sepanjang sungai, di antara Januari dan Julai 2017, selaras dengan musim hujan dan musim kering. Setelah kaedah penghadaman tertutup bom Teflon dengan asid campuran, kepekatan logam ditentukan menggunakan spektrometri jisim plasma gandingan aruhan (ICPMS). Dari keputusan yang diperoleh, kepekatan purata Pb, Zn, Cu dan As adalah 19.9±9.89 µg/g berat kering, 68.4±31.8 µg/g berat kering, 1.30±0.66 µg/g berat kering dan 3.05±0.53 µg/g berat kering. untuk musim hujan (Januari), manakala, 16.7±15.1 µg/g berat kering; 68.9±48.5 µg/g berat kering, 14.7±16.9 µg/g berat kering dan 2.46±2.78 µg/g berat kering untuk musim kering (Julai). Penilaian kualiti sedimen menggunakan indeks geoakumulasi (I_{geo}) menunjukkan bahawa kawasan tersebut masih boleh dianggap tidak tercemar hingga sederhana tercemar kerana nilai purata Igeo dikategorikan dalam Kelas 0 hingga 2. Sementara itu, indeks beban pencemaran (PLI) mendedahkan peningkatan kepekatan logam yang dikaji, menunjukkan sumber antropogenik, terutama di kawasan akuakultur. Sungai Setiu boleh dianggap sedikit tercemar kerana nilai PLI lebih dari 1; 1.25±0.34 (musim hujan); 1.00±1.00 (musim kering). Secara amnya, kepekatan Pb, Zn, Cu dan As telah menunjukkan bahawa logam tersebut dipengaruhi oleh aktiviti manusia di sekitar sistem sungai tersebut.

Kata kunci: logam berat, sungai tropikam pencemaran, indeks geoakumulasi, indeks beban pencemaran

Introduction

Environmental contaminants from human and natural activities are the most severe problems confronting communities today. Industrial and economic growth and the production of various compounds and chemicals pose serious environmental and human health risks [1–3]. Moreover, heavy metal contaminants from human activities accumulate in the environment, most notably in river sediments [4-6]. Nonetheless, river sediments are complex and heterogeneous media. The roles of river sediments as a sink or source of contaminants has yet to be understood entirely, while numerous biogeochemical processes determine the fate of trace metals [7, 8].

The Setiu River is located in the Setiu district in the northern region of Terengganu, on the eastern coast of Peninsular Malaysia. The river possesses a catchment area of 188 km^2 and is approximately 52 km long. The northeast monsoon or the wet season strongly influences the river between November and March, while the southwest monsoon or the dry season occurs from May to September. Consequently, the river is vital to the surrounding communities, and it supplies freshwater to the Setiu Wetland as it flows southeast towards the wetland [9, 10]. Furthermore, water for irrigation and freshwater aquaculture is obtained from the Setiu River [11]. Intake points are also constructed along the riverbanks to extract raw water, providing water for domestic use [11].

Metal contaminants might have a more significant impact compared to organic and microbial contaminations, as metals could cycle between the aqueous and particulate phases over an extended time [12, 13]. Consequently, the current study aimed to determine the concentrations of heavy metals in the surficial sediment of the Setiu River system. The data would be crucial in highlighting the potential threat of the metals to humans and ecosystems. Furthermore, the present investigation aspired to evaluate the seasonal changes in the distribution of selected heavy metals and the Setiu River sediment pollution status.

Materials and Methods

Sample collection and sample analysis

For each season, wet (January) and dry (July), 60 bottom sediment samples were collected by employing Ponar Grab along the Setiu River (see Figure 1). Foreign objects that were not sediment were discarded in the field. The acquired samples were kept in plastic bags, preserved at low temperatures, and transported to the laboratory. Subsequently, the sediment samples were transferred to Petri dishes and oven-dried at 60 °C for several days to complete dryness. The dry samples were then ground into a fine powder with pestle and mortar and stored in polyethylene vials before subjecting the samples to the digestion process.

The heavy metals present in the samples were analysed by employing the Teflon bomb closed digestion method [14–16]. A total of 0.0.5 g of sediment samples were transferred to Teflon beakers. Subsequently, 1.5 mL of HNO_3, HCl, and HF (3:3:1) was added to each beaker. Following that, the samples were digested in the oven for eight hours at 100 ℃. The digested samples were transferred into 10 mL test tubes, and deionised water was added until the volume was 10 mL. Finally, the lead (Pb), zinc (Zn), copper (Cu), and arsenic (As) contents were determined and identified with inductively coupled plasma mass spectrometry (ICP-MS) [14–16].

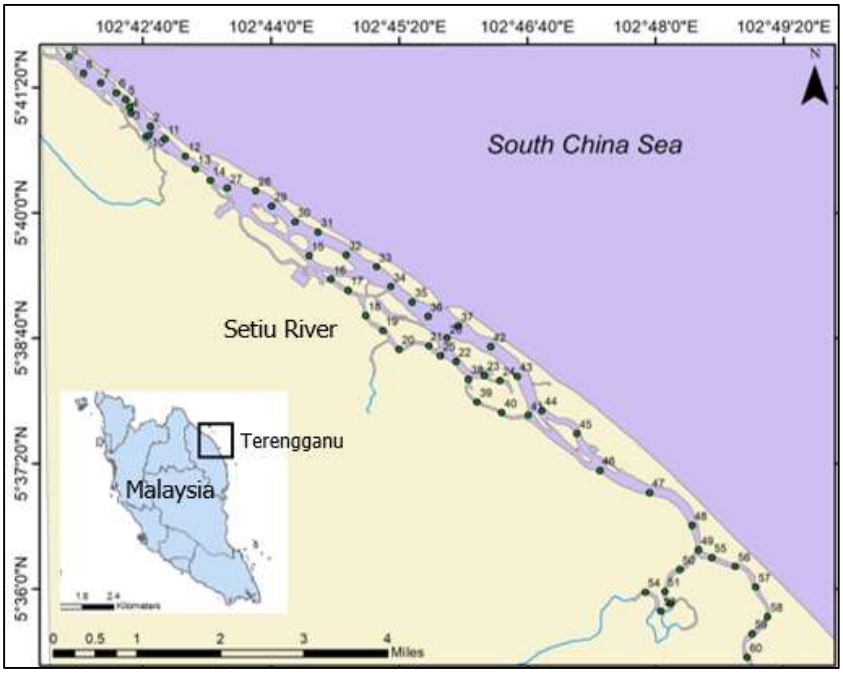

Figure 1. Sampling stations along Setiu River, Terengganu

Index of geoaccumulation (I_{gno})

The contamination of heavy metals in sediments was determined according to the geoaccumulation index (I_{geo}) [17, 18]. Moreover, the I_{geo} assessed the relationship between the geochemical background values of sediments and the measured metals concentrations in the sediment samples. Table 1 lists the sediment contamination categories suggested by Haris et al. [19] and Williams and Antoine [20]. The I_{geo} values of the samples collected in the present investigation were calculated with Equation (1).

Table 1. Sediment contamination categories according to I_{geo} value

Class	I_{geo} value	Sediment Quality
0	$I_{geo}<0$	Practically uncontaminated
1	$0<I_{geo}<1$	Uncontaminated to moderately contaminated
2	$1<I_{geo}<2$	Moderately contaminated
3	$2<I_{geo}<3$	Moderately to heavily contaminated
4	$3<I_{geo}<4$	Heavily contaminated
5	$4<I_{geo}<5$	Heavily to extremely contaminated
6	$I_{geo}>5$	Extremely contaminated

$$\text{Index of geoaccumulation (Igeo)} = \text{Log}_2 \frac{C_n}{1.5B_n} \quad \text{(Eq. 1)}$$

Where C_n is the concentration of the heavy metals in the sediment sample (n), B_n is the background value in the average shale of the metals (n), and 1.5 is the background matrix correction factor due to lithogenic effects.

Pollution Load Index

Pollution load index (PLI) value indicates the number of times the metal content in the sediment surpassed the mean background concentration, serving as an indicator of the overall level of heavy metal toxicity in a given sample. The PLI recommended by Tomlinson et al. [21] was employed to establish the mutual contamination status of the measured metals in the current study. The PLI is calculated as a contamination factor (CF) for each metal in relation to the background value in the sediment sample [22, 23]. The CF value expresses the pollution by a single heavy metal in a sample (Table 2) [24]. The CF was defined by Equation 2, while Equation 3 was utilised to express the PLI. Table 3 demonstrates the contamination status according to the calculated PLI values [21].

Table 2. Contamination factor categories based on CF value

CF Value	Contamination Factor
CF < 1	Low contamination factor
1 ≤ CF ≤ 3	Moderate contamination factor
3 ≤ CF < 6	Considerable contamination factor
CF ≥ 6	Very high contamination factor

$$\text{Contamination Factor (CF)} = \frac{C_{\text{sample}}}{C_{\text{background}}} \quad \text{(Eq. 2)}$$

Where C_{sample} is the metal concentration in the sediment sample and $C_{background}$ represents the background value of the metals.

$$\text{PLI} = (\text{CF1} \times \text{CF2} \times \text{CF3} \times \ldots\ldots \times \text{CF}_n)\ 1/n \quad \text{(Eq. 3)}$$

Where n is the number of metals examined.

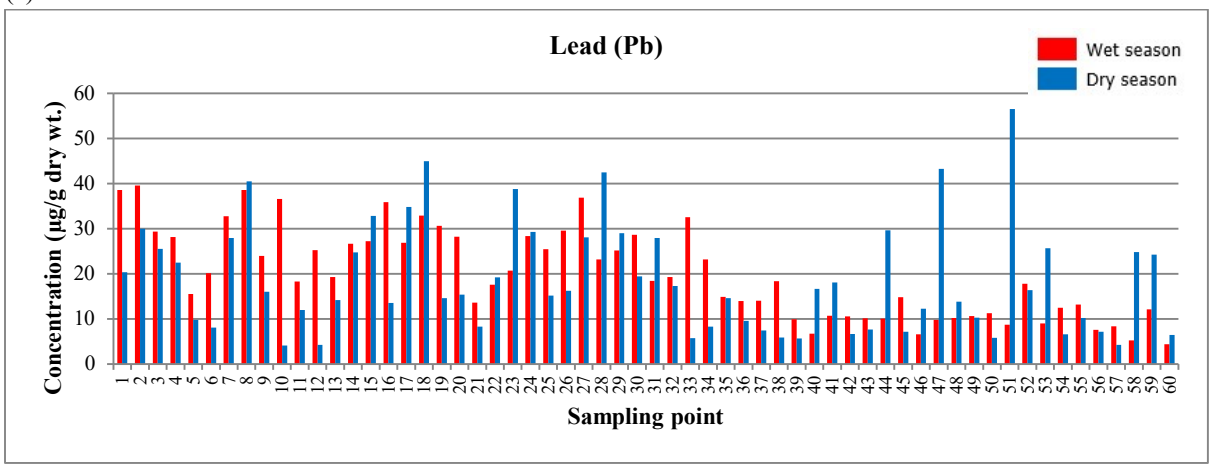

Table 3. Contamination status based on PLI value

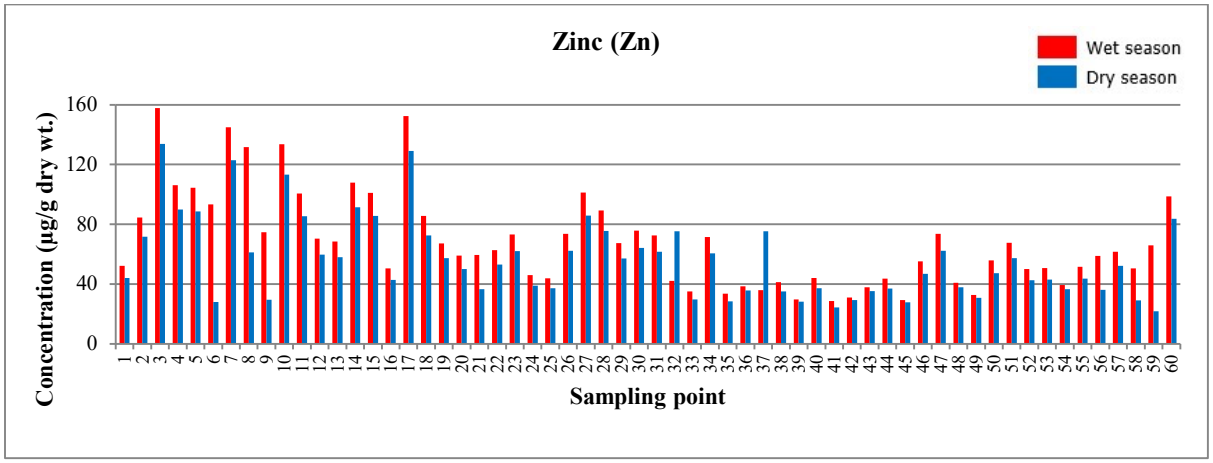
PLI Value	Contamination Status
PLI<1.0	No heavy metal contamination occurs
PLI>1.0	Heavy metal contamination occurs



Results and Discussion

The distribution of Pb, Zn, Cu, and As concentrations in the Setiu River during the wet and dry seasons in 2017 are displayed in Figure 2. The concentrations of the studied metals were higher than the estimated average concentrations of shales and crust materials on Earth [25]. Possible sources of contamination of the metals in the sampling area were likely anthropogenic activities, such as boating, aquaculture, agriculture, plantation, sand mining, and discharge of untreated waste into the river system.

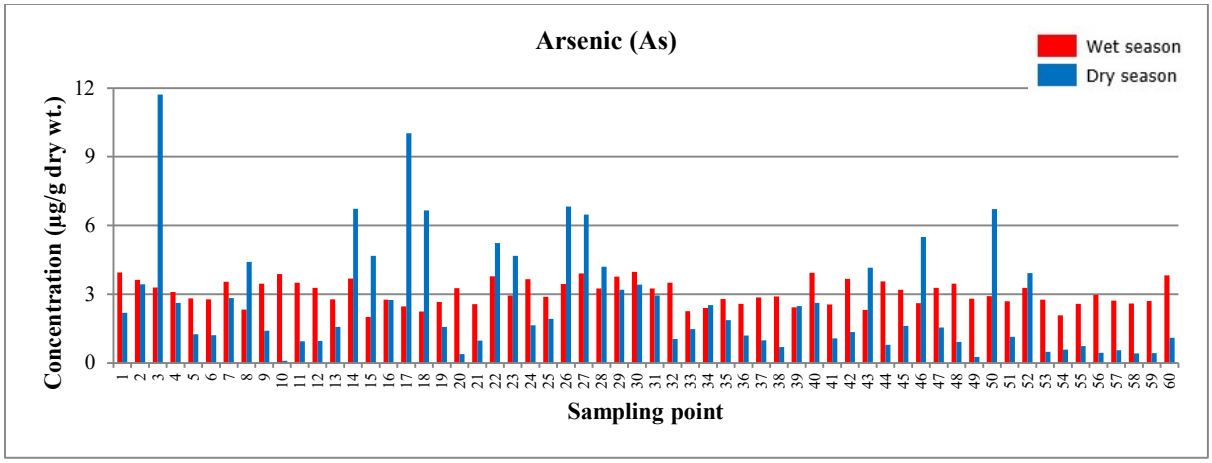

Figure 2. The distribution of (a) Pb, (b) Zn, (c) Cu, and (d) As concentration in the sediment samples from Setiu River during the wet and dry seasons

Lead has been known as poisonous since medieval times [26]. The sources of exposure to Pb vary from country to country, depending on historical and current uses [27]. Environmental Pb is from anthropogenic sources, such as lead-based paints, gasoline, and past and present mining and industrial activities [28]. Figure 2(a) displays the distribution of the concentration of Pb in the Setiu River sediment samples. The highest Pb concentration for the wet season was 39.5 µg/g dry wt., while the lowest was 4.38 µg/g dry wt. with an average of 19.9 ± 9.89 µg/g dry wt., which was considered to be slightly higher compared to the average background level of 17.0 µg/g dry wt.

The sediment with the lowest Pb concentration was obtained from station (St.) 60, while St. 2 contained the highest concentration of Pb. Nevertheless, during the dry season, the highest concentration of Pb concentration was 92.9 µg/g dry wt., recorded by the sample from St. 17, while the lowest concentration was in St. 60 at 1.58 µg/g dry wt. The average concentration for the dry season was 16.7 ± 15.1 µg/g dry wt., which was considered slightly lower than the average background level of 17.0 µg/g dry wt. [25].

Zinc is utilised in various consumer, agricultural, infrastructure, and industrial products [29]. Most importantly, Zn is vital to life as the substance is essential in the biological processes of living organisms, including humans. The chemical is crucial to cell division, protein synthesis, the immune system, and growth [30, 31]. A small part of Zn in soils, rocks, and sediments is constantly moved and transported throughout the environment via natural erosion processes [32].

Figure 2(b) displays the distribution of Zn concentration in the Setiu River sediment samples acquired during the wet and dry seasons of 2017. The highest concentration of Zn for the wet season was 158 µg/g dry wt., while the lowest concentration was 28.6 µg/g dry wt. The average concentration of Zn was 68.4±31.8 µg/g dry wt., which was higher than the average background level at 52.0 µg/g dry wt. The lowest concentration of Zn was from St. 41, while the sample from St. 3 exhibited the highest concentration of Zn. The highest concentration of Zn was 323 µg/g dry wt. from St. 17, while the lowest was from St. 40 at 12.4 µg/g dry wt. during the dry season. The average concentration for the dry season was 65.9 ± 48.5 µg/g dry wt., which was above the average background level of 52.0 µg/g dry wt. [25].

Copper is an essential micronutrient required for the growth of plants and animals [33, 34]. The substance is usually present in drinking water distributed in Cu pipes and additives designed to control algal growth [35]. The highest Cu concentration in the wet season was obtained from St. 35 at 39.9 µg/g dry wt., while the lowest

concentration value was recorded by the sample collected from St. 21 at 5.94 µg/g dry wt. The average value was 18.7 ± 9.48 µg/g dry wt., which was higher than the average background level of 14.3 µg/g dry wt. During the dry season, the highest concentration of Co was exhibited by the sample from St. 17 at 109 µg/g dry wt., while the lowest concentration was 1.05 µg/g dry wt. from St. 56. The average concentration value for the dry season was 14.7±16.9 µg/g dry wt., which was slightly higher than the average background level of 14.3 µg/g dry wt. [25].

Arsenic naturally occurs in the Earth's crust and is found in water, air, and land [36]. The inorganic form of the metal is highly toxic to organisms [37]. The chemical is employed in industrial activities, including as an alloying agent and in textile, glass, paper, wood preservatives, and metal adhesives processing [38]. The highest As concentration for the wet season was 3.98 µg/g dry wt., while the lowest concentration was 2.01 µg/g dry wt. The average value of 3.05 ± 0.53 µg/g dry wt. was considered higher than the background average of 2.0 µg/g dry wt. The lowest concentration of As was in St. 15, while the highest concentration of As was recorded by St. 30. During the dry season, the maximum As concentration was documented in St. 17 at 15.8 µg/g dry wt. and the minimum concentration was demonstrated by the sample from St. 52 with a value of 0.04 µg/g dry wt. The average concentration during the season was 2.45 ± 2.78 dry wt. and appeared to be above the average background concentration of 2.0 µg/g dry wt. [25].

Anthropogenic activities might significantly affect metal contaminations in the sediment of the Setiu River. Based on Figure 1, the concentration of metals is notably well distributed among most of the sampling points during the wet season. The observation might be due to the higher rainfall during the season [39] (November to March), with November being the wettest month of the year. Nevertheless, during the dry season, the concentration of metals was higher, mainly at St. 16 and 17 in July. The conditions might be due to heavy aquaculture and boating activities in the region. Theoretically, the dry season starts in May and ends in September, with June being the driest month [40].

The bottom sediments are the most prominent heavy metals reservoirs in aquatic systems. The metals accumulated in the sediments threaten the entire aquatic ecosystem [41]. Heavy metal contamination was widely distributed in the Setiu River system. Table 4 lists the I_{geo} values of the sediment samples for two seasons, the wet and dry seasons of 2017. Resultantly, all studied metals were classified in Classes 0 to 2, indicating that the sediments were uncontaminated to moderately to heavily contaminated.

Table 4. The I_{geo} value based on the average concentration obtained from the sediment of Setiu river for wet and dry seasons

Metal	Min – Max I_{geo} Value		Average I_{geo} Value		I_{geo} Class	
	Wet Season	Dry Season	Wet Season	Dry Season	Wet Season	Dry Season
Pb	(–2.54) – 0.63	(–4.01) – 1.87	–0.55	–1.11	0–1	0–2
Zn	(–1.44) – 1.02	(–2.66) – 2.05	–0.33	–0.52	0–2	0–3
Cu	(–1.85) – 0.90	(–4.35) – 2.35	–0.40	–1.24	0–1	0–3
As	(–0.58) – 0.41	(–6.36) – 2.40	0.004	–1.26	0–1	0–3

* Class 0 = $I_{geo}<0$ Practically uncontaminated; Class 1 = $0<I_{geo}<1$ Uncontaminated to moderately contaminated; Class 2 = $1<I_{geo}<2$ Moderately contaminated; Class 3 = $2<I_{geo}<3$ Moderately to heavily contaminated

The severity and variation of metal pollution at the 60 sampling points were assessed according to the PLI. Consequently, PLI was employed to determine the contamination status of the measured metals in the present investigation. Resultantly, the CF values for As, Pb, Cu, and Zn in the wet and dry seasons in the studied

areas exceeded 1, as summarised in Table 5. The findings indicated a moderate CF, although the value for Pb in the dry season was less than 1.

Table 5. The CF values of the metals in the sediment samples from Setiu River during the wet and dry seasons of 2017

Metal	Min – Max Value		CF Value		Contamination Factor	
	Wet Season	Dry Season	Wet Season	Dry Season	Wet Season	Dry Season
Pb	0.26–2.33	0.09–5.47	1.18	0.98	Moderate	Low
Zn	0.55–3.03	0.24–6.22	1.32	1.27	Moderate	Moderate
Cu	0.42–2.79	0.07–7.65	1.30	1.03	Moderate	Moderate
As	1.01–1.99	0.02–7.90	1.53	1.23	Moderate	Moderate

The PLI values obtained in the current study were more than 1, thus classifying Setiu River as slightly polluted due to heavy metals contamination (Table 6). Anthropogenic activities along the river contributed to the As, Pb, Cu, and Zn contamination. Fish loading and offloading, cleaning, maintenance practices such as painting, antifouling applications, fuelling activities, and urban runoff could also be the sources of metal pollution. Moreover, the usage of leaded gasoline by fishers led to increased Pb concentration in the region.

Table 6. The PLI values obtained based on the concentration of metals in the sediment samples from Setiu River in the wet and dry seasons of 2017

Min – Max Value		PLI Value		Metal Contamination Status	
Wet Season	Dry Season	Wet Season	Dry Season	Wet Season	Dry Season
0.76–2.00	0.17–6.73	1.25±0.34	1.00±1.0	Polluted	Polluted

Conclusion

Generally, the concentrations of metals in Setiu River sediments were significantly influenced by anthropogenic activities in the surrounding areas. The present investigation proved that heavy metals contamination occurred in the Setiu river system based on the I_{geo} and PLI values. Furthermore, the levels of heavy metals in the samples obtained during the dry season (July) were higher than in the wet season (January). The observations might be due to the dilution of metals in the aquatic system through precipitation. Consequently, comprehensive studies that include other pollutants, such as hydrocarbon, persistent organic pollutants, and microplastics should be conducted to ensure good water quality for aquaculture purposes.

Acknowledgement

This research was conducted with funding from the Ministry of Higher Education Malaysia, under the Niche Area Research Grant Scheme (NRGS) project number NRGS/2015/53131/32. The authors wish to acknowledge their gratitude to the anonymous reviewers who gave freely time and effort, constructive recommendations that enhanced the value of this manuscript. The authors also wish to express their appreciation to Oceanography Laboratory, Faculty of Science and Marine Environment staff for their invaluable assistance and providing the facilities to carry out the research. The authors also would like to thank Mr. Joseph Bidai for his assistant in detecting heavy

metals using ICPMS at the Institute of Oceanography and Environment.

Abstract

Natural radioisotopes' occurrence on the earth's surface and the crust might raise concerns for the environment in terms of their radiation risk. Their existence in the environment can be measured through the evaluation of soil from the targeted areas. This study aimed to assess the radionuclides content including thorium-232, uranium-238, and potassium-40 in surface soil samples from Temenggor Reserved Forest areas. The radiation assessment of the environment was done by calculating the Radium Equivalent (Ra_{eq}), Absorbed Dose Rate (AD), Outdoor Annual Effective Dose (AED), and External Hazard Index (H_{ex}). The surface soil samples were collected from twelve locations surrounding Temenggor Reserved Forest using a hand auger. The radionuclides content was measured using the Energy Dispersive X-Ray Fluorescence (EDXRF) Spectrometer and was converted to activity concentration for the risk assessment calculation. The activity concentration of ^{232}Th, ^{238}U and ^{40}K was found to be in the range of 28.92-179.92, 32.56-110.10 and 214.45-1083.38 Bq/kg, respectively. The values of Ra_{eq}, AD, AED and H_{ex} that were obtained were in the range of 103.90-312.17 Bq/kg, 49.99-149.65 (nGy/h), 0.06-0.18 mSv/y and 0.29-0.86, respectively. The results showed that the activity concentration and radiation risk were higher than the limit set by the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR 2000) at certain study locations. However, the AED and H_{ex} were very low compared to the UNSCEAR 2000 limit. The high content of radionuclides might be caused by the types of soils and rocks as well as the anthropogenic sources from past activity in the targeted area.

Keywords: energy dispersive X-ray fluorescence, Perak, radionuclides, risk assessment, surface soil

Abstrak

Kewujudan radionuklid semulajadi di permukaan bumi dan di dalam kerak bumi mungkin menimbulkan kebimbangan kepada alam sekitar dari segi risiko radiasi mereka. Kewujudan mereka di dalam alam sekitar boleh diukur melalui penilaian tanah dari kawasan yang di kenalpasti. Kajian ini menyasarkan untuk menilai kandungan radionuklid termasuk torium-232, uranium-238 dan potasium-40 didalam sampel tanah permukaan di kawasan Hutan Rizab Temenggor. Penilaian risiko radiasi di kawasan sekitar telah dijalankan menggunakan penggiraan *Radium Equivalent (Ra_{eq}), Absorbed Dose Rate (AD), Outdoor Annual Effective Dose (AED) and External Hazard Index (H_{ex})*. Sampel-sampel tanah permukaan telah dikumpulkan dari dua belas (12) lokasi disekitar kawasan Hutan Rizab Temenggor dengan menggunakan gerimit tangan. Kandungan radinuklid telah diukur dengan menggunakan Energy Dispersive X-Ray Fluorescence (EDXRF) Spektrometer dan ditukar kepada aktiviti kepekatan untuk penggiraan risiko radiasi mereka. Aktiviti kepekatan tiga radionuklid ^{232}Th, ^{238}U dan ^{40}K telah direkodkan masing-masing dalam julat 28.92-179.92, 32.56-110.10 dan 214.45-1083.38 Bq/kg. Keputusan aktiviti kepekatan dan risiko radiasi yang direkodkan adalah melebihi had yang telah ditetapkan oleh United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR 2000) di beberapa lokasi kajian. Walaubagaimanapun, keputusan AED dan H_{ex} adalah sangat rendah berbanding had yang ditetapkan oleh UNSCEAR 2000. Kandungan radionuklid yang tinggi mungkin disebabkan oleh jenis tanah dan batu serta sumber antropogenik daripada aktiviti terdahulu di kawasan kajian.

Kata Kunci: energy dispersive x-ray fluorescence; perak; radionuklid, penilaian risiko, tanah permukaan

Introduction

Primordial radionuclides are long-lived radionuclides that are present on earth since their formation [1,2]. These radionuclides exist in various geological formations in the environment including the earth's crust, rocks, soils, plants, water and air. Radionuclides in the ^{238}U and ^{232}Th decay series and non-series of ^{40}K are called primordial radionuclides. Every radionuclide emits radiation at a specific rate, which is calculated as its half-life. Half-life is the time for the half-radionuclides that are present to decay, thus forming another type of radioisotope. Therefore, the radionuclides emit some radiation during this process. Exposure to a high level of radiation can cause acute health effects such as skin burns and acute radiation syndrome as well as long-term effects such as cancer and cardiovascular disease. However, exposure to low-level radiation does not cause immediate health effects but can be a minor contributor to an overall cancer risk [3]. Thus, the activity concentrations of these radionuclides play an important role in environmental public health.

Soils play a vital role in transporting radionuclides into the environment, and act not only as the source but also as a medium to transport radionuclides into other environmental media such as air and water. Thus, from the perspective of radiation protection, the assessment of the level of radionuclides in the environment and the consequent radiation exposure to humans is mostly carried out in soil [1]. However, the distribution of these radionuclides in the soil is not uniform; it varies according to the soil type, mineral content, geological features and geological conditions [4-8]. The types of rock also elevate the concentrations of the radionuclides in the soil. Higher concentrations of radionuclide are mostly found in igneous rocks such as granite whereas the lower concentration is discovered in sedimentary rocks [1, 2]. Moreover, anthropogenic activities in an area can alter the distribution of radionuclides in such an environment.

Many countries around the world have begun to achieve the Sustainability Development Goals (SDGs) that has been launched by the United Nation (UN), whose agenda aims to protect the environment for future generations. Correspondingly, Malaysia is no exception in jointly making the agenda a success. To ensure the sustainability of the environment, early data should be documented to allow other research or appropriate steps to be taken to achieve SDGs. To date, the radionuclides data of Temenggor areas are still not comprehensively available. Thus, this study aims to evaluate the activity concentration of ^{238}U, ^{232}Th and ^{40}K in the surface soil of the surrounding Temenggor Reserved Forest area. Furthermore, Temenggor Reserved Forest is part of Belum-Temenggor Forest Complex (BTFC) [9] which is well known for its nature attractions. During the peak

season, BTFC will be busy with tourists for activities such as bird watching, water activities, fishing and others. Moreover, the Temenggor area has lithosolos and shallow red-yellow podzolic solids with s-types granitoid soil [10, 11]; granite, phosphate and igneous rocks contain a higher concentration of uranium and thorium. Thus, another objective of this study is to estimate their possible radiation risk to the environment in terms of Radium Equivalent (Ra_{eq}), Absorbed Dose Rate (AD), Outdoor Annual Effective Dose (AED), and External Hazard Index (H_{ex}). These predictions allowed the researches to observe and categorised the sampling locations according to their risk exposure to humans. The calculated risk was compared to the limit set by UNSCEAR 2000 as well as other research studies.

Materials and Methods

Study area

Temenggor Reserved Forest is situated in the North part of Peninsular Malaysia. Located in Gerik, Perak, Temenggor Reserved Forest is a part of the bigger Belum-Temenggor Forest Complex (BTFC) and is one of Malaysia's biggest premier ecotourism spots. The main attractions of this ecotourism area include bird watching, Rafflesia tracking and water activities. This reserved forest consists of several small islands such as Pulau Tali Kail, Pulau TNB, and Pulau MARA. Several Orang Asli localities are also located in the surrounding the Temenggor Reserved Forest.

Sampling

The surface soil samples were collected from twelve (12) points surrounding the Temenggor Reserved Forest. The locations were determined based on their accessibility and random judgmental method. The exact sampling sites were marked using the Global Positioning System (GPS) as tabulated in Table 1, and illustrated in a map as shown in Figure 1. About 1 kg of each sample was collected using a hand auger from a 15 cm depth, at the marked sampling site. The samples were collected from a 1 m^2 area of five (5) different holes and mixed in a labelled plastic bag to represent one (1) sample.

Sample preparation and analysis of radionuclides

The wet soil samples were dried in an oven at 60-70°C for about 24-72 hours until they were completely dried. Before drying, unnecessary materials were removed from the soil to avoid contamination. The dried soil was grounded into a powder form using an agate type planetary ball mill and sieved through 250 µm sieves. About 2 g of sample was then placed in a clean pellet mold using a Fluxana Vaneox Technology Pressing machine and pressed with 15 tons pressure. The pellet form samples were stored in a desiccator prior to analysis. The concentration of uranium (U), thorium (Th) and potassium (K) were measured using an Energy Dispersive X-Ray Fluorescence (EDXRF) Spectrometer (Model of EPSILON 3XL by PANalytical), and reported in the unit of mg/kg. The measured concentration was then converted into activity concentration with the unit of Bq/kg using the conversion factors in equations 1-3 [12, 13].

$$^{23}\ \mathrm{Th}\left(\frac{\mathrm{Bq}}{\mathrm{kg}}\right) = 0.246\ \mathrm{ppm\ Th} \qquad \text{(Eq. 1)}$$

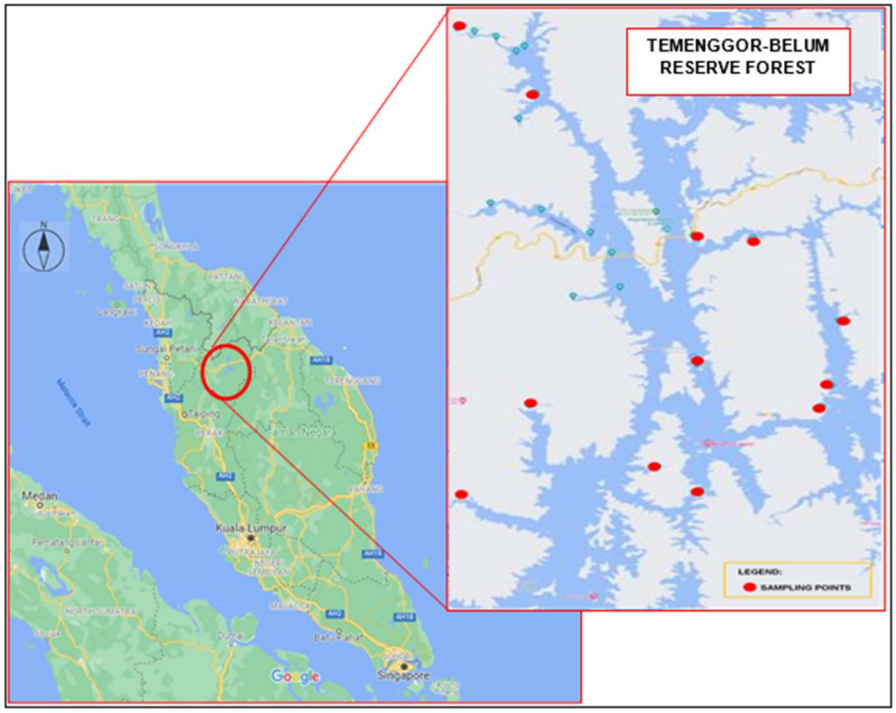

Figure 1. Maps showing the surface soil sampling sites

$$^{238}\mathrm{U}\left(\frac{\mathrm{Bq}}{\mathrm{kg}}\right) = 0.081 \text{ ppm U} \quad \text{(Eq. 2)}$$

$$^{40}\mathrm{K}\left(\frac{\mathrm{Bq}}{\mathrm{kg}}\right) = 32.2 \text{ ppm K} \quad \text{(Eq. 3)}$$

Method validation

The accuracy of the EDXRF was performed by analyzing the standard reference material (JLK-1, SRM 2709a and SO-7) for soil. The results obtained were compared with the established method of ICPMS. For this purpose, the samples were analyzed in the Agensi Nuklear Malaysia laboratory.

Radiology assessment

The content of ^{238}U, ^{232}Th and ^{40}K in soil are not uniformly distributed. The uniformity concerning radiation exposure can be expressed as Radium Equivalent Dose Rate (Ra_{eq}) measured in Bq/kg [14]. This calculation is for the comparison of the specific activity concentration level of constituents including radium, thorium and potassium as a constituent in varying amounts [10]. Before that, the activity concentration of ^{238}U was converted into ^{226}Ra activity concentration using Equation 4. Then, the Ra_{eq} was calculated using Equation 5. In addition, the Annual Effective Dose Rate (AED) is estimated to access the health effects of the absorbed dose. The AED used a conversion coefficient (0.7Sv/Gy) to transform the absorbed dose in the air into the absorbed dose received by humans with an outdoor occupancy factor (0.2) for adults (refer to Equation 7) [14, 15], whereby the absorbed dose rate (D) was calculated using Equation 6. On the other hand, multiple radionuclides contribute to the γ-dose, therefore the radiological hazards are presented as a single quantity that is known as the hazard index [10]. The hazard index is divided into two-internal and external hazard index. This study has only calculated the external hazard index to observe the radiological health risks of this locality since the

exposure to radiation from the soil is externally measured. The external hazard index was calculated using Equation 8 [14, 16, 17];

$$^{226}\mathrm{Ra}\left(\frac{\mathrm{Bq}}{\mathrm{kg}}\right) = 0.76 + 0.84\ (\mathrm{A}_{^{238}\mathrm{U}}) \quad \text{(Eq. 4)}$$

$$\mathrm{Ra}_{\mathrm{eq}}\left(\frac{\mathrm{Bq}}{\mathrm{kg}}\right) = \mathrm{A}_{^{226}\mathrm{Ra}} + 1.43\ \mathrm{A}_{^{232}\mathrm{Th}} + 0.077\ \mathrm{A}_{^{40}\mathrm{K}} \quad \text{(Eq. 5)}$$

$$\mathrm{D\ (nGy/h)} = 0.427\ \mathrm{A}_{^{238}\mathrm{U}} + 0.662\ \mathrm{A}_{^{232}\mathrm{Th}} + 0.0432\ \mathrm{A}_{^{40}\mathrm{K}} \quad \text{(Eq. 6)}$$

$$\mathrm{AED}\left(\frac{\mathrm{mSv}}{\mathrm{yr}}\right) = \mathrm{D}\left(\frac{\mathrm{nGy}}{\mathrm{h}}\right) \mathrm{x}\ 8760\ (\mathrm{h})\ \mathrm{x}\ 0.2\ \mathrm{x}\ 0.7\left(\frac{\mathrm{Sv}}{\mathrm{Gy}}\right) \mathrm{x}\ 10^{-6} \quad \text{(Eq 7)}$$

$$\mathrm{H_{ex}} = \frac{\mathrm{A}_{^{226}\mathrm{Ra}}}{370} + \frac{\mathrm{A}_{^{232}\mathrm{Th}}}{259} + \frac{\mathrm{A}_{^{40}\mathrm{K}}}{4810} \quad \text{(Eq. 8)}$$

where $\mathrm{A}_{^{226}\mathrm{Ra}}$ = Activity concentrations of ^{226}Ra, $\mathrm{A}_{^{238}\mathrm{U}}$ = Activity concentration of ^{238}U, $\mathrm{A}_{^{232}\mathrm{Th}}$ = Activity concentration of ^{232}Th, $\mathrm{A}_{^{40}\mathrm{K}}$ = Activity concentrations of ^{40}K, D (nGy/h) is the total air absorbed dose rate in the outdoors, 8760h is the number of hours in one year; 0.2 is the outdoor occupancy factor (AELB standard); 0.7 Sv/Gy is the conversion coefficient from absorbed dose in the air to the effective dose that is received by adults (AELB standard); 10^{-6} is the conversion factor between nano- and milli measurements.

Results and Discussion

In this study, the EXDRF method was validated using a variety of standard reference materials (SRM) including JLK-1, SRM 2709a and SO-7. Good recoveries were obtained in the range of 87-115%. The accuracy of the EDXRF method was also compared with the inductively coupled plasma-mass spectrometer (ICPMS) in the Agensi Nuklear Malaysia laboratory using similar samples. The results obtained were relatively comparable with the recoveries in the range of 70-136 %, showing the reliability of the EXDRF method that was used for the analysis of elements in the soil samples.

The activity concentrations of three (3) radionuclides of ^{238}U, ^{232}Th and ^{40}K from twelve (12) locations surrounding the Temenggor area are presented in Table 2. The measured concentration from the EDXRF in the unit of mg/kg was converted into activity concentration with the unit of Bq/kg. As tabulated in the table, the activity concentrations ^{238}U, ^{232}Th and ^{40}K were in the range of 32.56-110.10, 28.92-179.92 and 214-1083 Bq/kg with the mean of 52.55, 79.49, and 476 Bq/kg, respectively. The lowest level of ^{238}U was observed at site S05 with a value of 32.56 Bq/kg and the highest was at site S03 (110.10 Bq/kg). Meanwhile, for ^{232}Th the lowest was at site S01 (28.92 Bq/kg) and the highest was at site S11 (179.92 Bq/kg). Site S11 gave the lowest concentration with a value of 214 Bq/kg, while S03 contained the highest activity concentration of ^{40}K (1083 Bq/kg). The difference in concentrations was most probably caused by the type of soil and the surrounding environment of the sampling site. According to Sanusi et al., granite soil has higher radionuclides content compared to other types of soil [11]. Temenggor areas are made up of lithosolos and shallow red-yellow podzolic solids with s-types granitoid soil [10]. Factually, this can explain the high concentrations of radionuclides in this area. Moreover, the additional anthropogenic sources might elevate the natural content of radionuclides. It was found that site S03 was located near the small jetty for a private boat, a site that has become a pickup and drop-off point for goods and other amenities. This site is also a place for small boats to refuel their engine oil. Furthermore, vehicles can also access to this location from the mainland. Thus, radionuclides can be released into the environment

through transportation as radionuclides are one of the burning fuel products [18, 19]. On the other hand, site S11 is located in a place named Tanah Banun (according to local people). This location has an open space which is a habitat for most of the wild animals to roam as well as rest. The transfer of radionuclides from their origin to the environment could be through the food chain. Plants absorb nutrients and other contaminants from the soil and are eaten by animals. Additionally, soil can also be ingested by animals through the licking or preening of their fur, feathers, or offspring [20]. Then, the absorbed radionuclides can be excreted in urine or endogenously excreted in the faeces and absorbed back into the soil of the areas [21]. This might explain the elevated concentrations of radionuclides in location S11. Furthermore, Site S11 is also near one of the Orang Asli localities in the Temenggor area. While samples from other locations have mostly been collected from the small island that has not been occupied anymore.

The standard permissible limit for radionuclides in soil that is reported by the UNSCEAR is 35, 30, and 400 Bq/kg for ^{238}U, ^{232}Th, and ^{40}K, respectively as shown in Table 2. The majority of the sampling sites have higher radionuclides content if compared to the world limit [3]. Additionally, the activity concentrations of the three radionuclides in this study were compared to other reported studies of soil around Malaysia. Mohammad Syazwan et al. [22] studied the influence of geological and soil formation on natural gamma (γ) radiation exposure. The study focused to obtain the baseline data of γ radiation exposure and radioactivity that were associated with soil in the granitic territory in the Western Region of Peninsular Malaysia. The study stated ^{238}U and ^{232}Th activity concentrations to be in the range of 7-554 and 23-1809 Bq/kg, respectively. Temenggor area has lower activity concentrations when compared to the Western Region of Peninsular Malaysia despite having the same soil types [22]. Another reported study of radionuclides from the soil samples that were collected in Bangi by Mei-Wo and Ali showed a different pattern [23]. The activity concentrations of ^{32}Th and ^{40}K are relatively in the range of the Temenggor area but there is a slightly higher range for ^{238}U. The author has stated that the noticeable difference may be attributed to the geochemical composition and origins of the soil types in the particular study areas. Moreover, the higher values of the activity concentrations belong to soil samples that may be attributed to soil types which were probably radioactive-rich granite, phosphate, sandstone, and quartzite [23]. Abdul Aziz and Khoo studied the assessed absorbed dose and radiation hazard index from the soil in Bukit Kledang, Perak [24]. The obtained results were in the lower range than this study for the three radionuclides, as shown in Table 2. The authors stated that the varied values that were obtained varied according to the location. It is most likely to be affected by several factors such as soil type, soil pH, the latitude of area, soil texture, the existence of underground rock, and organic matter [24].

The findings of activity concentrations surround Temenggor area was also compared to some studies from oversea. The vertical distributions of forty-four soil samples from Qatar were studied by Ahmad et al. [7]. The mean concentrations of this study are presented in Table 2 and have lower concentrations compared to this study. The authors agreed that the different levels of radionuclides in the soil depend primarily on the concentration of radionuclides in bedrocks from which the soil originates. Besides, the author said that the natural radionuclides levels (^{226}Ra, ^{232}Th, and ^{40}K) in the soil might be affected by the physiochemical characteristic of the soil [7]. Another reported study of activity concentrations for the three natural radionuclides (^{226}Ra(^{238}U), ^{232}Th, and ^{40}K) using soil samples was carried out in Korea [8]. The in-situ and laboratory γ-ray spectroscopy techniques were compared to evaluate the activity concentration of natural radionuclides in soil. Table 2 shows the results of the in-situ measurement using gamma spectroscopy techniques. The authors reported that all-natural radionuclide concentrations were lower on Jeju Island due to its geological origin of quarternary basalt/trachyte, while they were higher in Chuncheon due to its geological origin of Jurassic granite. Moreover, a strong correlation was observed between the techniques with linear regression lines of 99% for ^{226}Ra and ^{232}Th, whereas for ^{40}K the correlation was 97.5% [8]. All of the reported studies have agreed that the difference and high concentrations of radionuclides

are most likely caused by the original, geochemical, and physiochemical types of the soil itself.

Table 2. The activity concentrations of ^{238}U, ^{232}Th and ^{40}K

Location	Activity Concentrations (Bq/kg)

Temenggor area has Ra_{eq} values between 103.90 - 312.17 Bq/kg. The Ra_{eq} of the study area is presented in Figure 2. It can be observed that this study has a lower concentration than the limit that is set by UNSCEAR 2000 of 370 Bq/kg. Meanwhile, it is relatively comparable with the reported values of other studies [1,14,22,25,26,27].

The absorbed dose date of radionuclides was calculated in the unit of nGy/h. This is the measurement of presented radionuclides in the air exposed to humans. The absorbed dose rate at sampling sites varies from 49.99 to 149.65 nGy/h (Figure 3). The highest value in the Temenggor area that has been observed at site S03 is about three times higher in value than the world limit (55 nGy/h). However, Temenggor areas have absorbed dose rates in a range comparable with other reported studies [1, 14, 25, 27].

The estimated outdoor absorption of radiation was calculated using the annual effective dose (AED) in the unit of mSv/y. The calculated AED for the Temenggor area was about four times lower than the reported world limit by UNSCEAR 2000 as illustrated in Figure 4. The value was between 0.0621 to 0.1835 mSv/y. The reported value from Nigeria in 2019 [26] has a higher AED than the Temenggor area, while the values in other reported studies were comparable with the study areas [1, 14, 25, 26, 27].

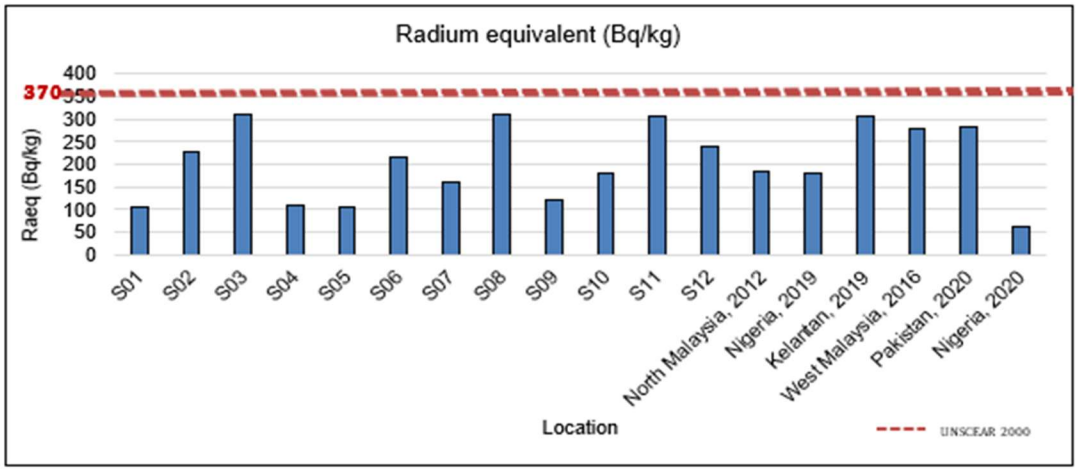

Figure 2. The radium equivalent (Ra_{eq})

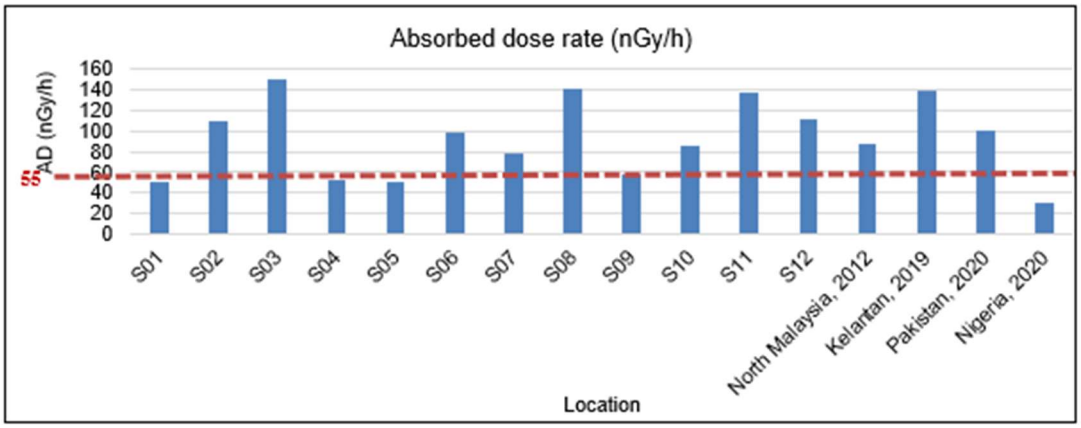

Figure 3. The absorbed dose rate (AD)

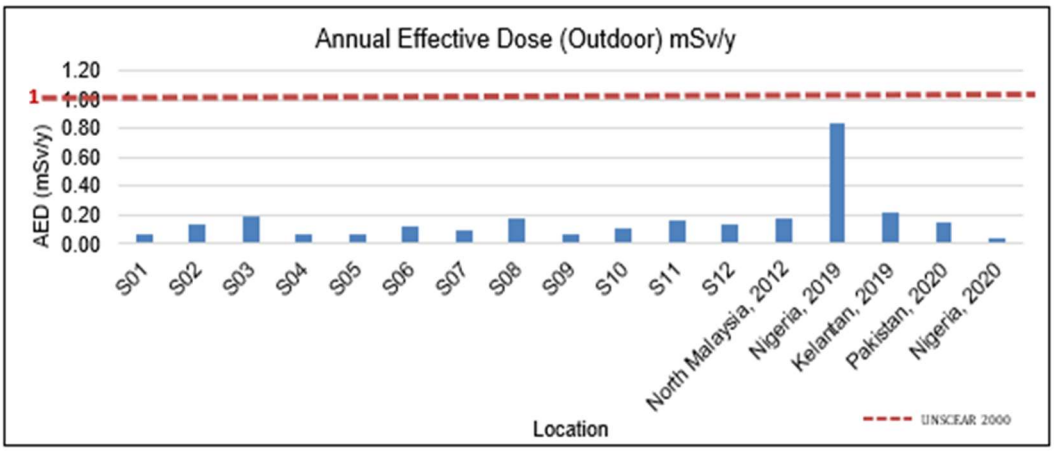

Figure 4. The annual effective dose (AED)

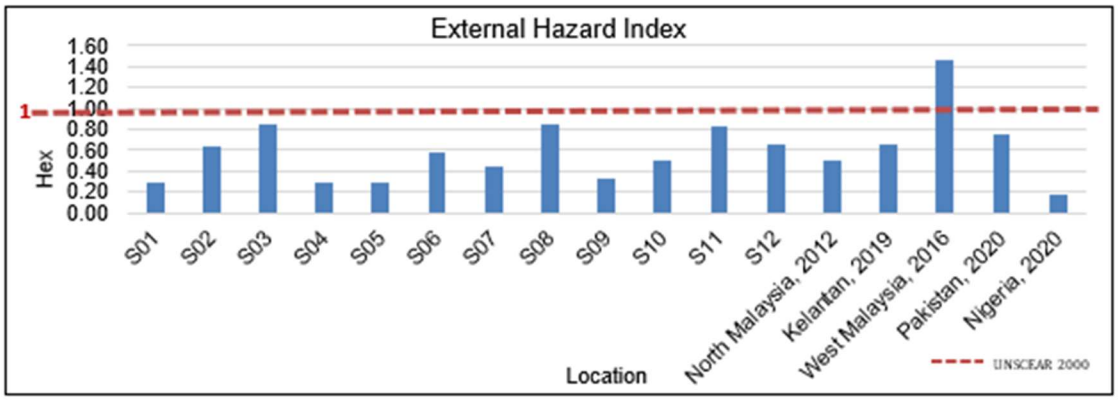

Figure 5. The external hazard index (H_{ex})

The total estimation of γ -dose radiation was calculated using the hazard index. In this study, researchers used the external hazard index since the estimation was based on the radiation in the soil. Figure 5 shows the distribution of the external hazard index for the Temenggor area and a comparison between the world limit and other reported studies. Temenggor area has a hazard index in the range of 0.2885-0.8577. All locations have a lower value than the world limit that is set by UNSCEAR 2000 with the value of 1. This implies that exposure to the gamma radiation from the soil has no significant consequence to health. The other reported values [1, 14, 25, 27] were also in-between the Temenggor area; except for West Malaysia [22] where it has a higher value.

Conclusion

A study to observe the distribution of three radionuclides- including ^{238}U, ^{232}Th and ^{40}K, has been conducted in the Temenggor Reserved Forest area. The mean activity concentrations of ^{238}U, ^{232}Th, and ^{40}K are 52.55, 79.49, and 476 Bq/kg, respectively. Some of the locations have higher activity concentrations than the world limit that is released by UNSCEAR 2000. Comparing the activity concentrations with the reported studies around Malaysia, the Temenggor area has a lower activity concentration. The type of soil in the study area contributes to the high activity concentrations of radionuclides. On the other hand, the radiation risk assessment has shown that the study areas do not pose a significant risk to humans. This is based on the calculation of Radium Equivalent (Ra_{eq}), Absorbed Dose Rate (AD), Outdoor Annual Effective Dose (AED), and External Hazard Index (H_{ex}).

Acknowledgment

The authors would like to thank Jabatan Perhutanan Negeri Perak, Bahagian Hulu Perak, the staff of Pulau Tali Kail Resort, and all individuals who were involved directly or indirectly throughout this study. The appreciation also includes the Institute of Sciences and Faculty of Applied Sciences of Universiti Teknologi MARA (UiTM) Shah Alam for permission to use their laboratory and facilities.

Abstract

Mosquitoes represent the deadliest animal species in tropical regions because they can affect human health. Personal protection which is mosquito repellent has been used since 20th century. Mosquito repellent which contains plant-based ingredients has high demand from consumers since its efficacy is as good as synthetic ones. Citronella genus plants are originally extracted to be used in perfumery, then they were used for ingredients of plant-based mosquito repellents as they have repellent properties. Citronellal-based repellent has an effective dose such as *N,N*-diethyl-meta-toluamide dose. However, the oil content has high volatility causing it to reduce its efficacy because the oil evaporates. Recently, the structure of citronellal compound has been modified into hydroxycitronellal by adding some functional groups to reduce the release rate, prolong the protection time and improve the stability of the compound. The release rate properties are affected by functional groups and the molar mass of the compounds. This paper presents a summary of recent catalyst and solvent usage during synthesis, characterization and comparison of mosquito repellents.

Keywords: synthesis, hydroxycitronellal, acetal derivatives, mosquito repellent

Abstrak

Perlindungan diri iaitu penghalau nyamuk telah digunakan sejak abad ke-20. Nyamuk mewakili spesies haiwan yang paling mematikan di kawasan tropika kerana ia boleh menjejaskan kesihatan manusia. Ubat nyamuk yang mengandungi bahan berasaskan tumbuhan mendapat permintaan tinggi daripada pengguna memandangkan keberkesanannya setanding dengan sintetik. Tumbuhan genus *Citronella* pada asalnya diekstrak untuk digunakan dalam minyak wangi, kemudian ia digunakan untuk bahan-bahan penghalau nyamuk berasaskan tumbuhan kerana ia mempunyai sifat penghalau. Penghalau berasaskan sitronelal mempunyai dos berkesan seperti dos *N,N*-dietil-meta-toluamida. Walau bagaimanapun, kandungan minyak mempunyai kemeruapan yang tinggi menyebabkan ia mengurangkan keberkesanannya kerana minyak menyejat. Struktur sebatian sitronel telah diubah suai dengan menambah beberapa kumpulan berfungsi untuk mengurangkan kadar pelepasan, memanjangkan masa perlindungan dan meningkatkan kestabilan sebatian. Sifat kadar pelepasan dipengaruhi oleh kumpulan berfungsi dan jisim molar sebatian. Kertas ini membentangkan ringkasan penggunaan pemangkin dan pelarut terkini semasa sintesis, pencirian dan perbandingan penghalau

nyamuk.

Kata kunci: sintesis, hidroksisitronelal, terbitan asetal, penghalau nyamuk

Introduction

Mosquitoes represent the deadliest animal among other species in the tropical regions as they can affect human health [1]. They can spread the pathogens among human in the regions because of the powerful vectors [1]. Malaria, oestridean parasites which can cause myasis, Japanese and encephatilis and the parasites come from the mosquito themselves [2]. Aedes albopictus is one of the common example of Asian tiger mosquito which can cause several reported severe disease cases [3]. There are many strategies which help to reduce infection by and transmission of vector disease especially in tropical regions, such as chemical control, genetic control and personal protection [4]. The use of insecticides represents the chemical control of mosquitoes in order to kill the adults [5]. There are many ways for environmental controls such as the removal of disused tires, draining of ponds and introducing predatory fish [6]. In addition, genetic control mosquito population can also be implemented by reducing mosquitoes's lifespan [7]. However, personal protection is the best way to protect user from mosquito bites as well as to reduce mosquito-borne disease outbreaks potential of user's surrounding [8].

Personal protection which commonly used by individual is mosquito repellent. Mosquito repellent is a key recommendation of health authorities to reduce the potential of mosquito-borne disease. *N,N*-diethyl-m-toluamide (DEET), picaridin and p-menthane-3,8-diol (PMD) are the most commonly used repellent products. The common repellent products have high demand from users because they have good efficacy since 1950s [9]. One of the repellent products which gains the highest demands from users and commonly commercialized by mosquitos repellent industries is DEET [10]. However, DEET can lead to negative impacts to humans [10]. It is reported that DEET can lead to neurotoxic effects not only to insects but as well as human because it can disturb the acetylcholinesterase's activity which is a key enzyme of synaptic transmission [1]. Besides, it can affect the channels of Na^+ and K^+ which are located at cortical neurons in mammalian and it can cause the pro-angigenic effects to human because DEET acts as an allosteric modulator of M3 mAchR [11]. Picaridin also one of the repellents which can cause dermatitis on our skin [12].

Therefore, there has been an effort to seek for environment-friendly repellent [13]. Plant-based repellents is an alternative mosquito repellent to be used for personal protection [13]. Geranyl acetate, citronellal, 6-methyl-5-hepten-2-one and geranyl acetone [8] give response to odor receptors of mosquito which the receptor also can receive the same respond from the gold-standard repellent DEET [14]. Citronellal is reported to be one of the plant-based repellent which has most effective repellent properties because it is monoterpenoid aldehyde and there is a carbonyl group [13]. On the other hand, the two functional or substituent groups of citronellal contributes to biological interaction towards mosquito receptor as mosquito repellent. On the other side of coin, citronellal has high release rate and high volatility because of the presence of carbonyl group [15] and low molecular weight [16]. The structure of citronellal can be modified by adding a functional group [14] and undergoes an acetalization in order to increase its molecular weight and protection time [15].

Acetal, ketal and their derivatives

Acetal and ketal

Acetal (Figure 1) or ketal (Figure 2) can be formed via the reaction between carbonyl and alcohols, for instance methanol or ethanol (Scheme 1) [7]. The reaction is catalysed by acid catalyst. The formaldehyde or higher aldehydes with diols such as 1,2-diols or 1,3-diols in the presence of an acid catalyst can react to form cyclic acetal (Figure 3) [17]. Usually, carbonyl compound will react with an alcohol and aided by catalyst such as Lewis acid to form acetal or ketal [18]. The reaction is stereotypically undergoes with homogenous catalysis; sulphuric acid and phosphoric acid which are mineral inorganic acids [19]. It is important to choose a suitable azeotropic solvent from ketone or aldehyde solution to aid in the process of water removing. Besides, acetal or cyclic acetal can act as protecting group of carbonyl

group against an attack by reagents, for example, reducing agents, basic, nucleophiles, catalytic and oxidant [20].

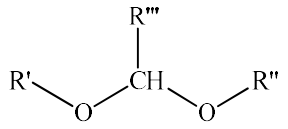

Figure 1. Structure of acetal [21]

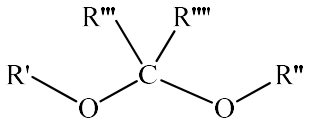

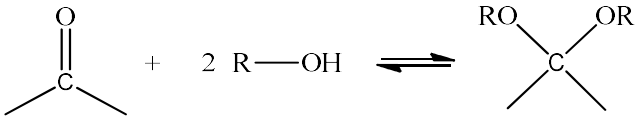

Figure 2. Structure of ketal [21]

Scheme 1. Chemical reaction on synthesizing ketal or acetal [21, 22]

Acetal and ketal can also be synthesized from orthoester carbonyl compound with the presence of glycol and a catalyst [23]. The structures of 1,3-dioxane and 1,3-dioxalane can be formed if the reaction undergoes between polyol and suitable ketone and aldehyde with the used of glycerol in the presence of catalyst [24]. The reaction produces 6 membered ring of 1,3-dioxane or 5 membered ring of 1,3-dioxalane because of the reaction between glycerol and steric blocking of hydrogen atom and radical. The reaction of diol will form a ketal or cyclic ketal (Fig. 4).

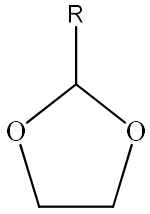

Figure 3. Structure of cyclic acetal [17]

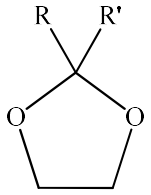

Figure 4. Structure of cyclic ketal [17]

Derivatives of acetal and ketal

Different substituents such as methanol or ethanol have been used in the reaction with aldehyde or ketone to produce our desired acetal or ketal derivatives [25]. The process of acetalization can modify the functional groups of compound in order to provide better efficiency and transformations of subsequent synthetic flexibility [26]. The characteristics of aroma, vapour pressure, flavour and solubility can be modified by using different methods in carbonyl compound conversion, for instance, the compound process is commonly called as attenuation in perfumery industry [23]. Besides, different methods also have been used to synthesize acetal or ketal derivatives by using different catalyst such as β-cyclodextrin. The use of this catalyst has been proven to reduce the release rate, the volatility and to prolong its insect repellent activities [27] in insect repellent industry. On the other hand, the process of synthesizing allysine ethylene acetal (Figure 5) can be simplified using amination method instead of using 8-step process to produce the acetal [28].

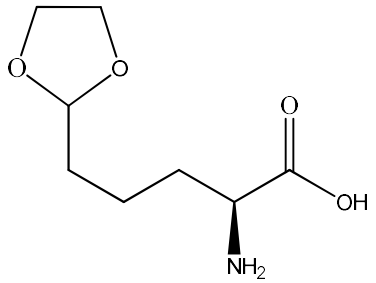

Figure 5. Structure of allysine ethylene acetal [29, 30]

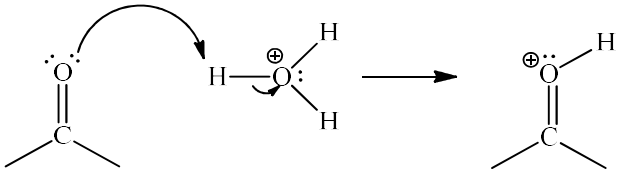
In a view of pharmaceutical industry, the acetal derivatives can improve the activity of anti-inflammatory [31]. The binding of the acetal derivatives to skin which has thiol groups can accumulate in the skin which resulted by the ring-opening of an intermediate of Schiff base. Ethylene ketal derivatives of prostaglandin E2 can also contribute in stability of solid-state improvement. The hydrocortisone 21-acetate spirothiazolidines and hydrocortisone spirothiazolidines have been prepared to be reacted to the substituents of cysteine esters or β-aminothiols and produce the derivatives [31].

Properties of acetal:

Physicochemical properties of acetal

Acetal is an organic compound which has pleasant odor such as earth, nutty, green, sweet [32] and ethereal [33]. The color of acetal in liquid form is colorless at standard state. Acetal has moderate toxicity and narcotic at high concentration [34]. Table 1 lists the physicochemical properties of acetal.

Synthesis:



Mechanism of formation of acetal

There are 7 steps of mechanism in the formation of hemiacetal and acetal. Scheme 2 displays the mechanism steps which consist of carbonyl protonation, alcohol's nucleophilic attack, hemiacetal formation through deprotonation, protonation of alcohol, removal of water, alcohol's nucleophilic attack and deprotonation of water [35].

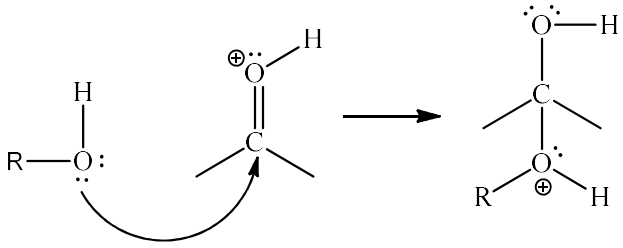


Table 1. Physicochemical properties of acetal

Property	Value	Reference

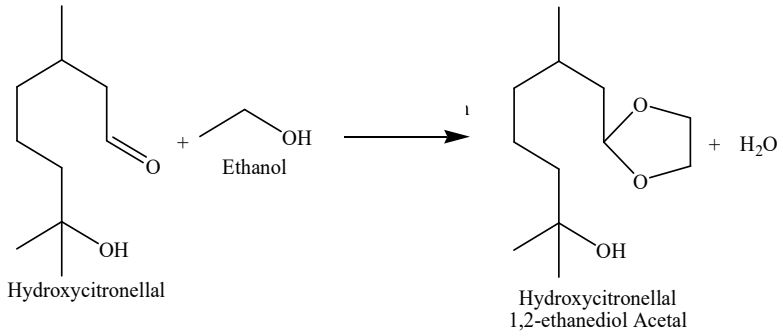
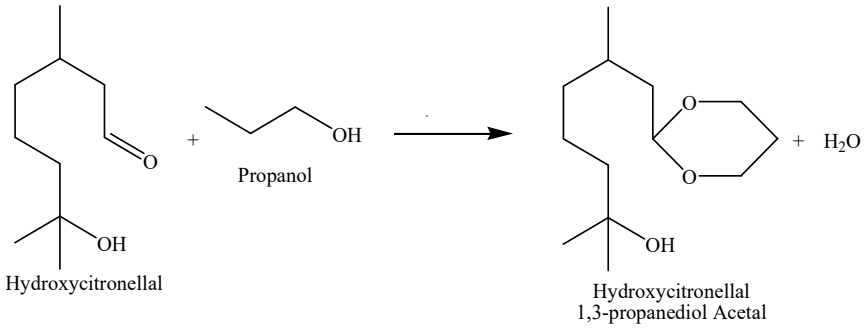


Scheme 2. Mechanism for Hemiacetal and Acetal Formation [35]

Synthesis of hydroxynellal acetal derovatives



Some plants such as *Cymbopogon* species, to be more specified, *Cymbopogon winterianus* has been traditionally used to repel mosquitoes because it has mosquito repellent properties [37]. The plant can produces a yellow liquid of citronella oil through distillation process of dried Cymbopogon plants [27]. Citronella oil has been approved by United States Environmental Protection Agency (US EPA) to be applied on skin for insect repellent activities [13]. Recently, one of the citronella oil terpenes which are citronellal has been further studied by Zongde [25] by synthesizing hydroxycitronellal acetal derivatives to prolong its protection time . Schemes 3-5 show the synthesis reactions between hydroxycitronellal and its substituents. The overall reactions will be synthesized by using the same type of starting material which is hydroxycitronellal and by using the same methods.

Scheme 3. Synthesis of hydroxycitronellal dimethyl acetal [25]

Scheme 4. Synthesis of hydroxycitronellal 1,2-ethanediol acetal [25]

Scheme 5. Synthesis of hydroxycitronellal 1,3-propanediol acetal [25]

Catalysts usage during synthesis of acetal and acetal derivatives

Hydroxycitronellal is an aldehyde which has been synthesized from citronellal through hydrolysis process. Previously, citronellal acts as starting material, but the repellent properties itself has protection time less than 23 minutes [38] although citronellal has various of effective concentration from 0.05 to 25% (weight/volume) [27]. Then, hydroxycitronellal acts as starting material and has been reacted with a substituent which is methanol and benzene as a solvent [25]. The mixture has been mixed with sulfamic acid that acts as a catalyst. The presence of common acid catalysts such as hydrochloric acid, sulphuric acid, p-toluenesulfonic acid and trifluoroacetic acid [39] in the formation of ketals or acetals by treating aldehydes or ketones with alcohols are corrosive [40]. Alkynes, alkenes, silyl-protected alcohols and N-Boc-protected amines are the subtrates of acid-sensitive groups which are not compatible with acidic condition [41]. Pyridinium salt derivatives [42], dialkyltriazolium salts [43] and imidazolium salts [44] are aprotic salts series which are capable to act as Brønsted acids in chemoselectively acetalization [45]. Ammonium salts also can be employed to the acetalization or ketalization process between aromatic aldehydes or ketones and diols with pentyl methyl ether as solvent in Dean-Stark condition [46]. Mesoporous polymelamine-formaldehyde polymer can be used as catalyst in chemoselectively of aldehydes acetalization [47]. Graphitic-carbon nitride can catalyse the aldehydes or ketones acetalization process with alcohols compound to form acetals or ketal by using light in ambient conditions [48].However, Songkro [27] has found another alternative to control the release rate of desired product by using β-cyclodextrin as a catalyst for the synthesis and can increase the solubility in water [4]. This is because β-cyclodextrin forms an inclusion complex by forming hydroxycitronellal dimethyl acetal-β-cyclodextrin inclusion complex [27]. β-cyclodextrin is a better catalyst to be used in this reaction. Table 2

summarizes the types of catalysts which have been used for acetalization.

Solvent usage during synthesis of acetal and acetal derivatives

Benzene has been used as a solvent in the synthesis of hydroxycitronellal acetal derivatives. However, based on human and animal studies by the International Agency for Research on Cancer (IARC) since 1982, benzene has carcinogenic potential toward both studies [49]. Inhalation is the primary cause of the benzene exposure and the highest amount of the exposure which is 95%-99% can be found in cigarettes [50]. Benzene compound is associated with asthma effect among children [51]. Ferreira [35] has used carbon tetrachloride as one of the solvents to investigate iron (III) porphyrins catalytic activities for acetalization process and the solvent usage shows no product in the reaction because it is non-polar solvent. Besides, carbon tetrachloride also has been observed as chemical that can give liver injury due to its toxic metabolites [52]. Tanaka and co-researchers have found that the usage of dichloromethane as solvent for the regioselectivity ring-opening of benzylidene acetal can produce to 83% of percentage yield [53]. Ethyl acetate also has been used for both processes of preparation of dioxanesldithianes using hydrogen sulphate and deprotection of dioxanesldithianes using hydrogen sulphate [20]. Then, cyclohexane can be considered as an effective and efficient solvent. The usage of the solvent in both process of carbonyl compound as 1,3-dioxalanes protection using indium (III) chloride as catalyst and carbonyl compounds as dialkyl acetals protection using indium (III) chloride as catalyst can give more than 80% of percentage yield [54]. It can create an azeotropic mixture of cyclohexane and water and according to Le Chatelier's Principle, it will favour towards the product [55] if the ratio of the substituent more than starting material. However, the acetalization process does not take place between 2-methylpentanal and 2-methyl-2-propyl-1,3-propanediol at 1:1 ratio using cyclohexane, hexane, heptane and 1,4-dioxane as the solvents. The solubility between the solvents and 2-methyl-2-propyl-1,3-propanediol was low because their dielectric constant values are low [56]. Apart from that, water, glycerol [57] and polyethylene glycol [58] also can be a better option compared to other solvents because of its low toxicity and low risk of hazard [59]. Water can contribute to highest percentage yield of product from acetalization process. Table 3 lists the red solvents and their alternative green solvents for acetalization process.

Characterization

Fourier transform infra-red (FTIR) spectroscopy

The FTIR spectra have shown the absorption of specific chemical groups such as hydroxyl groups, carbonyl groups and alklyl groups [60] which are related to the synthesized acetal derivatives. The FTIR spectra will be recorded in the range of 3040-780 cm^{-1}. The stretching frequency of the C=C group in the aromatic shown at 1400 cm^{-1} and 1460 cm^{-1}. On the other hand, the stretching frequency of C-O in the compound has shown at 1100-1220 cm^{-1}. The peaks of C-H stretching vibration in the benzene ring of the acetal appeared at 759 cm^{-1}, 701 cm^{-1}, 3039 cm^{-1} and 3069 cm^{-1}[61]. Table 4 possess the IR frequency range and band assignment of acetal derivatives.

Proton nuclear magnetic resonance (^{1}H NMR) spectroscopy

The synthesized of hydroxycitronellal dimethyl acetal detected the resonance peak at 3.58 ppm which attributed to hydroxyl group in the acetal compound. On the other hand, result of the ^{1}H NMR showed signal at 4.19 ppm which attributed to methine group. Methyl group can be detected from the peak at 3.50 ppm. ^{1}H NMR chemical shift of hydroxycitronellal acetal derivatives is shown in Table 5.

CHNS elemental analysis

CHNS elemental analysis is a technique to identify the elements namely carbon, hydrogen, nitrogen and sulphur. The analyzed compound will undergo oxidative decomposition [62]. The compound also will undergo reduction of nitrogen and sulfur dioxide. The characteristic of thermal decomposition and the properties of the analyzed compounds that we have synthesized will affect the errors. There is potential of the under oxidation of the compound which will affect the determination of carbon and hydrogen. The speciation of nitrogen in synthesized compound will affect the decomposition of nitrogen-containing

compound [62]. Table 6 show the percentage of the C and H elements.

Mosquito repellent activities

Mosquito repellent

There are variety ways to measure the spread of mosquito disease such as chemical measure, genetic measure, environmental measure and personal protection; mosquito repellents [4]. Chemical measure has been used larvicides and insecticides [71] to kill the larvae and adults. However, the use of the chemicals have contaminated the water source and this measure have not developed to control all mosquito species [63]. The non-biological pesticides have high toxicity which gave severe impact to our environment and wildlife [4]. Environmental measure also has been applied by monitoring or removing the unused tires, draining the ponds; mosquito habitats, putting the predator fish in the ponds and building the water flow system in the pools [6]. Unfortunately, this measure has many difficulties for its maintenance and requires a good cooperation between local people [4]. Genetic measure also has been used by manipulating the mosquitoes genetic, for instance, the lifespan of the mosquito becomes shorter to reduce the transmit rate of malaria [64] and the sterilized males has been released to mate with females but the females cannot fertilize eggs [65]. This measure requires high expense to produce males and only works on the islands because of the variability of genetics is high [4] and the insects are migrate from place to place. The usage of personal protection; mosquito repellents become our first line defense from mosquitoes because this measure has lowered the transmit of malaria above 80% [66]. This reason have brought awareness to use personal protection control [1] to prevent from getting mosquito bites [4]. The synthetic mosquito repellents which have been commercialized are N,N-diethyl-meta-toluamide (DEET) [9] and ethylbutylacetylaminopropionate (IR3535) [67] which are synthetic repellent and citronellal [68], [69] which is essential oil mosquito repellent.

N,N-diethyl-meta-toluamide (DEET)

DEET (Figure 6) has been considered as gold mosquito repellents standard [14] because of its effectiveness [70]. The efficacy of DEET at 15% solution is 7-8 hours of protection time against mosquitoes [71]. However, DEET has been highlighted to has high potential severe effects on human health as well as surrounding [1]. It can cause neurotoxic effects on human and other insects by inhibiting an specific enzyme key activities [72]. In addition, it also can cause effects of pro-angiogenic on human by inhibiting specific ion channels in mammalian cortical neurons [73].

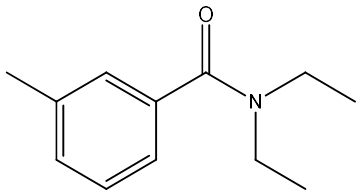


Figure 6. Chemical structure of DEET [1, 14, 70, 71, 72, 73]

Ethylbutylacetylaminopropionate (IR3535)

IR3535 (Figure 7) is one of the efficient repellents against mosquitoes. IR3535 has same effectiveness as DEET, also known as gold standard [1]. IR3535 has 7-10 hours protection times against Culex and Aedes mosquitoes and 3-4 hours protection time against Anopheles mosquitoes [67]. However, it has potential in dermal and oral toxicity [74] after the repellent has been tested on rats. It can cause eye irritation and skin irritation on human [1]. Then, IR3535 also can cause damage to synthetic material [75]. The positive point of IR3535 is this mosquito repellent may not has toxic potential towards life in water and it also not accumulates in our environment [76]. Figure 7 shows the chemical structure of IR3535.

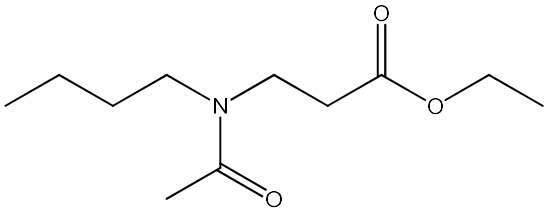

Figure 7. Chemical Structure of IR3535 [1, 67, 74, 75, 76]

Hydroxycitronellal acetal derivatives

Plant-based material have been used for thousand years by human as a personal protection against mosquitoes; a practice which is still widely uses in developing countries [77]. *Cymbopogon winterianus* has been extracted to produce citronellol, citronellal (Figure 8) and geraniol [78]. Citronella oil has been registered as mosquito repellent under United States Environmental Protection Agency (US EPA) [13], [37] because of its efficacy and it has low toxicity on test animal. Although, the gold-standard synthetic repellent DEET [14] can protect against various insect species, but it was reported that the repellent can give negative effect to human as mentioned earlier. Citronella-based repellents can repel in a certain period from mosquitoes. However, the oils rapidly leave the user unprotected because of the citronella itself is chemically has high rate of evaporation property [79]. Thus, Zongde [25] has modified the structure citronellal oil into hydroxycitronellal acetal derivatives (Figure 9) using acetalization process and Songkro [27] has formed inclusion complex [80] which will increase the number of molecules [81]. These efforts can enhance the protection time of the oil against mosquitoes.

Table 6. Composition of carbon and hydrogen element in acetal derivatives

Compounds	Element Composition (%)		Reference
	C	H	
Hydroxycitronellal dimethyl acetal	66.06	11.93	[62]
Hydroxycitronellal 1,2-ethanediol acetal	66.67	11.11	
Hydroxycitronella1,3-propanediol acetal	67.83	11.30	

Method of repellency test using human assay

The neutral soap will be used to wash the forearm and hand of a human subject. The forearm and hand will be thoroughly rinsed and dried for 10 min before apply synthesized compound. The hand will be wear a glove to protect against bites [83]. The forearm will be covered using a paper sleeve with a 25 mm circle to expose the skin. 3 mL product will be applied to the skin. The other forearm will be protected with a same paper sleeve without applying any products to the skin as a control. 20 mosquitoes will be placed in 20 × 20 × 20 cm cages. The cage will have a cotton stockinet on the front, clear glass at the back and top, an aluminum sheet bottom and screen on the sides. The test must be 27 °C temperature. Test will be conducted by placing the forearm with the repellent into a test cage for 5 minutes [84]. After 5 minutes of repellent application the stopwatch will be started. Every 30 minutes will be recorded as protection time until the test subject received a mosquito bite. Protection time will be recorded as the period time between repellent application and the observation period until the forearm obtain a bite. If no bites in 90 min, test will be stopped and protection time will be recorded as 90 minutes. It will be considered as a bite if a mosquito attempt to insert its stylets [83]. For the rare case, if there is no mosquito bite on the without repellent application arm during the observation, the trial will be stopped and will be repeated with new mosquito batch. This situation is to make sure that no bites is due to the repellent compound. Every synthesized compound will be used three times on the subject [10]. Each of the product will be tested once a day. Since, there are three different acetal derivatives that will be obtained, so the repellence test will be taken 9 days to complete it. Each of the repellency test will be conducted at night.

Method of repellency test using animal assay

The soap will be used to wash the abdomen of 4 mice and dried the mice for 20 minutes. The fur of mice's abdomen has been shaved in square shape of 2.5 cm x 2 cm. Hydroxycitronellal oil has been applied to first mice on its skin, which acts as controlled mice. Then, the remaining mice's have been applied hydroxycitronellal dimethyl acetal, hydroxycitronellal 1,2-ethandiol acetal and hydroxycitronellal 1,3-propanediol acetal. Then, they have prepared a cylindrical applicator with the diameter 5.5 cm and height of 12 cm with a square opening area of 2 cm x 2 cm at the lower end [25]. The applicator has been filled with 30 mosquitoes. The test has been repeated three times to obtain an average protection time of mice against mosquitoes.

Protection time of mice against mosquitoes

According to result, the first mice which has been applied to hydroxycitronellal oil has the shortest protection time. The last mice which have been applied with hydroxycitronellal 1,3-propanediol acetal has the longest protection time. Table 7 shows the repellence times of synthesized hydroxycitronellal derivatives which are hydroxycitronellal dimethyl acetal, hydroxycitronellal 1,2-ethanediol acetal and hydroxycitronellal 1,3-propanediol acetal.

Table 7. The repellence time of the compounds against mosquitoes

Compounds	Repellence Times (min)			Reference
	Number of Trial			
	1	2	3	
Hydroxycitronellal	10	8	9	[10, 25]
Hydroxycitronellal dimethyl acetal	20	18	29	
Hydroxycitronellal 1,2-ethanediol acetal	30	28	40	
Hydroxycitronellal 1,3-propanediol acetal	60	58	57	

Protection time of human against mosquitoes

According to the result, the first human hand which has been applied to hydroxycitronellal oil has the shortest protection time. The last human hand which has been applied with hydroxycitronellal 1,3-propanediol acetal has the longest protection time. Table 8 lists the repellence times of synthesized hydroxycitronellal derivatives which are hydroxycitronellal dimethyl acetal, hydroxycitronellal 1,2-ethanediol acetal and hydroxycitronellal 1,3-propanediol acetal.

Table 8. The repellence time of the compounds against mosquitoes

Compounds	Repellence Times (min)			Reference
	Number of Trial			
	1	2	3	
Hydroxycitronellal	10	8	9	[10, 25]
Hydroxycitronellal dimethyl acetal	20	18	29	
Hydroxycitronellal 1,2-ethanediol acetal	30	28	40	
Hydroxycitronellal 1,3-propanediol acetal	60	58	57	

Conclusion

DEET, IR3535 and citronellal are initially used for mosquito repellent because of the potential protection time and release rate. However, DEET and IR3535 recently have been reported to have high potential effect towards human health and surroundings. Citronellal oil, plant-based oil has similar efficacy as mosquito repellent compared to the commercial repellents. The green oil undergoes hydrolysis process to produce hydroxycitronellal oil and recently hydroxycitronellal oil undergo acetalization process to produce its derivatives. The modification of functional groups of

green citronellal oil has been take place to improve the protection time and efficacy. During the synthesis process, acid catalysts can improve in protection time. However, by using green catalyst which is β-cyclodextrin, it can form inclusion complex. The complex improves the release rate mosquito repellent. The usage of solvent in acetalization can improve to percentage yield of our desired product. Benzene, carbon tetrachloride, chloroform, toluene, acetone and xylene are listed in red solvents. This is due to one of the solvents which is benzene has carcinogenic potential towards human and animal through primary exposure of benzene which is through inhalation. There are many alternatives solvents which can be used for this reaction such as water, glycerol and polyethylene glycol. The alternatives solvents are not just green solvents but it can contribute to the reaction to obtain products with better percentage yield. Green synthesis of mosquito repellent can be undergoing by wisely selecting potential plant-based starting material, non-hazardous solvent and green catalyst. Apart from that, there are two types of assays to examine our mosquito repellent products which are human assay and animal assay. Acetal derivatives of hydroxycitronellal oils have promising protection time. The derivatives have promising release rate and volatility which affected by their molecular weight and inter-molecular bonding.

Abstract

Metallodielectric photonic crystal has emerged as a formidable asset in the realms of light trapping materials. Inverted silica, and alloy noble metal nanoparticles of gold-silver alloy(Au-Ag) exhibited promising light trapping capabilities that have the potential of applications across many fields including solar cell, and biomedical device production. This composite was prepared via self-assembly; a fast, simple, and low-cost method capable of generating photonic crystals of greater surface area. Poly(methyl methacrylate) (PMMA) was used as the crystal template, and hydrolysed tetraethyl orthosilicate (TEOS) as the cementing component. In this study, methyl methacrylate monomer underwent a complete polymerisation reaction to form PMMA due to the absent of C=C bond around 1639.83 cm^{-1} as characterised by IR spectroscopy. Alloy(Au-Ag) nanoparticles displayed good light absorption ability as shown from UV-Vis analysis of the nanoparticles at wavelength of 437nm. SEM imaging revealed that after the removal of PMMA template from Si-Alloy(Au-Ag)-PMMA composite, an inverted structure that possessed a hole skeleton structure was produced. The performance of the inverted Si-alloy(Au-Ag) composite was tested via a dye sensitive solar cell (DSSC) that showed an amplification in voltage reading.

Keywords: nanostructure, photonics, metallo-dielectric, alloy nanoparticles, inverse opal

Abstrak

Kristal fotonik metallodielektrik telah muncul sebagai aset yang menggerunkan dalam bidang bahan perangkap cahaya. Silika songsang, dan aloi nanopartikel logam adi daripada Aloi emas-perak (Au-Ag) mempamerkan keupayaan memerangkap cahaya yang mempunyai potensi aplikasi merentasi banyak bidang termasuk sel solar, dan pengeluaran peranti bioperubatan. Komposit ini disediakan melalui pemasangan sendiri; kaedah yang cepat, mudah dan kos rendah yang mampu menghasilkan kristal fotonik dengan luas permukaan yang lebih besar. Poli(metil metakrilat) (PMMA) digunakan sebagai templat kristal, dan tetraetil orthosilikat terhidrolisis (TEOS) sebagai komponen penyimenan. Dalam kajian ini, monomer metil metakrilat menjalani tindak balas pempolimeran lengkap untuk membentuk PMMA kerana ketiadaan ikatan C=C sekitar 1639.83 cm^{-1} seperti yang dicirikan oleh spektroskopi IR. Nanozarah aloi (Au-Ag) menunjukkan keupayaan penyerapan cahaya yang baik seperti yang ditunjukkan daripada analisis UV-Vis bagi nanozarah pada panjang gelombang 437nm. Pengimejan SEM mendedahkan bahawa selepas penyingkiran templat PMMA daripada komposit Si-Alloy(Au-Ag)-PMMA, struktur songsang yang mempunyai struktur rangka lubang dihasilkan. Prestasi komposit Si-aloi(Au-Ag) songsang telah diuji melalui sel suria sensitif pewarna (DSSC) yang menunjukkan penguatan dalam bacaan voltan.

Introduction

Nobel laureate Richard Smalley once pointed out that energy and environmental problems will be the hardest challenges mankind will face in the next 50 years [1]. Solar photovoltaic (PV) technology gained traction as a popular renewable energy source due to its cost effectiveness, easy fabrication, and environmental friendliness [2]. In particular, solar cell devices, which harness sunlight and convert it into usable energy and electricity, became the focal interest of the photovoltaic industries that are ever-expanding due to the increasing prices of fossil fuel and to accelerate the push towards sustainable energy options [3]. Many endeavours had been made in researching and developing thin film materials that are capable of reducing costs of mass producing efficient solar strategies and mechanically flexible devices [4, 5]. Silicon is a prevalent material in solar cells, provided it yields strong low-light performances and is non-toxic [6, 7]. However, a shortcoming of the current silicon thin-film solar cells is the insufficient absorption of the near-bandgap light. The limitation could possibly be overcome by efficient light trapping which points towards the expansion of different light trapping geometries, one of which is the photonic crystal [8-10].

A photonic crystal is a periodic optical nanomaterial that manipulates the movement of the light (photons) directed by their lattice structure [11]. Photonic crystals have different dielectric constants and these materials cause a photonic band gap (PBG) that allows precise control over the flow of light [12]. This unique property has been applied in various advance technological devices such as sensors, photovoltaic and solar concentrators [13-16].

PMMA is used as the crystal template because higher yield of monodispersed particles can be produced [17]. PMMA will be synthesised through free-emulsifier emulsion polymerisation in water. This method is much safer for environment compared to methods that utilise toxic solvents such as toluene, dimethylformamide and dimethyl sulfoxide as medium of reaction. The removal of PMMA template results in inverse opal capable of achieving a complete band gap.

“Bottom up” method is used in the fabrication of film. This simple step reinforces the quality of long range ordered structures with greater strength. “Bottom up” co-crystallisation method is used rather than “top down” as the “top down” approach is complex, involves multi-steps and costly procedures [18–20].

Materials and Methods

Synthesis of PMMA colloidal nanoparticle

PMMA was synthesised through free-emulsifier emulsion polymerisation reaction with potassium persulphate as initiator, methyl methacrylate monomer, and deionised water as dispersion medium under nitrogen condition at 90 $°C$. The reaction was kept

stirring at speed of 350 rpm. Deionised water of 64 ml was bubbled with nitrogen gas and heated for 15 minutes at 90 $°C$. MMA monomer was added and kept stirring for 30 minutes. Lastly, potassium persulphate was added, with the solution kept stirring for another 40 minutes until polymerisation reaction was completed. The milky colloidal was centrifuged and washed for 6 times.

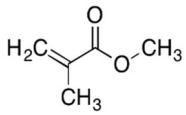
Synthesis of hydrolysed TEOS

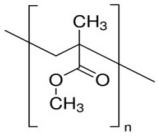
Hydrolysed TEOS was prepared utilising the sol-gel method. Tetraethylorthosilicate (TEOS) of 1 ml, 8 ml of ethanol, and 1 ml of HCL were mixed together and stirred at speed of 350 rpm for 1 hour.

Synthesis of alloy(Au-Ag) nanoparticles

Deionised water of 78 ml was heated at 100 $°C$. 1 ml of 0.05M $HAuCl_4$, 1 ml of 0.05M $AgNO_3$ and 8 ml of 0.1M sodium citrate were added and stirred for 15 minutes at 100 $°C$.

Fabrication of inverted silica alloy(Au-Ag) film





Silica, alloy(Au-Ag), and PMMA film were prepared by utilising vertical deposition of the self-assembly method. A clean glass substrate was placed in the mixture of PMMA+TEOS+Alloy(Au-Ag) with a volume ratio of 50µl:5µl:40µl. Then, the mixture was placed in the oven for 3 days at 60 $°C$. Inverted silica and alloy(Au-Ag) were prepared by soaking the film in acetone and heated on hot plate at 300 $°C$ to remove the PMMA template.

Results and Discussion

Characterisation of PMMA

The synthesised PMMA colloidal nanoparticles were investigated by using Fourier-transform infrared spectroscopy (FTIR). The FTIR spectra (Figure 1), of the synthesised PMMA was compared to MMA to gauge the complete polymerisation reaction of MMA to form PMMA. As shown in Table 1, there is a distinct difference in presence of C=C functional group between MMA and PMMA.

Table 1. Comparison of functional group of MMA and PMMA

Functional Group	Absorbance of MMA(cm^{-1})	Absorbance of PMMA(cm^{-1})
		
O-H	3437.68	3445.11
Sp^3 CH	2969.64-2857.88	2996.14-2843.33
C=O	1748.47	1731.91
C=C	1639.83	-
CH_3	1329.97	1449.45 & 1388.57
C-O	1169.36	1242.77

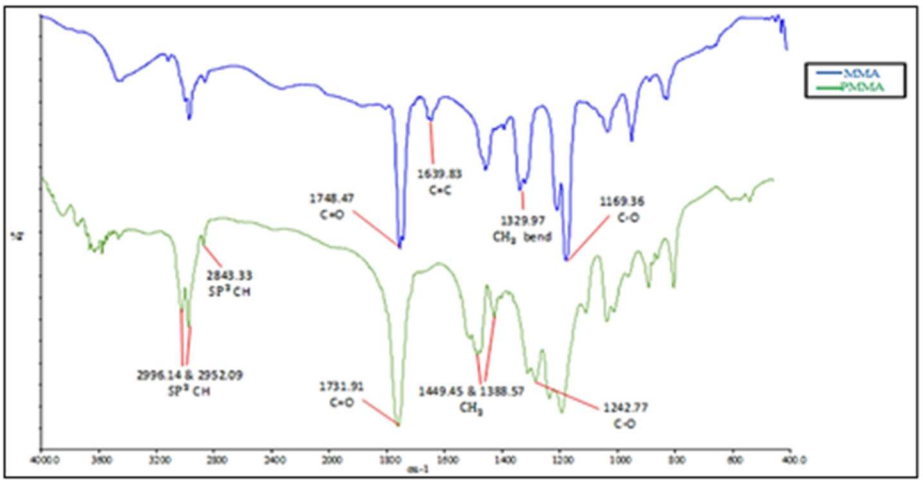


Figure 1. FTIR of methyl methacrylate(MMA) and poly(methyl methacrylate)

From the IR spectra obtained, the synthesised PMMA nanoparticles were concluded to be successful due to the absence of C=C peak at 1639.83 cm^{-1} which would be present should there be incomplete polymerisation leaving residual MMA.

Structural elucidation of the synthesised PMMA was determined by using X-ray diffraction (XRD). Figure 2 shows the XRD diffractogram of synthesised PMMA. PMMA powder was analysed in the range from 0 to 80 of 2θ at a scan speed of 2°/min. Bragg's angle was observed at $2\theta = 13.75^{0}$. Based on the XRD diffractogram, PMMA had a broad peak that suggested a complete amorphous, non-crystalline trait in nature.

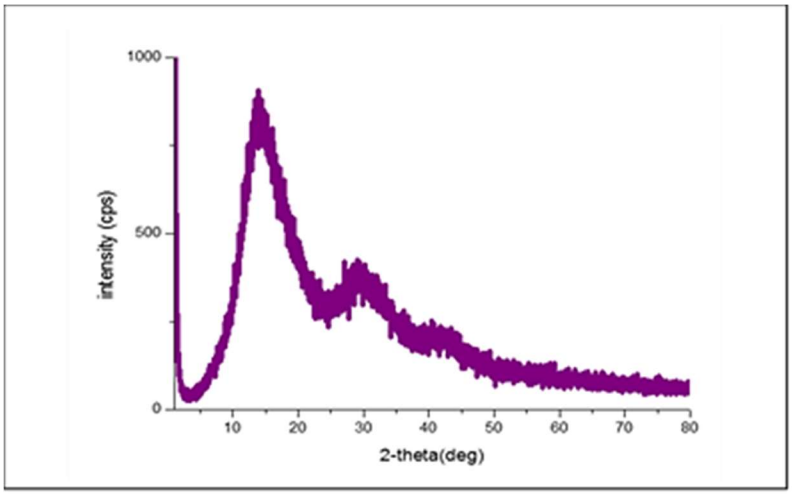

Figure 2. X-ray diffraction of synthesised PMMA

Thermogravimetric analysis (TGA) was used to further probe the purity and composition of the synthesised PMMA. Figure 3 shows the TGA curve, whereby the decomposition of PMMA and mass loss occurred in three stages.

According to Gałka et al. [21], thermal degradation of PMMA involved three stages; the first stage happened due to depolymerisation process that initiated involving head-to-head linkages, second stage involving unsaturated vinyl ends, and the last stage involving

chain scissions. For the synthesised PMMA, first stage of decomposition of PMMA occurred at 264 °C due to the loss of water and weak head-to-head bonds become decomposed. Second stage happened at 339 °C due to the radical transfer to unsaturated chain, which led to the decomposition of unsaturated chain-ends. Last stage of decomposition of PMMA occurred at 422 °C due to the random scission of polymer chains. These results conformed to established thermogravimetric analysis of PMMA thermal stability, suggesting that the success in PMMA synthesis via the method of free-emulsifier emulsion polymerisation reaction, which was the 'greener' option for fabrication.

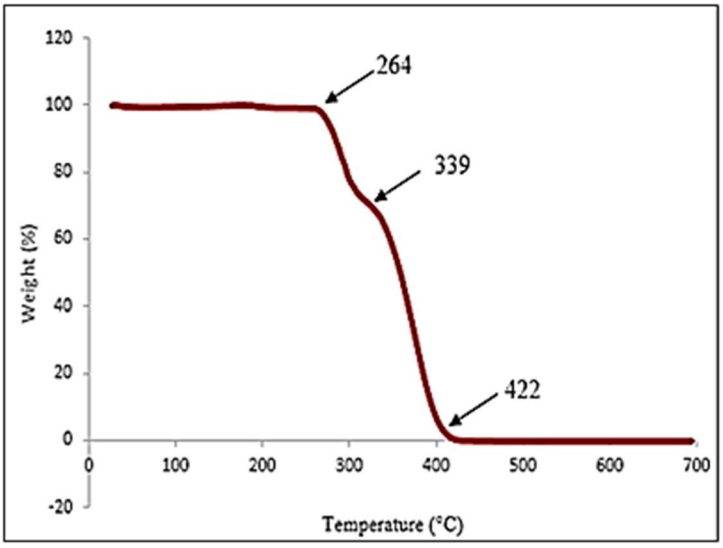

Figure 3. TGA graph of the synthesised PMMA

The surface morphology of PMMA was characterised by using scanning electron microscopic (SEM). Figure 4 shows that the PMMA produced were homogeneous sphere-shaped particles with average size of 495 nm. The homogeneous sphere shape of PMMA was obtained due to the stable control temperature throughout the experiment. Centrifugation also aided in separating PMMA particles based on density and eliminated the small particles of PMMA. The SEM images also shows the formation of well-ordered arrangement of the nanosized particles. The PMMA particles were not aggregated and had good monodispersity, which was fundamental for yielding high quality photonic crystals.

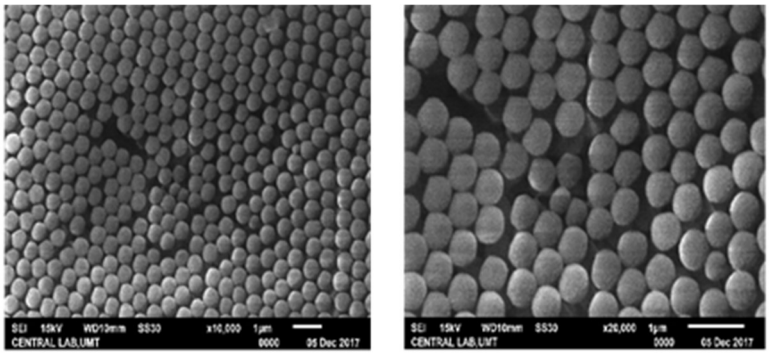

Figure 4. Scanning electron microscopic characterization of synthesised PMMA at 20000x (left) and 10000x (right)

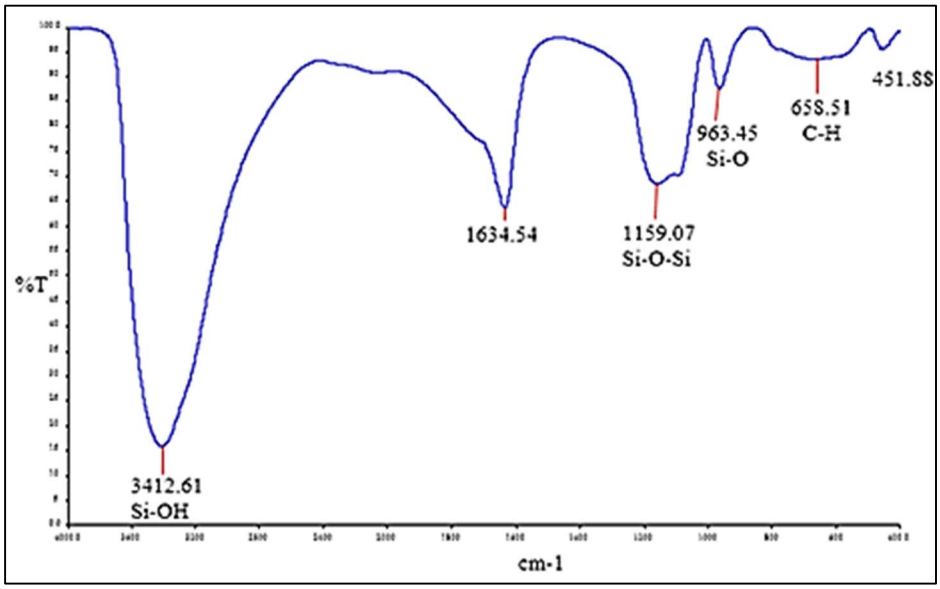
Characterisation of hydrolysed TEOS

Hydrolysed TEOS was prepared utilising sol-gel polymerisation and the functional groups of the TEOS molecule were determined by Fourier-transform infrared spectroscopy (FTIR). The functional groups in the FTIR spectra of the hydrolysed TEOS (Figure 5), is translated into Table 2.



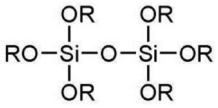


Figure 5. FTIR of hydrolysed TEOS

Table 2. Functional groups of hydrolysed TEOS

Molecular Structure of TEOS

where R is an alkyl chain

Vibrational mode	Hydrolysed TEOS (cm^{-1})
Si-OH	3412.61
Si-O-Si	1159.07
Si-O	963.45
C-H	658.51

A strong peak can be seen at 3412.61 cm^{-1} due to the stretching of Si-OH bond. Peak at 1159.07 cm^{-1} indicated the formation of Si-O-Si bond. A weak peak appeared at 963.45 cm^{-1} due to the Si-O bond. Lastly, C-H peak appeared at 658.51 cm^{-1}. This indicated the successful synthesis of hydrolysed TEOS to be used as the cementing component. The sol-gel polymerisation method involved hydrolysis and condensation

processes. First, TEOS underwent catalytic hydrolysis in the presence of HCL and water. Ethanol was added as a homogenising agent between water and TEOS, which were immiscible, and HCL was added to expediate the hydrolysis process. The condensation reaction took place under acidic condition. The Si became more electrophilic and susceptible to nucleophilic attack, forming a longer polymer network.

Characterisation of alloy(Au-Ag)

Au and Ag can strongly interact with sunlight. Silver is the commonly chosen metal nanoparticle due to its low cost and great absorption. However, silver is not the most stable. On the other hand, gold is much more stable in comparison. According to Al-Azawi et al. [22], the bimetallic nanoparticle (Au–Ag alloy nanoparticle) structure possessed a good stability, a greater ability to absorb light in a wider range of wavelength (broad LSPR peak). Also, capacity to tune the nanoparticle optical properties compared with that originating from individual nanoparticle. These; thus suggested a potential in increasing the effectiveness of a solar cell.

Absorption of alloy(Au-Ag) was determined by using ultra-violet visible spectroscopy. Typical absorption of Au is located at 521 nm, and Ag at 407 nm. Figure 6 shows a single absorption peak at 437 nm, which is the intermediate position between typical absorption of Au and Ag. This broad absorption band strongly indicated the formation of Au–Ag alloy NPs and not simply a mixture of Au and Ag NPs.

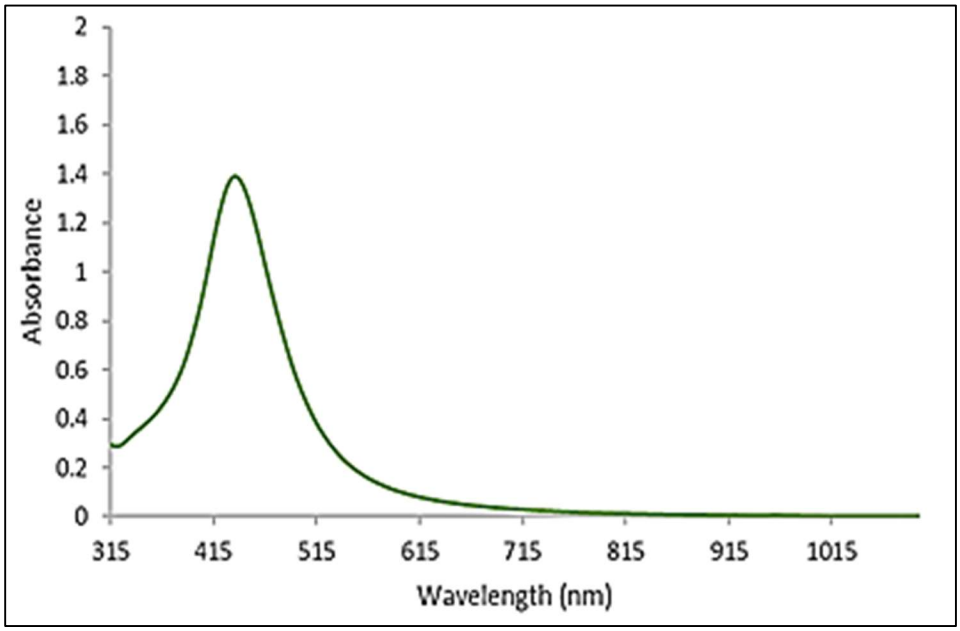

Figure 6. Ultraviolet–visible spectroscopy of alloy(Au-Ag)

Figure 7 shows the morphology of alloy(Au-Ag) characterised by SEM. SEM image revealed the properties of aggregation of alloy(Au-Ag) nanoparticle. Based on SEM image, alloy(Au-Ag) with volume ratio 1:3 had a uniform spherical shape. Au has a tendency to aggregate more than Ag due to its smaller size.

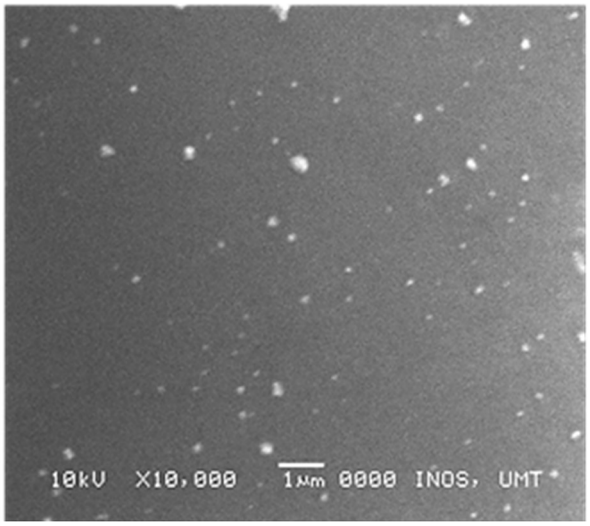

Figure 7. Morphology of alloy(Au-Ag).

Characterisation of inverted silica alloy(Au-Ag) film

The surface morphology of silica-PMMA, inverted silica, PMMA-silica-Alloy(Au-Ag) and inverted silica-alloy(Au-Ag) had been characterised by using scanning electron microscope (SEM) as shown in Figure 8.

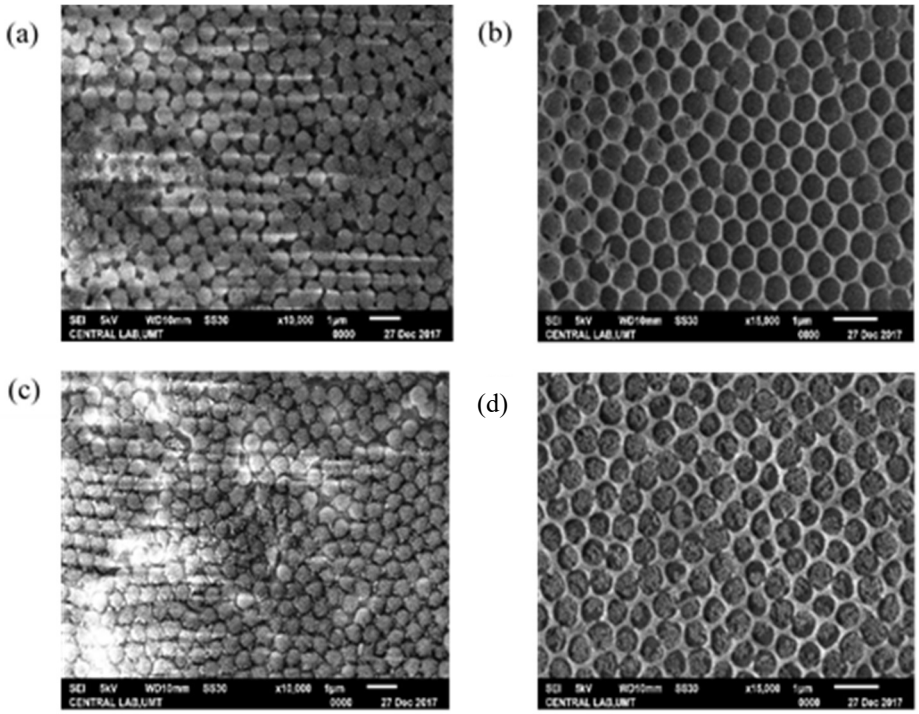

Figure 8. SEM image of silica-PMMA morphology (a), inverted silica morphology (b), silica-PMMA-alloy(Au-Ag) morphology (c), and inverted silica-alloy(Au-Ag) morphology (d)

The morphology of silica-PMMA (a) was sphere-shaped with homogenous structure of the same size. The addition of hydrolysed TEOS held the PMMA structure together and prevented cracking in the film. The structure was packed closely with almost consistently-sized spaces in between. The morphology of the inverted silica (b) showed a skeleton structure of silica after the removal of PMMA. The 'holes' were almost uniform in size and arrangement. With the addition of alloy(Au-Ag) into the solution of silica-PMMA, morphology of PMMA-silica-alloy(Au-Ag) (c) appeared to also possess spherical shape with homogenous structure of the same size, including the presence of alloy(Au-Ag) scattered around the PMMA. The morphology of the inverted silica-alloy(Au-Ag) (d) too had a skeleton structure, similar to the inverted silica (b). However, the inverted silica-alloy(Au-Ag) (d) had a 'grainy' appearance from the successful embedding of the alloy(Au-Ag) within the inverted silica structure. Precise control must be applied to obtain a completely inverted structure by tuning the volume ratio of PMMA suspension, alloy nanoparticles solution and TEOS solution during fabrication. The average diameter of the hole was observed to shrink after the removal of PMMA spheres. However, no silica backbone cracking was observed. This proved that the suitability of hydrolysed silica or TEOS as cementing agent for crack-free inverted structure. This inverted structure with the plasmonic properties of the alloy(Au-Ag) has potential in increasing the light trapping capabilities, particularly in increasing the effectiveness of a solar cell.

Performance of inverted structure towards dye sensitive solar cell (DSSC)

Inverted Si-alloy(Au-Ag) substrate with spherical holes structure contained voids that had the potential in fully trapping light within a solar cell for photovoltaic applications. The performance of inverted Si-alloy(Au-Ag) substrate in DSSC was tested by utilising a multimeter. Figure 9 illustrates the multimeter setup. It was found that the voltage reading of the multimeter increased by 0.4V when the inverted silica-alloy(Au-Ag) was applied. This showed that the inverted structure, possessing plasmonic properties of alloy(Au-Ag), had successfully trapped light and the increased the voltage of the multimeter.

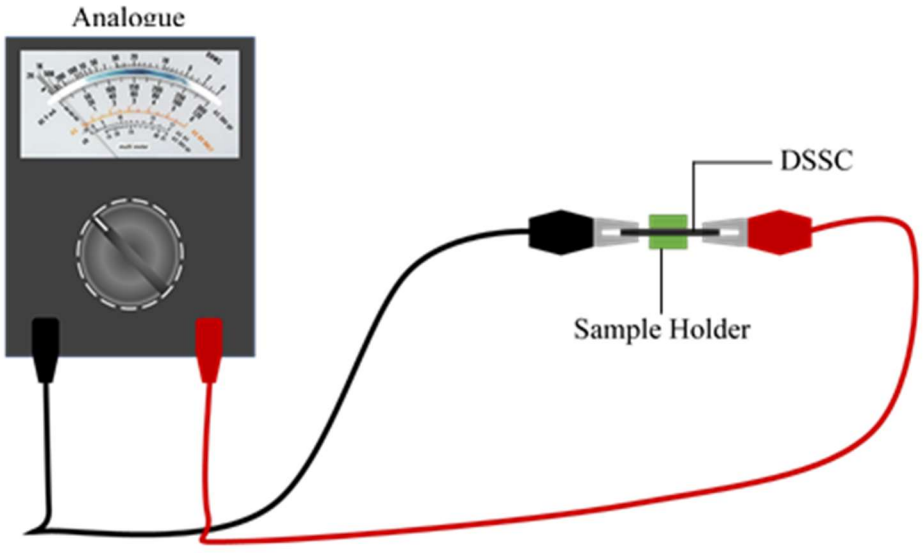

Figure 9. Simplified illustration of the multimeter setup

Conclusion

Photonic crystals or photonic band gap materials have harnessed global interest for the past decades due to the special periodic structure capable of modulating the propagation of electromagnetic waves [23, 24]. Presently, more attention is turned towards adapting inverted opal photonic crystals in light trapping and solar energy harvesting, allowing improvements in the photo-collection efficiency in dye desensitised solar cell (DSSC) and silicon solar cell through enhanced electron transport [13, 24].

In this work, the researchers presented the fabrication and structural, and optical characterisations of inverted Si-alloy(Au-Ag) composite photonic crystal via co-crystallisation method involving tetraethyl orthosilicate (TEOS) solution, poly(methyl methacrylate) (PMMA) spheres, and alloy of gold and silver nanoparticles. Polymer PMMA was synthesised via free-emulsifier emulsion polymerisation and used as template. Free-emulsifier emulsion polymerisation is an environment-friendly method of synthesising PMMA because of the absence of harmful surfactants that negatively impact the environment, particularly wastewater pollution. The reaction utilised water as dispersion medium instead of toxic solvents. The complete polymerisation of PMMA from MMA via this technique was confirmed via the absence of C=C peak at 1639.83 cm^{-1} in the FTIR spectra and further characterised via XRD diffraction analysis, thermogravimetric analysis, which aligned with the established pattern of PMMA TGA curve. Also, SEM analysis that revealed homogeneous sphere-shaped PMMA nanospheres of 495 nm in average size and good monodispersity. TEOS was successfully prepared via sol-gel polymerisation consisting of hydrolysis and condensation reaction. The initial reaction began with the use of an alkoxysilane in ethanol and resulted in a solution of siloxane polymer suitable to be used to produce a crack-free inverted structure. The FTIR spectra of TEOS collated with the molecular structure of hydrolysed TEOS to be used as cementing component. TEOS used in this research is a cheaper and non-toxic alternative to other silica precursors. Gold and silver nanoparticles were alloyed and characterised through UV-vis spectroscopy and SEM analysis. The synthesis of alloy(Au-Ag) was deemed successful as the absorption spectra of the produced alloy nanoparticles was absent of single Au and Ag absorbance peaks, indicating the absence of single Au and Ag species in the solution. Inverted silica alloy(Au-Ag) film was successfully synthesised via co-crystallisation method by implementing 'bottom-up' vertical deposition fabrication method. At each stage of the fabrication process, SEM analysis was conducted. The SEM imaging of silica-PMMA, inverted silica, silica-PMMA-alloy(Au-Ag), and inverted silica-alloy(Au-Ag) compared the 3D nanostructures pre-PMMA removal and post-removal through calcination process, and the absence and presence of the alloy(Au-Ag). The inverted silica-alloy(Au-Ag) film fabricated possessed consistent skeleton hole structure of rough-textured grainy surface appearance, notably ideal for light manipulating functions [25, 26].

In this paper, the researchers also investigated briefly the effect of silica-alloy(Au-Ag) substrate towards DSSC, as it is one of the most common purposes of photonic crystals in solar technology. The two are almost synonymously mentioned in any search. The inverted structure of silica-alloy(Au-Ag) had proven to trap light within a solar cell, consequently increasing its effectiveness. This is due to the skeletal structure of the substrate combined with the plasmonic properties of alloy(Au-Ag) of which increased the multimeter reading by 0.4V once applied.

The systematic light trapping properties of inverted silica-alloy(Au-Ag) nanostructure provide much room for future work in exploring further applications of the material synthesised in this work. Surface-enhanced Raman spectroscopy (SERS) is an excellent vibrational analytical technique for probing minute molecules bound in proximity to plasmonic surfaces [27,28]. The material synthesised in this study allowed for effective light trapping and photon density state, combining with the alloy nanoparticles of Ag that produced impressive SERS signal intensities, and Au that is highly resistant to oxidation [29]. Aside from that, the procedures in synthesising these substantially homogenous inverse silica-alloy(Au-Ag) by using PMMA and environment-friendly surfactant-free dispersion medium and linking agent makes mass producing this material an easier,

cheaper, a 'greener' sustainable approach to SERS substrate. Inverse silica-alloy(Au-Ag) requires a short fabrication time and could be integrated into plasmonic biosensors and point-of-care devices in the studying and monitoring of disease progression. Moreover, the composite could be easily modified or coated to be relatively safe and biocompatible for further study in *in vivo* applications [30,31]. Optical microchips could significantly minimise the power consumption of computers and permits exponentially faster data processing speed. With some fine-tuning, the photonic band gap of 3D silica-alloy(Au-Ag) photonic crystal allows for not just the simple trapping of light but also guiding light beyond the traditional method that is rooted in total internal reflection, such as optical fibres [32]. Incorporation of silica-alloy(Au-Ag) in optoelectronics could be made possible in offering important advantages over 2D electronic chips and expand the class of optical telecommunications in a variety of fields, including engineering and medicine in future studies [33].

Abstract

Metal-organic frameworks (MOFs) have been touted as prospective materials for drug storage and delivery. Functionalizing MOFs with an amine group has proven to be a successful strategy to achieve enhanced drug adsorption. To the best of our knowledge, however, there no report has been published showing the impact of increasing a common functional group such as amine on MOF's performance for drug adsorption. With the aim of exploring this possibility, IRMOF-74-III (IRM3) was functionalized with the amine group in various numbers and positions on the phenyl ring of the organic linker. The ability to adsorb several candidate drugs, including aspirin (Asp), fenbufen (Fen), ibuprofen (Ibu) and naproxen (Nap), were tested using density functional theory calculations and molecular docking. When the number of the amines increased, the MOF's pore polar surface area increased, but the energy gap between the HOMO and LUMO orbitals was reduced. Different pockets on the amine-functionalized IRM3's pore wall were analyzed by electrostatic potential contours, and then further investigated by a docking simulation. Fen@MOF was shown to be the most stable drug@MOF complex system, as demonstrated by the highest binding affinity. Coordinatively unsaturated magnesium sites in the frameworks, as well as hydroxyl and carbonyl groups on the drugs, are crucial for the interactions and charge transfer. This work successfully highlighted that having different numbers and positions of the amine group on the organic linker can affect the drug adsorption behavior of IRM3 MOF.

Keywords: amine-functionalized, anti-inflammatory drug adsorption, IRMOF-74-III, metal-organic frameworks, molecular docking

Abstrak

Rangkaian logam-organik (MOF) telah diketengahkan sebagai bahan prospektif bagi penyimpanan dan penghantaran ubatan. Berkenaan ini, memfungsikan MOFs dengan kumpulan amina adalah strategi yang berjaya bagi menambah baik jerapan ubatan. Walaubagaimanapun, mengikut pengetahuan kami, buat masa kini masih tiada laporan menunjukkan impak penambahan kumpulan berfungsi umum seperti amina terhadap prestasi MOF bagi jerapan ubatan. Dengan tujuan menerokai kemungkinan ini, IRMOF-74-III (IRM3) telah difungsikan dengan kumpulan amina dengan jumlah dan kedudukan yang berbeza pada cincin fenil penyambung organik. Kemampuan untuk menjerap beberapa calon ubat termasuklah aspirin (Asp), fenbufen (Fen), ibuprofen (Ibu) dan naproxen (Nap) telah diuji menggunakan pengiraan teori berfungsi ketumpatan dan pendokkan molekul. Adalah didapati bahawa jika jumlah kumpulan amina meningkat, permukaan berkutub MOF juga meningkat tetapi jurang tenaga di antara orbital HOMO dan LUMO adalah berkurang. Saku berbeza pada dinding rongga IRM3 terfungsi-amina dianalisa menggunakan kontur keupayaan elektrostatik dan disiasat lebih lanjut oleh simulasi pendokkan. Fen@MOF mempamerkan sistem kompleks drug@MOF yang paling stabil dan disahihkan oleh afiniti pengikat tertinggi. Tapak magnesium tak tepu yang terselaras di dalam rangkaian, dan juga kumpulan hidroksil dan karbonil pada ubat adalah penting bagi saling tindakan dan pemindahan cas. Kerja ini berjaya mengetengahkan yang memiliki kumpulan amina pada jumlah dan posisi berbeza pada penyambung organik boleh memberi kesan kepada sifat penjerapan ubatan MOF IRM3.

Kata kunci: terfungsi-amina, penjerapan ubat anti-inflamasi, IRMOF-74-III, rangka logam-organik, pendokkan molekul

Introduction

Metal-organic frameworks (MOFs) are a class of porous materials constructed by a mixture of metal nodes and organic linkers [1]. They have been extensively investigated in numerous applications, such as catalysis [2], gas adsorption and separation [3], biosensing and bioimaging [4], water purification [5], and drug delivery [6]. MOFs with partially coordinated metals, commonly known as coordinatively unsaturated metal sites (CUSs), can be obtained by removing the solvent via the activation step [7, 8]. MOF structures containing CUSs have great potential for drug adsorption. IRMOF-74 is a series of isoreticular MOF-74 that possess a similar topology that was initially synthesized by Yaghi et al. [9]. IRMOF-74 MOFs have become attractive for encapsulating drugs, since the magnesium (Mg) metal ion has low toxicity, and polycarboxylic linkers can be removed under physiological conditions [10].

The IRMOF-74 series comprises a variety of pore sizes such that each MOF can be employed for a specific amount of drug loading. For example, MOF-74-I demonstrated the lowest methotrexate (MTX) and 5-fluorouracil (5-FU) loading at 0.31 and 0.71 $g.g^{-1}$, respectively, primarily due to the smallest pore size among the IRMOF-74 family members [11]. In contrast, IRMOF-74-XI showed 2.78 and 4.24 $g.g^{-1}$ for MTX and 5-FU storage, respectively. Preparing IRMOF-74s comprising CUSs has made them more efficient for drug adsorption. Fairen-Jimenez et al. elucidated that the adsorption of ibuprofen (Ibu) inside MOF-74 pores was influenced by hydrogen bond (HB) interactions among polar hydrogen atoms in Ibu and the oxygen atoms surrounding Mg, and more importantly, the coordination bond between oxygen atoms in Ibu and Mg CUSs (O–Mg) [12].

The intrinsic tunability of pore size and pore wall surface in IRMOF-74-III (Figure 1-a) is achievable by incorporating functional groups on organic linkers via either pre-functionalization [13] or the post-synthetic modification (PSM) method [14]. For example, seven reactions based on the PSM method were carried out for sequential incorporating tripeptides on amine-functionalized IRMOF-74-III [14]. Amine functionalization onto MOFs have been shown to improve drug adsorption [15–17]. Among the frequently investigated amine-functionalized MOFs, however, the effect of increasing the number of amine-functionalized organic linkers on drug adsorption has not been further investigated. Incorporating two amine groups on the phenyl ring in organic linkers as *ortho*, *meta* and *para* positions may potentially generate different dynamic and electronic conditions on the pore wall. Theoretical design and computational explorations are useful tools for a better understanding by reducing the cost of time and chemicals. Moreover, computational strategies provide a conceptual understanding of the physiochemical properties of organic linkers, desirable conformation of drug molecules on the MOF pore

surface, and host-guest interactions. These are crucial factors for rational functionalization, higher drug loading and controlled drug release.

In this work, we utilized computational methods to characterize a variety of amine-functionalized IRMOF-74-IIIs, hereafter referred to as IRM3 (Figure 1-b). Corresponding amine-functionalized IRM3 MOFs were then employed to encapsulate four non-steroidal anti-inflammatory drugs (NSAIDs), including aspirin (Asp), fenbufen (Fen), ibuprofen (Ibu) and naproxen (Nap) (Figure 1-c). NSAIDs are consumed to ease the pain and inflammation by inhibiting the cyclooxygenase enzyme [18]. These drug compounds are frequently used by numerous researchers, as they are cheap and abundantly available in laboratories [19, 20]. Due to the hydrophobic property of NSAIDs, they are poorly-water soluble, which can result in erratic absorption and low bioavailability. Hence, encapsulating NSAID drug molecules within porous solid material such as MOFs is highly recommended to improve drug adsorption and delivery [21, 22].

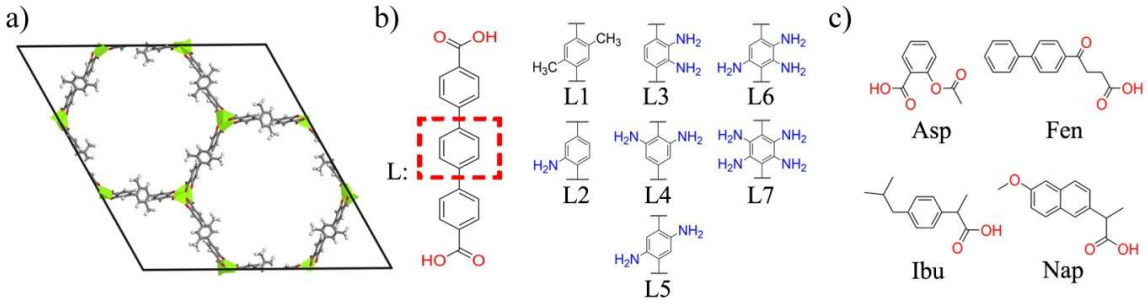

Figure 1. a) Unit cell of IRMOF-74-III, b) parent organic linker (L1) and the amine-functionalized organic linkers (L2-L7), and c) structure of NSAID drugs molecules

Computational Details

Geometry optimization of the organic linkers (L1-L7) was carried out using Gaussian 09 [23]. The structures were optimized at their ground state and gaseous phase. In order to characterize the organic linkers using an accurate level, DFT-B3LYP functional with a basis set of 6-31+G(d) was adopted. This level of computation generates highly accurate electronic properties. The corresponding basis set supports all atom types used in the frameworks (Mg, O, N, C, and H) and drug molecules (O, C, and H). Subsequently, the outputs allow us to analyze frontier molecular orbitals (FMOs), polarizability (α), topological polar surface area (TPSA) and dipole moments (μ) for organic linkers. At the same level of computation, single point energy calculation was carried out for the frameworks derived from the organic linkers to obtain the electrostatic potential (ESP) contours.

All amine-functionalized IRM3s were derived from the crystal structure of Mg-IRMOF-74-III available at the Cambridge Crystallographic Data Centre (CCDC), with deposition code 841643 [9]. The unit cell was extended to 2×2×5, and the supercell model was situated in a vacuum box for docking calculation. Then, the center of the supercell was set for the grid box as 120×90×60 points in the three dimensions for the docking simulation. In addition, a grid spacing of 1.000 Å was set to cover the two central pores of the large frameworks. AutoDock version 4 and AutoDock Vina version 1.1.2 [24] were employed to implement the automated molecular docking calculation of drug molecules inside the MOFs. The Lamarckian genetic algorithm (LGA) combined with a grid-based energy evaluation method were applied to evaluate the grid maps. Gaussian 09 was utilized to calculate the atomic partial charges using the CHarges from ELectrostatic Potentials using a Grid-based (CHELPG) method [25] based on B3LYP/6-31+G(d) level.

The optimal pose of the drug molecules on the MOF surface was considered for natural bond orbital (NBO) analysis. The smaller cluster structures containing drug@MOF were separated from the docking results

and used for single point energy calculation at B3LYP/6-31+G(d) level. NBO version 3.1 [26], available in the Gaussian 09 package, was used for the energy calculation. The second-order perturbation theory from the NBO calculation was then used to identify the electron donor and acceptor between the NSAID drugs and the IRM3 frameworks.

Results and Discussion

Geometry optimization at level DFT-B3LYP/6-31+G(d) was implemented to interpret the physiochemical properties of the organic linkers (L1-L7). FMO analysis described the chemical reactivity of the proposed organic linkers. FMOs were divided into the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO). HOMO orbitals were found to be distributed on the whole of the parent organic linker (L1). However, they were clearly localized on the middle phenyl ring when the methyl groups were replaced by amine groups (L2-L7) (Figure 2). The formation of HOMOs in all types of amine-functionalized linkers followed the number and position of amine groups. Being localized HOMOs in the middle phenyl ring with different formations can be useful for donating electrons to the electrophilic sites in the drug molecules. On the other side, the formation of LUMO orbitals remained almost constant in all organic linkers (L1-L7).

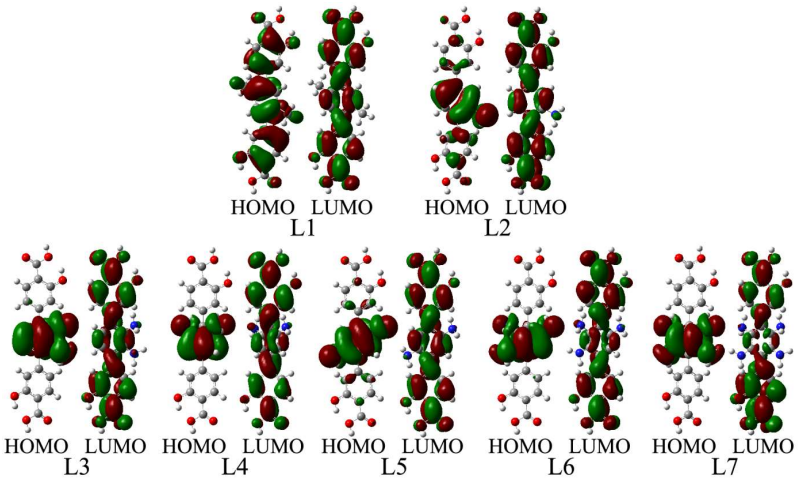

Figure 2. HOMO and LUMO orbitals for all the organic linkers

According to Table 1, the organic linkers demonstrated different values for the energy gap between the HOMO and LUMO orbitals (E_{HL}), polarizability, TPSA and dipole moments. The values of E_{HL} showed that increasing the substitution of the amine functional group on the organic linkers made them more kinetically stable. For example, the large value of E_{HL} in L1 implies difficult electron transfer, whereas a small value of E_{HL} in L7 indicates more facile electron transfer between HOMO and LUMO, as well as easier electrons donating to the electrophilic sites in the drug molecules. Incorporating the amine functional group generally caused the polarizability (α) of the organic linkers to improve. The TPSA parameter determines the overall surface on all polar atoms within the molecular structure. The calculated TPSA confirmed the enhancement of the polar surface by increasing the amine group on linkers. Although the organic linker containing one amine group (L2) had the lowest polarizability (α), it produced a high amount of dipole moments (μ). Dipole moments play an important role in adsorption using MOFs. Srepusharawoot *et al*. studied the capability of four different metal-organic framework-525, namely, M-MOF-525 (M= Ti, V, Zr and Hf) for hydrogen adsorption using first-principles calculations [27]. The authors found that Zr- and Hf-MOF-525 were able to trap the hydrogen molecules on the surface due to stronger dipole moments. Also, zero values of dipole moment for L1 and L5 were obtained from *para* position of the functional groups, which means equal electron distributions on the middle phenyl ring.

Table 1. Physiochemical properties for the organic linkers

Compound	E_{HL} (eV)	α (A^3)	TPSA (A^2)	μ (D)
L1	4.41	46.24	115.1	0.00
L2	3.77	45.84	141.1	1.70
L3	3.58	46.52	167.1	1.29
L4	3.57	46.66	167.1	1.65
L5	3.14	47.59	167.1	0.00
L6	3.12	47.73	193.1	0.86
L7	2.76	48.24	219.1	0.64

In this report, the frameworks derived from the proposed organic linkers (L1-L7) are referred to as IRM3 (L1), IRM3-1 (L2), IRM3-2*o* (L3), IRM3-2*m* (L4), IRM3-*p* (L5), IRM3-3 (L6) and IRM3-4 (L7). The electrostatic potential (ESP) contours for all the frameworks are illustrated in Figure 3. The ESP contours revealed a highly distinguished pattern for each MOF's pore when the functionalized-amine groups were increased or placed in the *ortho*, *meta* or *para* positions. The conversion of the hexagonal ESP pattern in L1 to the trigonal ESP pattern for L2-L7 was attributed to the different symmetry point group of the functional groups. The symmetry point group for the methyl and amine functional groups is C_{3v} and C_{2v}, respectively. Therefore, an R-3 symmetry was detected for the crystal structure of IRM3, whereas an R3 symmetry was observed for all amine-functionalized IRM3s. The EPS contours of the MOF crystals represented by red lines indicate negative potentials on the phenyl rings and the amine groups due to stronger electron distribution. This feature was amplified by increasing the amine groups on the linkers (the most for L7).

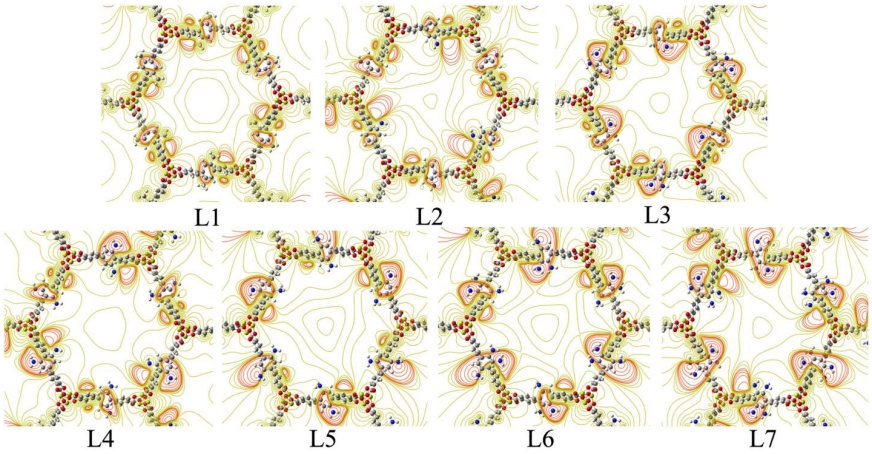

Figure 3. Electrostatic potential (ESP) contour for the frameworks

Overall, the DFT study of the organic linkers (L1-L7) and their corresponding frameworks demonstrated that HOMOs were localized where amine functional groups were incorporated in the middle phenyl ring. These changes were also illustrated by the ESP contour patterns. Middle phenyl rings had a higher electron density as the number of amine groups was increased. In addition, the values of polarizability (α) and TPSA demonstrated that increasing functional groups on IRM3 organic linker enhanced the polarity. It is expected that increasing the number of amine groups on IRM3 organic linkers would activate the MOF pore surface to trap more drug molecules by donating more electrons. All frameworks were further investigated for the adsorption of NSAID drug molecules by means of molecular docking simulation and NBO calculation to determine

the most favorable interaction site and the intensity of electron transmission, respectively. As depicted in Figure 4, all amine functionalized IRM3s produce different pockets (orange color) in the CUSs. This property could also be observed in the EPS contour. In comparison, the tightest pocket in the CUSs tend to be in IRM3-2*o* and IRM3-4, whereas the largest pocket was in IRM3-2*m*. The distance between the amine groups on the linker clearly influence the size of pockets in the CUSs.

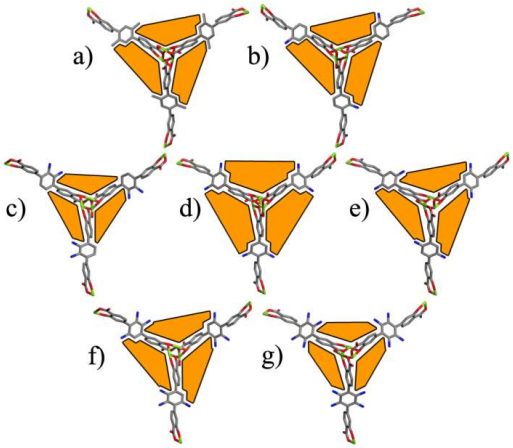

Figure 4. 2D schematic presentation of the pockets in CUSs for a) IRM3, b) IRM3-1, c) IRM3-2*o*, d) IRM3-2*m*, e) IRM3-2*p*, f) IRM3-3 and g) IRM3-4

Binding affinity can be defined as the degree of the binding of the drug molecules in the MOF pores [28]. Docking simulation using Autodock Vina produced nine modes of binding affinity (kcal mol^{-1}) for each drug@MOFs complex system. The first (best) mode value was used to construct Figure 5. The variety of binding affinity values generated by each drug@MOF complex confirmed that the pockets on CUS sites had various spaces and morphologies. The highest binding affinity was produced by the Fen molecule, whereas the lowest binding affinity was exhibited by Asp. This result could be attributed to their molecular size, as Fen and Asp have the largest and the smallest molecular size, respectively. The measured drug molecular size was shown as the order of Asp (10.6 × 8.9 Å) < Ibu (12.9 × 7.8 Å) < Nap (13.6 × 7.9 Å) < Fen (17.2 × 7.5 Å). Being the largest size of Fen led to the strongest fitting into the CUS pockets. In contrast, being the smallest size of Asp made it the least fitting. Moreover, Ibu and Nap docked into the CUS pockets and Asp due to a larger molecular size.

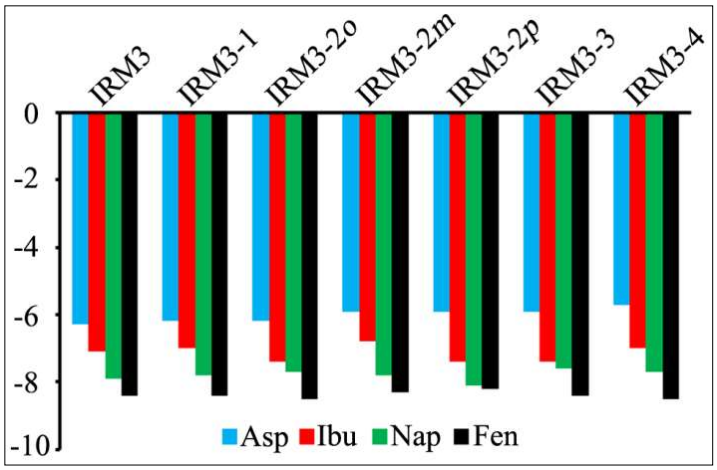

Figure 5. Bar chart derived from the first mode of the binding affinity

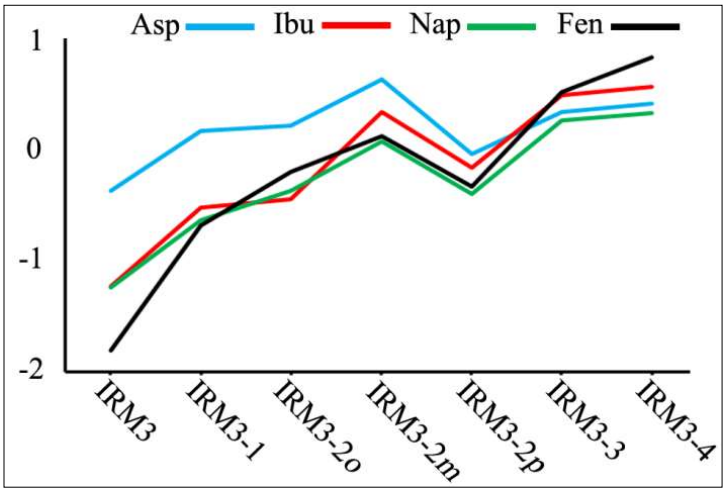

Figure 6. Line chart derived from the first rank of the binding energy

The highest rank of binding energy calculated by AutoDock is presented in Figure 6. The line chart shows a general upward trend for binding energies as the number of functionalized amine groups increase. These results suggest that the strength of the total interactions between the NSAID drug molecules and the frameworks was reduced. Drug molecules had a lower binding energy and stronger interactions when they were complexed in IRM3-2*p* compared to the other two isomers, IRM3-2*o* and IRM3-2*m*. Additionally, among the two isostructures, IRM3 and IRM3-2*p*, which differ only on the type of functional group, the positive charge of magnesium (Mg) (+1.3184) in IRM3 was reduced to +1.3003 in IRM3-2*p*. This change was governed by the inductive effect of the polar functional group such as the amine group [29]. Thus, the binding energies produced by drug@IRM3 complex systems had the lowest values (the strongest interactions). In general, increasing amine groups on organic linkers reduced the strength of interactions in the drug@MOF complex systems.

Using MOF-1 and MOF-4, which have identical pore sizes, Zhang et al. observed reduced drug loading due to weaker interactions between Ibu and the pore surface [30]. It was shown that stronger interactions between the carboxyl group in Ibu and MOF-1 pore surface resulted in a two fold higher loading compared to MOF-4. In addition, the abundance of the secondary interactions such as hydrogen bond (HB), and electrostatic and hydrophobic interactions, play a crucial role in controlled drug release after drug loading [12, 31, 32].

Considering the matter of host-guest interactions, all types of interactions between the frameworks and the drug molecules were collected in Table 2. An analysis of the interactions indicated that the drug molecules mainly built interactions on the CUSs in IRM3, IRM3-1, IRM3-2*m* and IRM3-2*p*. On the other side, NSAID drugs were observed to have amine-based HB interactions when they were complexed in IRM3-2*o*, IRM3-3 and IRM3-4. The presence of two neighboring amine functional groups on the middle phenyl ring seemed dominant to CUS sites, since they provide large enough polar surfaces. Figure 7 shows an example of this behavior. The top three binding modes of Nap indicated that they were preferably placed on CUS sites in IRM3-2*p*. In contrast, they were concentrated on amine functional groups in IRM3-3. By comparing the interaction distances in Table 2, we found that IRM3, IRM3-1, IRM3-2*m* and IRM3-2*p* generally provided abundant and strong interactions with drug molecules on CUSs. Some examples are metal-acceptor interactions ($Mg_{framework} \cdots OC_{drug}$), oxygen-based HB interactions ($O_{framework} \cdots HO_{drug}$), and plenty of hydrophobic (π-based) interactions. In contrast, drug molecules had amine-based HB interactions with IRM3-2*o*, particularly in IRM3-3 and IRM3-4. The results obtained indicate that the functionalizing of MOFs using two neighboring amine groups on organic linkers close to CUS sites would disrupt the capability of CUS for the adsorption of drug molecules.

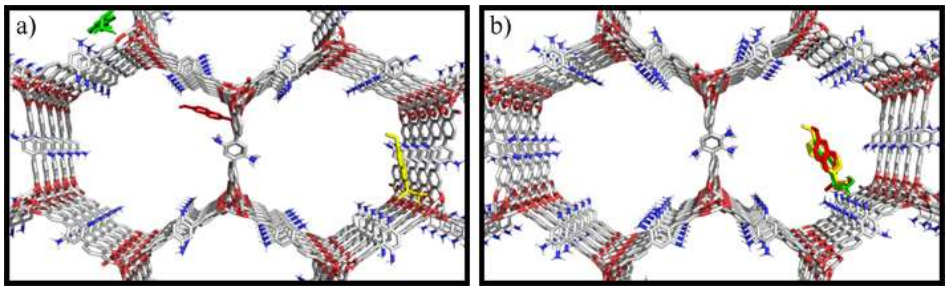

Figure 7. The top three binding modes of Nap in a) IRM3-2*p* and b) IRM3-3

Single point energy calculations allowed us to evaluate the electron transfer between the NSAID drug molecules and the frameworks using NBO analysis. The four highest NBO donor-acceptor interactions between the drug molecules and the frameworks are compiled in Tables 3 to 6. The atomic numbers of NSAID drug molecules are illustrated in Figure 8. The calculated stabilization energies (E_{ij}) indicate that all the drug molecules transferred the most electrons when they were complexed with IRM3. Lone electron pair (LP) of oxygen atoms in the drug molecules and unfilled valence-shell nonbonding (LP*) of Mg in the frameworks played the primary role as the electron donor and the electron acceptor, respectively, in drug@IRM3, drug@IRM3-1, drug@IRM3-2*o*, drug@IRM3-2*m*, and drug@IRM3-2*p*. However, the NBO donor-acceptor interactions derived from drug@IRM3-3 and drug@IRM3-4 complex systems primarily involved the amine functional group, and the corresponding values of stabilization energies (E_{ij}) were relatively poor. This evidence from NBO analysis confirmed that CUSs were the most favorable sites for stronger electron transfer and adsorption of the NSAIDs molecules.

Conclusion

In this computational work, a set of amine-functionalized IRM3 was derived from the parent structure (IRMOF-74-III). Initially, all organic linkers (L1-L7) were characterized at the DFT level. The results indicated that the increase of the amine group on organic linkers extended the polarity of the MOF pore surface and decreased the values of E_{HL}. The reduced E_{HL} in the MOFs containing more amine groups indicate their capability to donate electrons to drug molecules during binding. This was corroborated by the evaluation of framework-drug interactions and NBO analysis. NSAID drug molecules were found to prefer accommodating on CUS sites, which resulted in a variety of framework-drug interactions and a stronger electron transfer. In this set of drug@MOF complex systems, NBO analysis revealed that electron transfer from lone pair of electrons on oxygen atoms in the drugs to magnesium CUSs had the highest energy stabilization. Meanwhile, drug molecules were found more on organic linkers, making amine-based HB interactions when two neighboring amine groups were present such as in IRM3-2*o*, IRM3-3 and IRM3-4 MOFs. In addition, it was found that larger NSAID drug molecules had better fit into the CUS sites in the order of Fen > Nap > Ibu > Asp. Our results provide valuable insights on functionalizing MOF containing CUS sites with amine groups to improve drug encapsulation.

Abstract

Rhodamine B (RhB) is an organic dye which is generally used in paint, paper and textile industries as a tracer dye. It is found to be highly toxic to living organisms and is expected of having carcinogenic effect. Therefore, the effluents containing RhB dye should be properly treated before releasing into water bodies, such as, rivers, ponds, etc. In this research work, attempts were made to prepare and use zinc doped ceria ($Ce_{1-x}Zn_xO_{2-\delta}$; x = 0, 0.1, 0.2, 0.3, 0.4, 0.5) nanoparticles as photocatalysts to remove RhB dye present in water. These nanoparticles were synthesized by simple wet chemical technique using cheap chemicals. The prepared materials were analyzed by X-ray diffraction (XRD), Fourier transform infra-red (FTIR), Energy-dispersive X-ray spectroscopy (EDX), scanning electron microscope (SEM), ultra violet-visible (UV-Vis) and photo-luminescence (PL) spectroscopy methods. The samples were indexed in face-centered cubic (FCC) crystalline structure. FTIR showed M-O bond in the samples. EDX notified the occurrence of appropriate elements. SEM exhibited smaller and bigger grains in the materials. The λ_{max} was found to be 349 nm by UV-visible analysis. The band gap energy (E_g) was reported in the range of 1.5-3 eV. The photoluminescence spectra for all suspensions were obtained in the range of 390 to 550nm. Then, the photocatalytic elimination of Rhodamine B (Rh B) with the help of $Ce_{1-x}Zn_xO_{2-\delta}$ nano-photocatalysts under UV light was studied. Among the several trials studied, highest photodegradation efficiency (58.71%) was found at pH=11 after 60 minutes irradiation in UV light at room temperature for $Ce_{0.60}Zn_{0.40}O_{2-\delta}$.

Keywords: Zn doped CeO_2 nanoparticles, Rhodamine B, dye removal, photocatalytic degradation, UV irradiation

Abstrak

Rhodamine B (RhB) ialah pewarna organik yang biasanya digunakan dalam industri cat, kertas dan tekstil sebagai pewarna pengesan. Ia didapati sangat toksik kepada organisma hidup dan dijangka mempunyai kesan karsinogenik. Oleh itu, efluen yang

mengandungi pewarna RhB hendaklah dirawat dengan betul sebelum dilepaskan ke dalam badan air, seperti sungai, kolam, dsb. Dalam kerja penyelidikan ini, percubaan telah dibuat untuk menyediakan dan menggunakan ceria terdop zink ($Ce_{1-x}Zn_xO_{2-\delta}$; x = 0, 0.1, 0.2, 0.3, 0.4, 0.5) nanopartikel sebagai fotomangkin untuk menghilangkan pewarna RhB yang terdapat dalam air. Nanopartikel ini telah disintesis dengan teknik kimia basah mudah menggunakan bahan kimia murah. Bahan-bahan yang disediakan telah dianalisis dengan pembelauan sinar-X (XRD), infra merah transformasi Fourier (FTIR), spektroskopi sinar-X penyebaran tenaga (EDX), mikroskop elektron pengimbasan (SEM), Ultra ungu-cahaya nampak (UV-Vis) dan kaedah spektroskopi foto-pendarcahaya (PL). Sampel telah diindeks dalam struktur hablur kubik berpusat muka (FCC). FTIR menunjukkan ikatan M-O dalam sampel. EDX memberitahu berlakunya elemen yang sesuai. SEM mempamerkan butiran yang lebih kecil dan lebih besar dalam bahan. λ_{maks} didapati 349 nm oleh analisis UV-cahaya nampak. Tenaga jurang jalur (Eg) dilaporkan dalam julat 1.5-3 eV. Spektrum foto-pendarcahaya untuk semua suspensi diperoleh dalam julat 390 hingga 550nm. Kemudian, penghapusan fotomangkin Rhodamine B (Rh B) dengan bantuan fotomangkin nano $Ce_{1-x}Zn_xO_{2-\delta}$ di bawah cahaya UV telah dikaji. Antara beberapa ujian yang dikaji, kecekapan fotodegradasi tertinggi (58.71%) didapati pada pH=11 selepas 60 minit penyinaran dalam cahaya UV pada suhu bilik untuk $Ce_{0.60}Zn_{0.40}O_{2-\delta}$.

Kata kunci: nanopartikel CeO_2 terdop Zn, Rhodamine B, penyingkiran pewarna, degradasi fotokatalitik, penyinaran UV

Introduction

Prestigious revolution by nanoscience especially nano metal oxides is being noticed nowadays because of its tremendous application in the fabrication of medical devices [1-4], sensors [5-7], photo catalysts [8-10], etc. The pollutants in particular organic dyes released by the textile industries are affecting the environment seriously. Hence, the elimination of organic dye molecules from the effluent water of textile industry is an urgent issue. Among different organic dyes reported, Rhodamine B is found to be highly harmful when swallowed, with acute oral toxicity, causes serious eye damage or irritation, hazardous to the aquatic environment with long-term side effects [11]. Different technologies, such as, adsorption, ozonation, advanced oxidation process (AOP), membrane filtration, biological methods [12-13] have been tried across the globe for the past two decades to remove the variety of organic dyes present in water. AOP was found to be good in removing different kind of dye molecules and other organic effluents [14-16].

Recently, it was noticed that photocatalysis can also be involved in degrading the organic dyes present in the textile effluents [17]. Metal oxide nanoparticles were found to be effective as photocatalysts [18]. Ceric oxide (CeO_2) is a widely used rare earth oxide material with attractive scientific, technological, energy and environmental applications [19]. The physico-chemical properties, such as, photoluminescence and photocatalytic activity were improved by doping Zn in Ce site of CeO_2 [20]. Further, 1% nickel (Ni) doping was found to retard the band gap of undoped ceria, which could be associated with the reduction of the average crysllite size and therefore, it is considered to be an optimum dopant for ceria [21]. The thermal stability of CeO_2 was improved by doping lanthanum (La) [22]. Iron (Fe) doped CeO_2 nanoparticles exhibited excellent dielectric properties and antimicrobial activity especially in the persistence of bacterial infection [23].

In this research work, to improve the material characteristics of ceria, the metal ion like Zn is doped in cerium lattice of CeO_2 with varying concentration. It was reported that doping Zn into CeO_2 could result in better UV absorptivity [24]. The present study deals with two parts. The first part involves the synthesis and characterization of zinc doped ceria ($Ce_{1-x}Zn_xO_{2-\delta}$; x = 0, 0.1, 0.2, 0.3, 0.4, 0.5) nanoparticles. The second part is about the photocatalytic studies of zinc doped ceria nanomaterials in degrading the Rh B dye found in the water sample under UV light illumination. The obtained experimental results were analyzed in a detailed manner in this research article.

Materials and methods

Chemicals and reagents

Analytical grade of ceric nitrate hexahydrate, zinc nitrate hexahydrate, sodium hydroxide and ethanol were procured and used in this study as such.

Material preparation

Stoichiometric quantities of metal nitrates (cerous nitrate and zinc nitrate) were dissolved in ultra-pure

water. The precipitant solution (NaOH) was mixed drop-wise to the metal nitrate salts solution with constant stirring in a magnetic stirrer. The pH of the solution was kept above pH 9 during the course of the reaction. The resultant precipitate (cerium hydroxide and zinc hydroxide mixture) was filtered-off using Whatman filter paper and cleaned thoroughly without any impurities using the mixture of distilled water and ethanol (9:1 v/v). Then, the precipitate mixture was dried in an air oven and calcined at 600 °C. This resulted as a pure $Ce_{1-x}Zn_xO_{2-\delta}$ (where x = 0, 0.1, 0.2, 0.3, 0.4 and 0.5) nanoparticles. The amount of chemicals used to prepare the materials is indicated in Table 1. The possible reaction mechanism for this preparation is indicated in Equation 1.

$$(1\text{-}x)\ Ce(NO_3)_3 + x\ Zn(NO_3)_2 + 2\ NaOH \rightarrow Ce_{1-x}Zn_xO_{2-\delta} + 2\ NaNO_3 + y\ H_2O \quad \text{(eq. 1)}$$

where x = 0, 0.1, 0.2, 0.3, 0.4 and 0.5

Characterization of materials

X-ray diffraction measurement (XRD) was conducted using X-ray diffractometer (in Shimadzu XRD 6000) at 30 mA current and voltage of 40kV involved the usage of Cukα (K=0.154059nm) radiation with a nickel filter. The 2θ scanning range was 2˚ to 80˚ at a continuous scan mode with a scan speed of 10˚/min. The unit cell parameter was measured by DOS computer programming. The average crystallite size for the samples was determined by Debye –Scherrer's formula. Fourier-Transform infrared (FT-IR) spectra of parent CeO_2 and Zn doped CeO_2 nanoparticles was measured by Shimadzu (IR Prestige 21) FTIR spectrophotometer, using KBr pellet technique in the range of 4000 to 400 cm^{-1}. Scanning electron microscopy (SEM) was performed to detect the surface morphology and the elemental composition of parent CeO_2 and Zn doped CeO_2 nanoparticles (SEM JEOL JSM-6610) equipped with an energy dispersive X-ray (EDAX) spectrophotometer which is operated at 20kV. The band gap of synthesized pure CeO_2 and Zn doped CeO_2 nanoparticles was determined by UV spectrophotometer (Shimadzu 1800). The synthesized samples were loaded into a quartz experimental set-up and the spectrum was recorded using absorbance method.

Table 1. Amount of precursor salts used for the synthesis of CeO_2 and Zn doped CeO_2 nanoparticles [Volume of each solution is 10 mL]

Sample	Weight of $Ce(NO_3)_3$ (g)	Weight of $Zn(NO_3)_2$ (g)	Weight of NaOH (g)
CeO_2	4.342	-	1.6
$Ce_{0.90}Zn_{0.10}O_{2-\delta}$	3.907	0.297	1.6
$Ce_{0.80}Zn_{0.20}O_{2-\delta}$	3.473	0.594	1.6
$Ce_{0.70}Zn_{0.30}O_{2-\delta}$	3.039	0.892	1.6
$Ce_{0.60}Zn_{0.40}O_{2-\delta}$	2.605	1.189	1.6
$Ce_{0.50}Zn_{0.50}O_{2-\delta}$	2.171	1.487	1.6

Photocatalytic experiment

To understand the photocatalytic behavior of Zn doped CeO_2 nanoparticles, Rhodamine B dye was used. For each experiment, 50 mL of RhB dye solution (0.005g of RhB dye was dissolved in one liter of ultra-pure water to make a solution) was mixed with 0.02g of Zn doped CeO_2 nanoparticles and kept in dark for 30 minutes until reach equilibrium. The sample was irradiated to the UV light and the study was carried out at 0, 15, 30, 45 and 60 minutes intervals and centrifuged. 3 mL of the photo reacted solutions was taken for UV-visible spectroscopy measurements at a wavelength of 554 nm. The removal efficiency and percentage of degradation of dye was determined using the Equation 2.

Percentage of degradation of dye = $(C_0-C_t/C_0)*100$ (eq. 2)

where, 'C_o' is the initial absorbance of the dye solution (Rh B solution) and 'C_t' is the absorbance of RhB dye solution after the photodegradation reaction, i.e., after certain time 't'.

Results and Discussion

XRD studies

The crystalline behavior of the prepared materials was analyzed by XRD. The XRD patterns obtained on Zn doped CeO_2 nanoparticles are reported in Figure 1. The resultant XRD results were matched well with the standard CeO_2 data (JCPDS No. 65-5923). The diffraction peaks found at 2θ values of 28.62˚, 33.17˚, 47.59˚, 56.45˚, 59.20˚ and 69.51˚ corresponding to (111), (200), (220), (311), (222) and (400) crystal planes respectively whose hkl values were concurrent with the reported data [25-27]. No impurity peaks relevant to any impurity phases were seen in the XRD diagrams. The crystalline structure of all compositions of CeO_2 was found to be face centered cubic (FCC). The crystallite size, D_x, was calculated by using Debye-Scherrer formula (Equation 3):

$D_x = K\lambda/\beta \cos\theta$ (eq. 3)

where, β is the full width at half maximum (FWHM) of a diffraction peak, K is the shape factor approx. 0.91, λ is the wavelength of the X-ray source that equals 1.54 Å and θ is the Bragg's angle. The calculated crystallite size values of Zn doped CeO_2 are presented in Table - 2. The crystallite size of the samples varied between ranges from 20.47 to 22.04 nm. The theoretical density (D_p) was calculated by using the formula (Equation 4),

$D_p = Z*M/NxV$ $(g.cm^{-3})$ (eq. 4)

where, Z is the number of chemical species in the unit cell, M is the molecular mass of the sample (g/mol), N is the Avogadro's number (6.023×10^{23}) and V is the unit cell volume equals to a^3 which is the lattice constant in cm. From the XRD data, it was found that there is no much variation in the unit cell parameter and unit cell volume of Zn doped CeO_2 samples. The XRD parameters were compared with the Joint Committee on Powder Diffraction Standards (JCPDS) data. Theoretical density values got reduced with regard to the enhancement of dopant concentration as reported in the literature [28].

$Ce_{0.60}Zn_{0.40}O_{2-\delta}$	Cubic (F.C)	5.40	157.46	20.47	5.96
$Ce_{0.50}Zn_{0.50}O_{2-\delta}$	Cubic (F.C)	5.40	157.46	20.90	5.65

FTIR studies

The FTIR analysis for all the samples were measured at room temperature. FTIR spectra obtained on Zn doped CeO_2 nanoparticles are shown in Figure 2. The absorption bands observed in the range of 600 cm^{-1} attribute to the stretching vibration modes of M-O [29]. FTIR showed a weak band at 842 cm^{-1} which may be due to the presence of CO_3^{2-} in the sample. Peak appeared at 1384 cm^{-1} may be due to the presence of NO_3^- in the sample. Peak appeared at 1700 cm^{-1} may be due to the presence of carboxylic acid in the sample. The above peaks were reported in the final product because of trace level of organic and inorganic impurities present in the sample as reported [30].

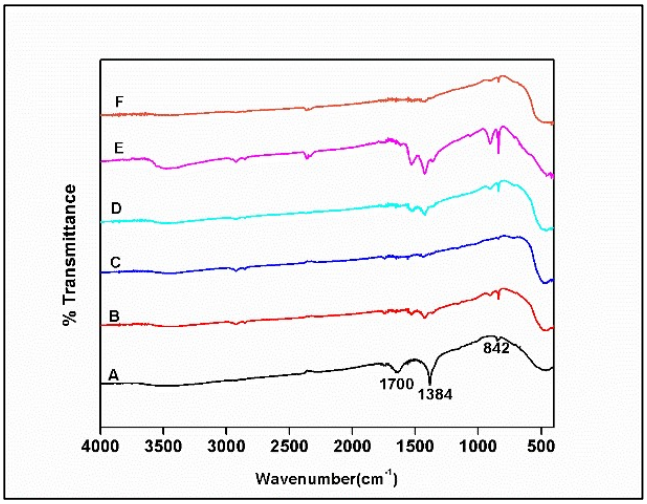

Figure 2. FTIR spectra obtained on CeO_2 based nanoparticles a) Pure CeO_2, b) $Ce_{0.90}Zn_{0.10}O_{2-\delta}$, c) $Ce_{0.80}Zn_{0.20}O_{2-\delta}$, d) $Ce_{0.70}Zn_{0.30}O_{2-\delta}$, e) $Ce_{0.60}Zn_{0.40}O_{2-\delta}$, f) $Ce_{0.50}Zn_{0.50}O_{2-\delta}$

Elemental analysis

The EDX spectra obtained on Zn doped CeO_2 based nanoparticles are shown in Figure 3 and the corresponding data are presented in Table 3. From the data, it was confirmed that appropriate quantities of Ce, Zn and O alone are present in the samples. No impurity elements were seen. So, all the synthesized materials are pure. The product formed is well matched with stoichiometric weight of the corresponding elements.

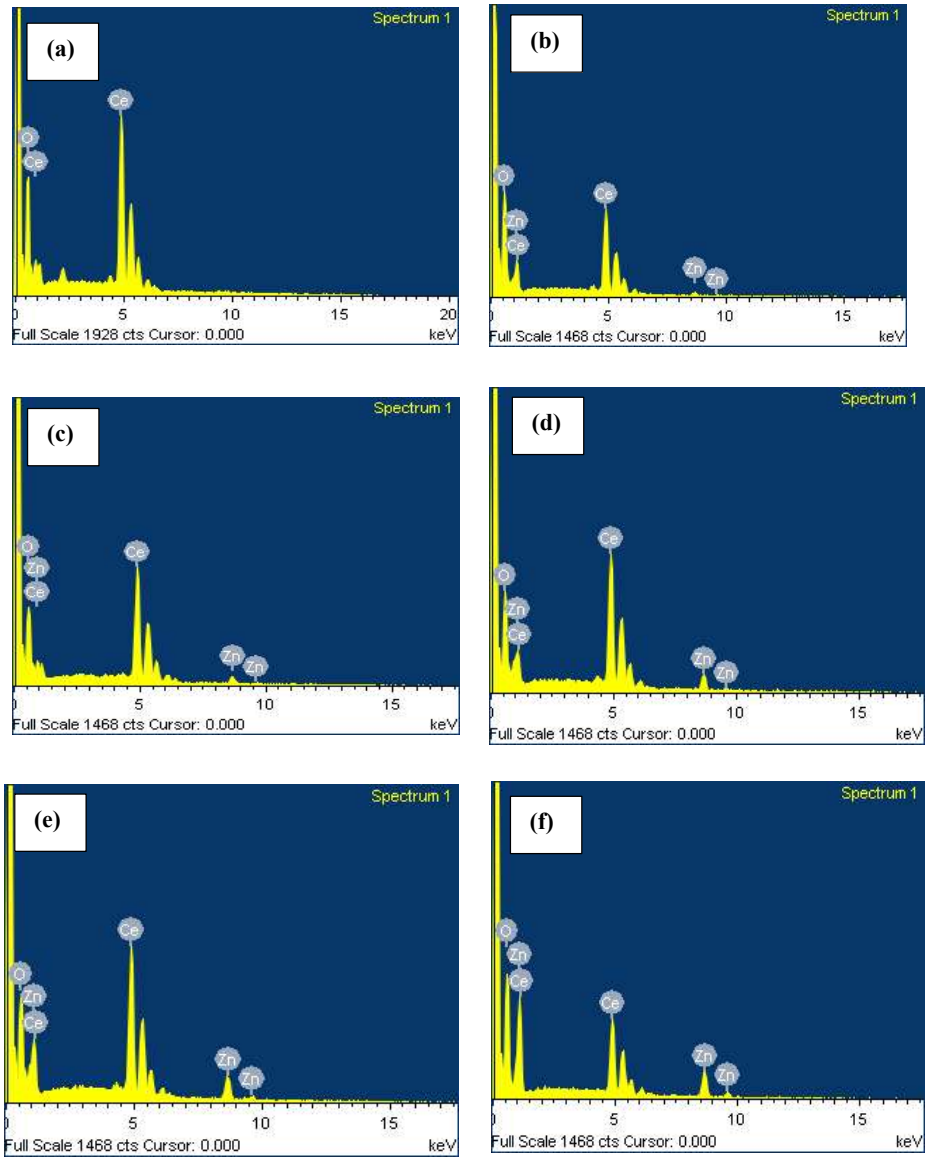

Figure 3. EDAX patterns obtained on CeO_2 based nanoparticles a) Pure CeO_2, b) $Ce_{0.90}Zn_{0.10}O_{2-\delta}$, c) $Ce_{0.80}Zn_{0.20}O_{2-\delta}$, d) $Ce_{0.70}Zn_{0.30}O_{2-\delta}$, e) $Ce_{0.60}Zn_{0.40}O_{2-\delta}$ and f) $Ce_{0.50}Zn_{0.50}O_{2-\delta}$

Morphological study

The SEM photographs of Zn doped CeO_2 nanoparticles are presented in Figure 4. The grain size was found to be 200 to 300 nm. The presence of bigger sized grains in the sample may be due to the agglomeration effect because of high temperature calcination process. Suitable heating rate needs to be followed during calcination which can control the grain growth of the materials [31].

Table 3. Elemental composition data obtained on CeO_2 and Zn doped CeO_2 nanoparticles by EDX analysis

Sample	Cerium		Zinc		Oxygen

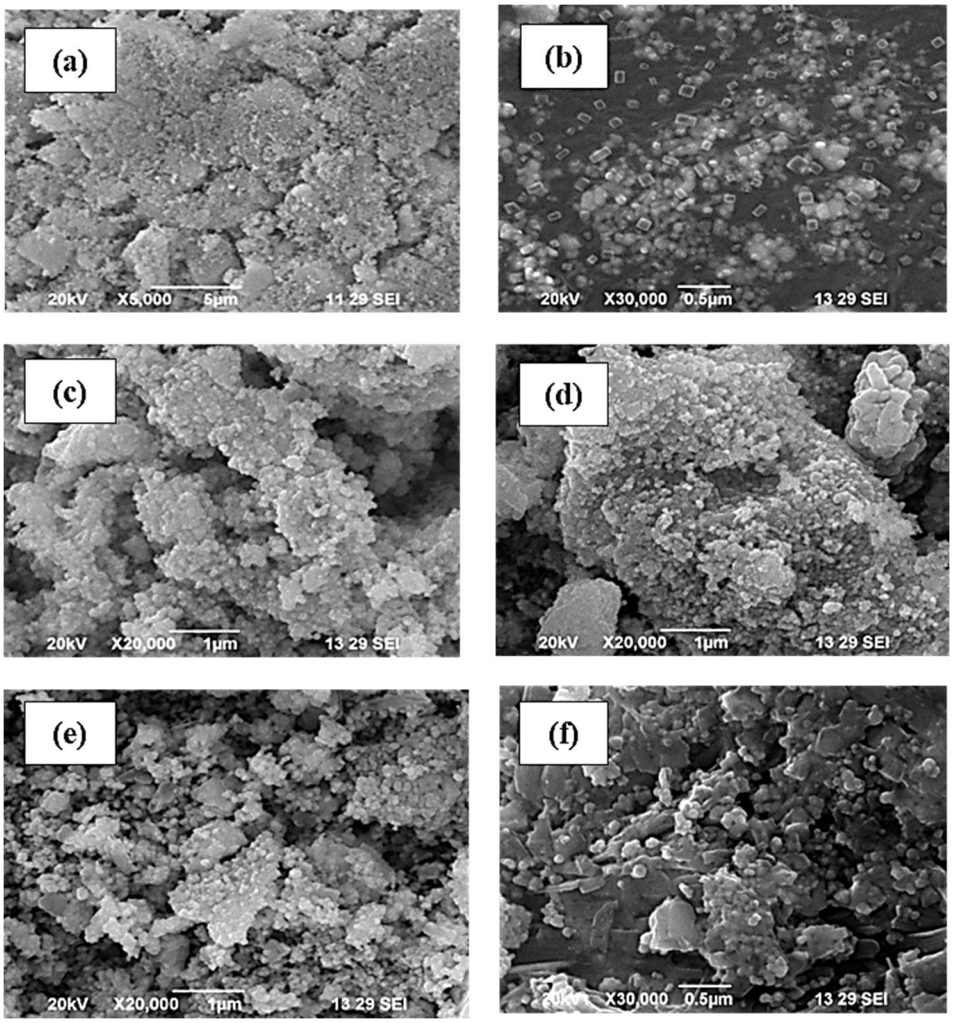

Figure 4. SEM photographs obtained on CeO_2 based nanoparticles a) Pure CeO_2, b) $Ce_{0.90}Zn_{0.10}O_{2-\delta}$ c) $Ce_{0.80}Zn_{0.20}O_{2-\delta}$, d) $Ce_{0.70}Zn_{0.30}O_{2-\delta}$, e) $Ce_{0.60}Zn_{0.40}O_{2-\delta}$ and f) $Ce_{0.50}Zn_{0.50}O_{2-\delta}$

UV studies

To investigate the effect of Zn ion doping on the optical band-gap of the CeO_2 nanoparticles, UV-visible absorption study was carried out. The absorption spectra for undoped and Zn doped CeO_2 nanoparticles were determined in the spectral range of 250nm -350nm as presented in Figure 5. A strong absorption peak is observed at 349nm by the incorporation of Zn ion at Ce

site. The peak shifted towards the lower wavelength side in the doped sample indicated a change in the electronic band structure. Using the absorption data, the energy gap (E_g) of the samples were estimated from Tauc equation [32-33] using the Equation (5)

$$\alpha h\nu)^n = A(h\nu - E_g) \quad \text{(eq. 5)}$$

where 'A' is proportionality constant, 'h' is the Planck's constant, 'ν' is the frequency of vibration, 'hν' is the photon energy, 'α' is the absorption coefficient and 'n' is either 2 for direct band transitions or ½ for indirect band transitions. The absorption coefficient (α) has been calculated using the relation (Equation 6)

$$\alpha = 2.303(A/t) \quad \text{(eq. 6)}$$

where 't' is thickness and 'A' is optical absorbance. The energy band gap (E_g) is estimated by extrapolating the linear region of a plot of $(\alpha h\nu)^2$ *vs* hν shown in the Figure 6. It was observed that the band gap of Zn doped CeO_2 nanoparticles is found to be in the range of 3.0 to 3.19 eV and our results are in close agreement with the reported data [33-34].

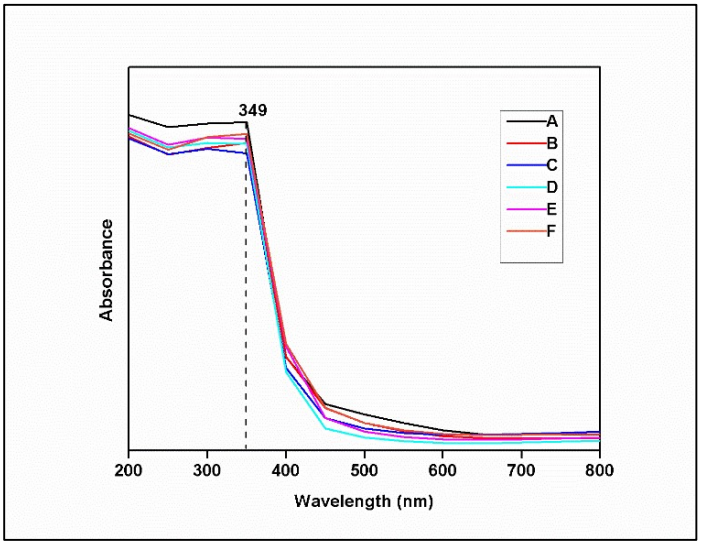

Figure 5. UV-visible spectra obtained on CeO_2 based nanoparticles a) Pure CeO_2, b) $Ce_{0.90}Zn_{0.10}O_{2-\delta}$, c) $Ce_{0.80}Zn_{0.20}O_{2-\delta}$, d) $Ce_{0.70}Zn_{0.30}O_{2-\delta}$, e) $Ce_{0.60}Zn_{0.40}O_{2-\delta}$ and f) $Ce_{0.50}Zn_{0.50}O_{2\delta}$

Photoluminescence studies

The optical, electronic and photochemical properties of the materials can be well studied by photoluminescence (PL) studies [35-36]. PL spectra of Zn doped CeO_2 nanoparticles are reported in Figure 7. This spectra show two emission peaks, one at 395 nm to 425 nm which may correspond to band gap excitonic emission and another one located in between 500 nm to 520 nm which may relate to the presence of surface defects. The occurrence of strong and broad peaks reveals that the fabricated CeO_2 based nanoparticles are pure and crystalline [37]. Based on the above results, UV light source has been utilized for the photodegradation experiments. The best photochemical properties are shown by $Ce_{0.60}Zn_{0.40}O_{2-\delta}$ nanophotocatalyst.

Photocatalytic studies

The photocatalytic activity Zn doped CeO_2 nanoparticles was performed for Rh B dye under UV light illumination. The photodegradation curves obtained the presence of CeO_2 based nanophotocatalysts with Rh B dye and Rh B dye alone without nanophotocatalysts are shown in Figure 8. The results revealed that the optimum photocatalytic efficiency (54.9 %) was shown by $Ce_{0.60}Zn_{0.40}O_{2-\delta}$ after 60 minutes of UV irradiation compared to the other compositions. Thus, the 40 mol% Zn doped CeO_2 nanophotocatalyst

was used as an optimized material to study the photocatalysis with respect to effect of pH and dye concentration. The photocatalytic degradation of the RhB dye can also be understood by plotting a first-order kinetic plot (Figure 9) described by Langmuir and Hinshelwood kinetic model [38]. The rate constant 'k' is calculated by using the Equation 7.

$$\ln C_t/C_0 = -kt \quad \text{(eq. 7)}$$

Where 'C_0' is the concentration at the beginning, 'C_t' is the final concentration and 'k' is the first order rate constant. The rate constant values were found to be 0.08 min^{-1} (CeO_2), 0.005 min^{-1} ($Ce_{0.90}Zn_{0.10}O_{2-\delta}$), 0.007 min^{-1} ($Ce_{0.80}Zn_{0.20}O_{2-\delta}$), 0.012 min^{-1} ($Ce_{0.70}Zn_{0.30}O_{2-\delta}$), 0.016 min^{-1}($Ce_{0.60}Zn_{0.40}O_{2-\delta}$) and 0.012 min^{-1} ($Ce_{0.50}Zn_{0.50}O_{2-\delta}$).

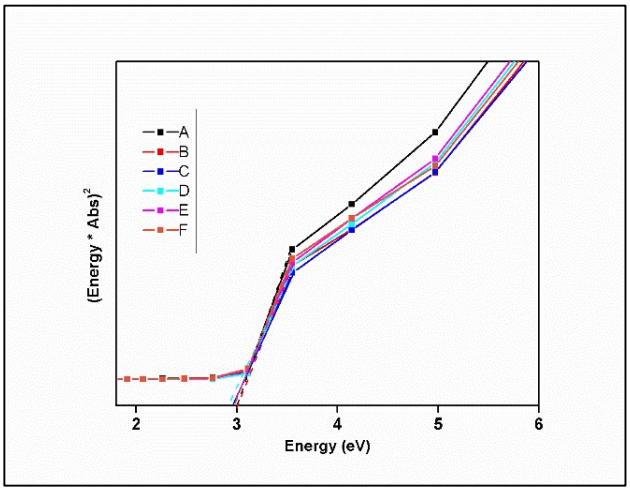

Figure 6. The band gap curves obtained on CeO_2 based nanoparticles a) Pure CeO_2, b) $Ce_{0.90}Zn_{0.10}O_{2-\delta}$, c) $Ce_{0.80}Zn_{0.20}O_{2-\delta}$, d) $Ce_{0.70}Zn_{0.30}O_{2-\delta}$, e) $Ce_{0.60}Zn_{0.40}O_{2-\delta}$ and f) $Ce_{0.50}Zn_{0.50}O_{2-\delta}$

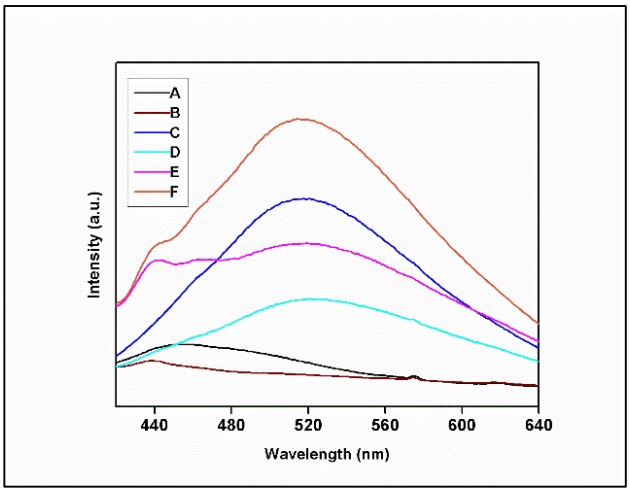

Figure 7. The PL spectra obtained on CeO_2 based nanoparticles a) Pure CeO_2, b) $Ce_{0.90}Zn_{0.10}O_{2-\delta}$, c) $Ce_{0.80}Zn_{0.20}O_{2-\delta}$, d) $Ce_{0.70}Zn_{0.30}O_{2-\delta}$, e) $Ce_{0.60}Zn_{0.40}O_{2-\delta}$ and f) $Ce_{0.50}Zn_{0.50}O_{2-\delta}$

Influence of pH

The most important parameter to control the adsorption process is pH [39]. The pH of the dye solution in the present study was adjusted by the addition of dilute hydrochloric acid and dilute sodium hydroxide. To this study, pH values, such as, 2.5, 4.3, 6.5, 9.0 and 11.0 were fixed and the photodegradation efficiency was measured after irradiation in UV light source for one hour. The influence of pH value on the photocatalytic efficiency of Rh B dye in the presence of $Ce_{0.60}Zn_{0.40}O_{2-\delta}$ (best sample) is shown in Figure 10. The photocatalytic phenomenon is optimum (58.71%) at pH 9 in comparison with other pH values. Generally, the dye removal efficiency is minimal at low pH ranges [40].

Influence of concentration of dye

The photocatalytic efficiency of the best performing material ($Ce_{0.60}Zn_{0.40}O_{2-\delta}$) was further studied at a standardized pH 9 of varying RhB dye concentrations, such as, 0.0025 g/L, 0.005 g/L, 0.0075 g/L and 0.01 g/L after 60 minutes under UV irradiation. Figure 11 shows the influence of RhB dye concentration on the photocatalytic efficiency of $Ce_{0.60}Zn_{0.40}O_{2-\delta}$ (best sample). The results revealed that the optimum photocatalytic efficiency is found at 58.71% for the dye concentration of 0.005g/L at pH 9. It was reported that the photodegradation is highly dependent on the probability of creation of OH radicals on the catalyst surface during the reaction process. If the concentration of dye is very high, it will retard the reaction between the dye molecules and OH radicals. Hence, optimum concentration of dye is required to have better efficiency of photodegradation process [41].

Conclusion

Simple wet chemical method was adopted for the preparation of pure CeO_2 and Zn doped CeO_2 ($Ce_{1-x}Zn_xO_{2-\delta}$; where x=0, 0.10, 0.20, 0.30, 0.40 and 0.50) nanoparticles in this research work. All the samples were assigned with cubic (F.C) crystalline structure based on XRD analysis. FTIR data confirmed the presence of M-O bond in the samples. EDX analysis reported the presence of Ce, Zn and O in the powder particles with appropriate concentration. Agglomeration of grains was revealed by SEM. The UV-visible spectra showed strong absorption peak around 349nm (λ_{max}) in all the composition of CeO_2 samples. The E_g of $Ce_{1-x}Cu_xO_{2-\delta}$ was found to be in the range of 3.0eV - 3.19eV. The PL spectra of samples exhibited two peaks, viz., at 420nm (blue emission) and the other at 520 nm (blue emission). The photocatalysts, such as, CeO_2, $Ce_{0.90}Zn_{0.10}O_{2-\delta}$, $Ce_{0.80}Zn_{0.20}O_{2-\delta}$, $Ce_{0.70}Zn_{0.30}O_{2-\delta}$, $Ce_{0.60}Zn_{0.40}O_{2-\delta}$ and $Ce_{0.50}Zn_{0.50}O_{2-\delta}$ delivered a photocatalytic degradation efficiency of 35.46, 38.06, 51.25, 51.30, 54.97 and 46.69 % at pH 4.3 under illumination of UV light after 60 minutes. The parameters like, effect of pH and effect of initial concentration of dye were studied for the best sample $Ce_{0.60}Zn_{0.40}O_{2-\delta}$. At different pH values of 2.5, 4.3, 6.5, 9 and 11, the photocatalytic efficiency for $Ce_{0.60}Zn_{0.40}O_{2-\delta}$ was found to be 42.39, 54.97, 55.59, 58.71 and 46.69% respectively. Therefore, among the different compositions studied, $Ce_{0.60}Zn_{0.40}O_{2-\delta}$ exhibited excellent performance towards elimination of Rhodamine B dye (Rh B) with 58.71% efficiency under UV irradiation. Further, the results revealed that the degradation efficiency was found to be maximum at pH = 9 and at a concentration of 0.005 g/L of RhB under a path route of pseudo-first order kinetic reaction.

Abstract

Gout has been detected as amongst the oldest disease since the 5th Century BC and to date it is arising. This disease occurs due to excess production of uric acid that leads to the formation of crystals around the joints. It may become worse when permanent tissue damage is involved. Nowadays, many advance treatments are found. However, it may be very costly. One of the cheapest alternatives is a synthetic drug called allopurinol, which has negative side effect for long term consumption. *Euphorbia milii* (Euphorbiaceae) was chosen as the sample due to various secondary metabolites being reported which might be beneficial for treatment of gout. Quantitative analysis of total phenolic content and xanthine oxidase inhibitory assay were done to the crude extracts of Malaysian *E. milii*, followed by IC_{50} to determine the concentration needed to reduce 50% of uric acid production. The result showed that methanol leaves extract of *E. milii* had the highest total phenolic content (0.77 ± 0.02 mg QAE/g of sample), which made this extract a potent uric acid inhibitor (Half maximal inhibitory concentration, IC_{50} = 0.0864 mM). This value had significantly reduced uric acid production by 65.6%. Therefore, methanolic leaves extract that was subjected to GC-MS and hexadecanoic acid and has anti-gout properties, was discovered in the crude extract. In conclusion, the Malaysian *E. milii* plant has potential to be developed as a new drug which might be beneficial for the treatment of gout.

Keywords: *Euphorbiaceae,* Malaysian plant, quantitative analysis, anti-gout, uric acid

Abstrak

Gout telah dikesan sebagai antara penyakit tertua sejak abad ke-5 SM dan ia terus wujud hingga kini. Penyakit ini berlaku akibat pengeluaran asid urik berlebihan yang menyebabkan pembentukan kristal di sekeliling sendi. Ia mungkin menjadi lebih teruk apabila melibatkan kerosakan kekal pada tisu. Kini, banyak rawatan awal telah ditemui. Walau bagaimanapun, ia mungkin sangat mahal. Salah satu alternatif yang paling murah ialah ubat sintetik bernama allopurinol yang mempunyai kesan sampingan negatif untuk penggunaan jangka panjang. *Euphorbia milii* (Euphorbiaceae) telah dipilih sebagai sampel kerana pelbagai metabolit sekunder yang mungkin bermanfaat untuk rawatan gout telah dilaporkan. Analisis kuantitatif jumlah kandungan fenolik dan ujian perencatan xanthine oxidase telah dilakukan terhadap ekstrak mentah *E. milii* Malaysia diikuti dengan IC_{50} untuk menentukan

kepekatan yang perlu untuk mengurangkan 50% daripada pengeluaran asid urik. Hasilnya, ekstrak metanol daun *E. milii* menunjukkan jumlah kandungan fenolik yang tertinggi (0.77 ± 0.02 mg QAE/g sampel) yang menjadikan ekstrak ini berpotensi sebagai perencat asid urik (Kepekatan perencatan separuh maksimum, IC50 = 0.0864 mM). Nilai ini mengurangkan pengeluaran asid urik dengan ketara sebanyak 65.6%. Oleh itu, ekstrak metanol daun kemudiannya tertakluk kepada GC-MS dan asid heksadekanoik serta mempunyai sifat anti-gout, telah dikenal pasti wujud dalam ekstrak mentah. Kesimpulannya, tumbuhan *E. milii* Malaysia ini berpotensi untuk dibangunkan sebagai satu ubat baru yang mungkin bermanfaat untuk rawatan gout.

Introduction

Gout has been alarming worldwide and it is now the most common type of inflammatory arthropathy in adults. This disease is caused by excess uric acid levels in blood due to oxidative stress that increases the production of xanthine oxidase incorporation to increase the uric acid production. This condition results in the deposition of urate (as monosodium urate monohydrate) crystals around joints, which causes an acute inflammatory response and induces a permanent tissue damage that is characterized by the appearance of ulceration of the joint cartilage, marginal osteophytosis, erosive lesions and chronic inflammation of synovial membrane [1, 2]. The most common urate lowering treatment is the development of xanthine oxidase (XO) inhibitor. Allopurinol is one of the best and the most widely used as XO inhibitor. However, prolonged usage of Allopurinol can cause negative side effects to the patient such as nephrolithiasis, hypersensitivity reaction, Stevens-Johnson syndrome, renal toxicity, allergic reactions, and fatal liver necrosis [3].

Flavonoids are secondary metabolites that are responsible to give color to plants. In medicinal aspect, it can also act as anti-oxidative, anti-inflammatory, anti-mutagenic, antifungal, antiviral, antibacterial activity and anti-carcinogenic properties coupled with their capacity to modulate key cellular enzyme function [4]. Moreover, flavonoids are known to inhibit a number of enzymes such as phosphodiesterase, Ca^{2+} ATPase, aldosereductase, lipoxygenase, cyclooxygenase [5], and human P450 enzymes. Recently, studies on flavonoids against xanthine oxidase (XO) had become a trend. The study by Yuan et al. [6] revealed that different structure of flavonoids would affect the binding process which affected the inhibition of xanthine oxidase. Research by Suyun Lin et al. [7] proposed that amongst the 20 flavonoids used in their project can be categorized into three groups based on activeness. The first group was composed of the most active flavonoids with low α values (≤10), which were chrysin and genistein (α values of 0.49 and 0.59, respectively). The first group had α values of below 1, which indicated that only compounds in small amount was needed to inhibit XO as compared to allopurinol. Additionally, quercetin (α = 9.76) and kaempferol (α = 5.76) were less active than apigenin (α = 1.20. The second group was referred as flavonoids that expressed intermediate activity ($10 < \alpha \leq 50$). Most of them were flavonols, such as morin, myricetin, diosmetin, isorhamnetin, and hyperin. In the last group ($\alpha > 50$), as compared to rutin (α = 57.29) and baicalin (α = 50.13), naringenin and silybin, exhibited much weaker inhibition (α = 140.4 and 189.6, respectively). Nonetheless, phloretin, curcumin, and epicatechin did not even show XO inhibition activity [8, 9].

Therefore, this study is designed to identify potential xanthine oxidase inhibitor properties contained in *Euphorbia milii* Malaysian species as it is rich in natural bioactive compound. *Euphorbia milii* Des Moul. *ex* Boiss var. *hislopii* is a decorative, cactus-like plant that contains milky sap and the branches and stems are covered with thick sharp black thorns. This plant is native to Inselberge, which is located in the central Plateau of Madagascar, Africa and it is also found in tropical and subtropical countries [10]. Phytochemical studies of methanolic extract of *E. milii* by Delgado et al. [11] revealed the presence of β-sitosterol, cycloartenol, β-amyrin acetate, lupeol, euphol, and flavonoid. Meanwhile, there were two triterpenoids (Taraxerol and 28-hydroxyfriedelan-1, 3-dione-29-oic acid), one flavone (Quercetin 3-O-(2”-O-galloyl)-a-L-arabinofuranoside) and two phenolic compounds (7 7’-dihydroxy, 8, 6’-bicoumarin and 9-acetyl-3’4’ dimethoxy dehydroconiferyl-3-alcohol) from the red flowers of *E. milii* that were isolated by Kamurthy et al. [12]. Based on literature review, *E. milli* was expected to show positive results towards the XO inhibitor properties which might give benefits as a safer approach for the prevention and treatment of gout [13]. Table 1 shows the taxonomic hierarchy of *E. milii* and its origin. Meanwhile, Figure 1 shows the *E. milii* plant used.

Materials and Methods

Plant identification

Plant material (flowers and leaves) were collected from Kota Tinggi, Johor and identified by Tuan Haji Muhamad Razali Salam, a senior lab assistant of Biological laboratory, Faculty of Science and Marine Environment, Universiti Malaysia Terengganu.

Sample preparation

Each sample was washed and dried at room temperature until it was completely dried. About 40 g of dried flower samples and 40 g of dried leaf samples were ground and extracted by using three different solvents with increasing polarities (hexane, ethyl acetate, and methanol) at room temperature. Then, each extract was concentrated by using a rotary evaporator to obtain the crude extracts.

Determination of total phenolic content

This test was performed by using Folin–Ciocalteu method that was developed by Chun and his teams with some modifications in 2013 [14]. A calibration curve was established by using gallic acid (0.01 to 0.05 mg/ mL) as standard references plotted. TPC was revealed as mg GAE/ g sample [15].

Preparation of calibration curve of standard uric acid

Standard uric acid (1 mM) was prepared by dissolving 1.69 mg of uric acid with a few drops of 0.2 M sodium hydroxide (NaOH) and added with distilled water until the calibration mark of 10 mL volumetric flask. Then, a series of concentrations of uric acid solution were prepared (0.01 mM to 0.2 mM) and the absorbance was recorded by using UV-Vis spectrophotometer (Shimadzu, UV- Vis 1800) at a wavelength of 295 nm.

Xanthine oxidase inhibitory activity

This test was carried out by referring to the method reported by Boumerfeg et al. [16] with some modification. The reaction mixture consisted of 1500 µL phosphate buffer solution, 300 µL of distilled water, 300 µL of 0.1 mg/mL extract solution and 300 µL of enzyme solution. After 5 min of incubation, 600 µL of xanthine solution was added to the mixture. The absorbance of the kinetic assay was measured immediately by using UV-Vis spectrophotometer (Shimadzu, UV- Vis 1800) at 295 nm at an interval of 2 min for 30 min. The blank was prepared by using the same method but the enzyme was replaced with a buffer solution.

A standard reaction mixture was prepared in the same way as the sample reaction mixture. However, the extracts solution was replaced with 0.1 mg/mL of

positive control of Allopurinol. Meanwhile, for negative control (blank) the extracts solution was replaced with distilled water. The percentage of XOI assay was calculated by using the following formula:

Concentration of uric acid produced for every 2 min of reaction (G),

$$(G) = \frac{(D-E)}{F} \quad \text{(eq. 1)}$$

where, D is absorbance of each sample, E is blank absorbance of each sample and F is slope from the calibration curve of standard uric acid.

Production rate of uric acid (activity of enzyme) (A) is,

$$(A) = \frac{B}{2} \quad \text{(eq. 2)}$$

where, B is slope (gradient) from G for 30 min of reaction.

Percentage of inhibition is,

$$\%\ inhibition = (1 - \left(\frac{C}{A}\right) \times 100 \quad \text{(eq. 3)}$$

where, A is absorbance of control at 30 min and C is absorbance of sample at 30 min.

IC_{50} evaluation for methanol leaves extract on XOI activity

The sample and positive control of Allopurinol were repeated as the xanthine oxidase inhibitory activity method. However, five different concentrations (0.02 mg/mL - 0.1 mg/mL) were used to evaluate the inhibitory percentage at 50%. The equation was calculated by using natural Log dose inhibition curve.

Gas chromatography - mass spectroscopy (GC-MS) analysis

Methanolic leaves extract of *E. milii* was subjected to GC-MS analysis by using GCMS-QP2010 Ultra (Shimadzu Co., Japan) equipped with SLB ™ – 5ms (Fused Silica Capillary Column; 30m x 0.25mm x 0.25µm film). Electron impact mode of 70 electron volt (eV) was used for ionization in the GC-MS analysis. The analysis was carried out by injecting 1µL of sample with split ratio of 10 with inert helium gas (99.99%) as carrier gas. The initial oven temperature was maintained at 50°C for 1 min, then increased up to 320 °C and held for 5 min. The injection was performed on the split-less mode with the injector port temperature maintained at 300 °C. The chromatograms were recorded at range 50 600 m/z MS - 600 m/z MS scan mode and the compounds were identified by comparing the molecular weight, intensity of peak and peak mass with NIST library and HMDB library.

Results and Discussion

In this research, the flowers and leaves of *Euphorbia milii* were selected as samples and underwent an extraction method by using three different solvents (hexane, ethyl acetate and methanol) to obtain the crude extracts. Then, the crude extracts underwent a total phenolic content test to determine the presence of phenolic compounds from the crude extracts.

Methanol leaves extract had the highest phenolic content (0.77 ± 0.02 mg GAE/g of sample), followed by methanol flowers extract (0.51 ± 0.03 mg GAE/g of sample), ethyl acetate leaves extract (0.17 ± 0.00 mg GAE/g of sample) and ethyl acetate flowers extract (0.07 ± 0.00 mg GAE/g of sample). Nonetheless, the lowest phenolic content was discovered in the hexane extracts; leaves (0.04 ± 0.01 mg GAE/g of sample) and flowers (0.05 ± 0.00 mg GAE/g of sample). Another study which used *E. splendida* also revealed that the methanolic extract showed the highest total phenolic content, which was 270.74 ± 0.005 mg GAE / g as compared to ethyl acetate extract (208.54 0.005 mg GAE / g sample) [17].

Referring to the plant parts, the highest phenolic content was contributed by leaves with 0.98 mg QAE/g of sample and followed by flowers (0.0.63 mg GAE/g of sample). A significant result was reported by Abu Arra et. al. [18], in which the leaves extract of *E. hirta* showed the highest amount of phenolic content (206.17 ± 1.95 mg GAE/g) as compared to flowers, roots and stems crude extracts. Figure 2 summarizes the estimation of phenolic contents in different crude extracts of *E. milii*.

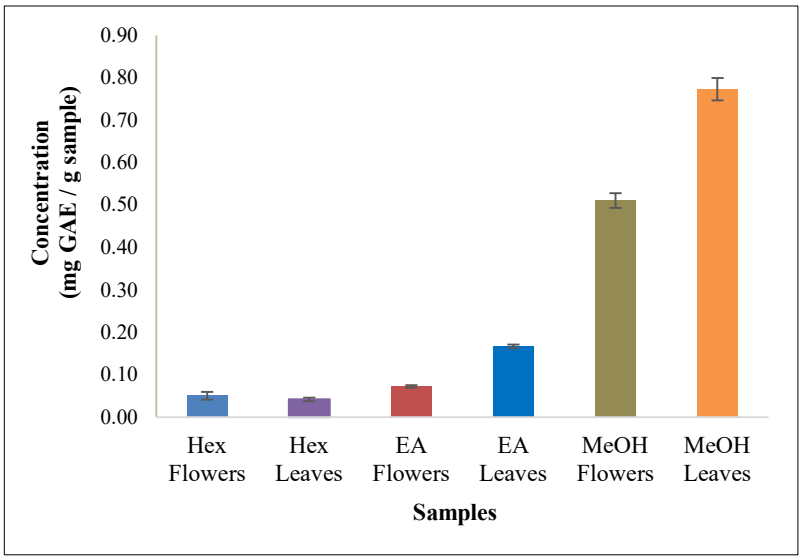

Figure 2. Estimation of total phenolic content in different crude extracts of *E. milii*

Xanthine oxidase inhibitor was tested on the ethyl acetate and methanol crude extracts which contain the highest phenolic and flavonoid content to identify the behavior of crude extracts in reducing the uric acid production [19, 20]. The reducing potential was measured by calculating the percentage of xanthine oxidase inhibition by using the absorbance recorded by UV-Vis spectrophotometer at wavelength 295 nm. Methanolic leaves extract showed the highest percentage of xanthine oxidase inhibition (66.5 ± 0.4%), followed ethyl acetate leaves (33.3 ± 4.3%), methanol flowers (29.3 ± 4.5%) and lastly ethyl acetate flowers (12.2 ± 1.4%). The standard allopurinol had 98.3 ± 1.3% XO inhibition. The results obtained were equivalence with the total phenolic and flavonoids content in *E. milii*. This result was in agreement with other researchers, in which it indicated that XO inhibition activity could be linked to the content and nature of flavonoids and phenolic compounds present in the extract [21]. Figure 3 shows the percentage of xanthine oxidase inhibition of the four crude extracts of *E. milii* and standard allopurinol.

Based on the result obtained, methanolic leaves extract and allopurinol were chosen to undergo IC_{50} test by using different concentrations (0 µg/mL - 100 µg/mL). The value of IC_{50} was obtained by using natural Log dose inhibition curve of a series of different sample concentrations against percent inhibition. Methanolic leaves extract showed a significant XO inhibitory activity with an IC_{50} value of 86.7 µg/mL (Figure 3). However, its activity was low and remained not as good as allopurinol with IC_{50}, 4.18 µg/mL. The obvious gap of activity between the extract and allopurinol due to the concentration of active flavonoid and phenolic compounds in the extract was very low as compared to the mass of pure allopurinol compound.

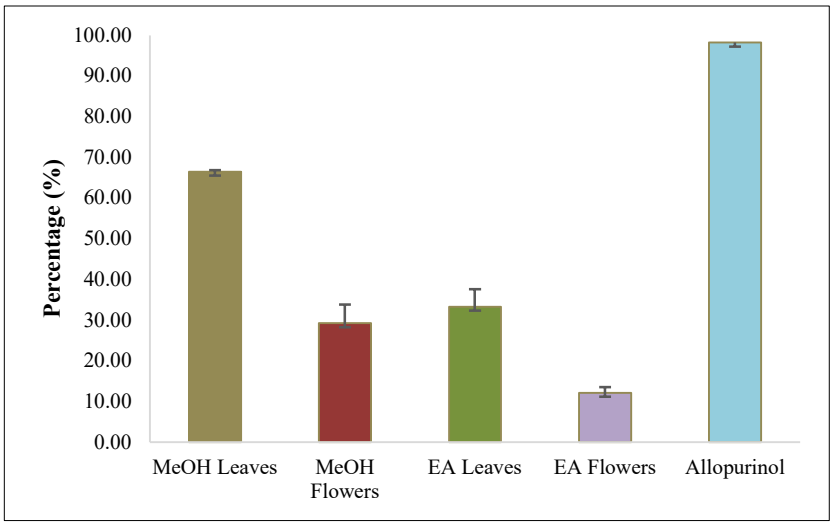

Figure 3. Percentage of xanthine oxidase inhibition of the four crude extracts of *E. milii* and the standard allopurinol

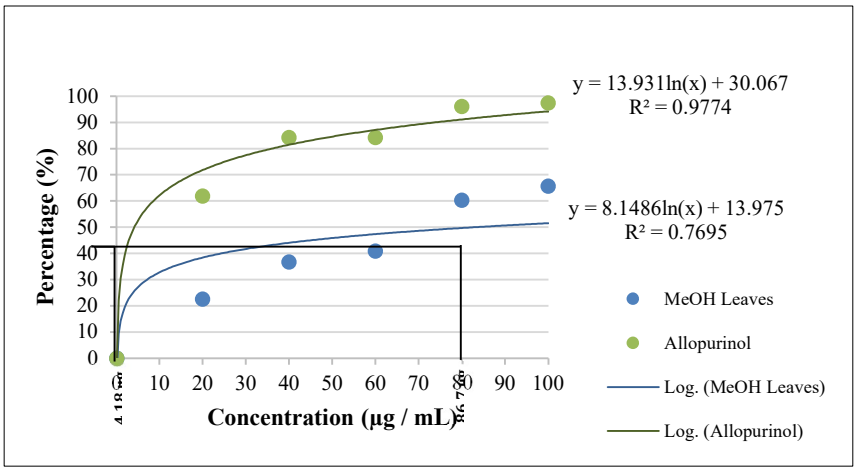

Figure 4. Percentage inhibition of IC_{50}

Therefore, methanolic leaves extract of *E. milii* was subjected to GC-MS in order to trace or identify phytocompounds that exist in the sample. The chromatogram obtained (Figure 5) revealed the presence of hexadecanoic acid [RT: 32.923, Peak Area (%): 14.79%, Molecular Formula: $C_{17}H_{34}O_2$] that possess anti-gout behavior. Hexadecanoic acid (Figure. 6) or also known as palmitic acid is one of the most common saturated fatty acid chains that can be found naturally in plant. Various studies had proven that hexadecanoic acid can act as an antifungal, antioxidant, antimalarial or a potent antimicrobial agent and inhibit the production of uric acid [22, 23]. According to Li and his team [24], oxidative stress played a crucial role in the pathogenesis of gout and the effective treatment was by lowering the oxidative stress. This was supported by Zamudio-Cuevas et al. [25], monosodium urate (MSU) crystals were shown to induce renal cell apoptosis through a mechanism which involved reactive oxygen species (ROS) generation and led to loss of cartilage repair and tissue damage observed in gouty patients. In part of that, Trevisan et al. [26], suggesting that oxidative stress (OS) was responsible for acute gout attack due to overproduction of OS traced. In fact, Masuoka et al. [27], have identified the possible mechanism pathway which relate the compounds that are superoxide radical antioxidants and XO activity inhibitor. Hexadecanoic acid was identified as able to induce the formation of hydrogen peroxide, H_2O_2 (source of oxygen-derived free radical) [28, 29]. In referring to Euphorbia species, the

leaves of *E. cuneata* [30], essential oil from dried leaves of *E. hirta* Linn [31, 32] and the culture cell of *E. tirucalli* and *E. milii* showed the presence of hexadecanoic acid as one of their phytocompounds. Table 2 shows a summary of the data obtained from the GC-MS and biological activity of hexadecanoic acid.

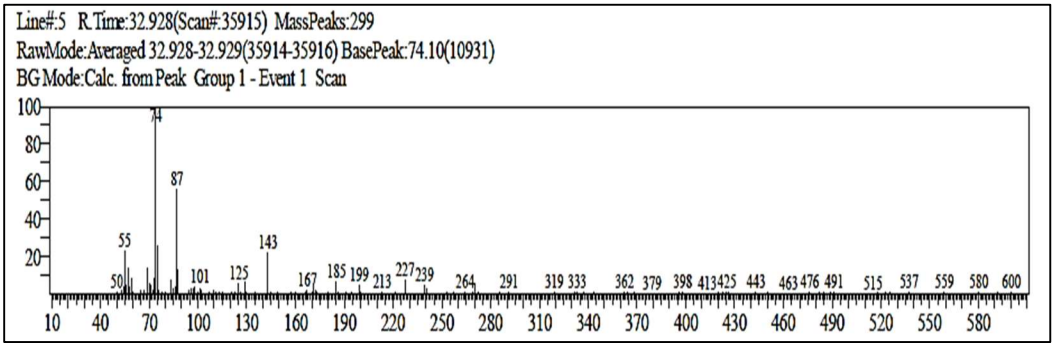

Figure 5. Mass spectra of hexadecanoic acid contained in methanolic leaves extract of *E. milii*

Figure 6. The molecular structure of hexadecanoic acid

Table 2. Name, retention time, percentage area, molecular weight, molecular formula, and biological activity of hexadecanoic acid

No	Name of Compound	Retention Time	Percentage Area (%)	Molecular Weight	Molecular Formula	Biological Activity
1.	Hexadecanoic acid	32.923	23.88	270	$C_{17}H_{34}0_2$	Antifungal, antioxidant, antimalarial, potent antimicrobial agent, inhibit production of uric acid [22, 23]

Conclusion

This study revealed that the methanolic leaves extract of *E. milii* possess anti-gout properties because it significantly reduced uric acid production and had higher xanthine oxidase inhibitor as compared to other crude extracts. Moreover, the estimation of phenolic contents contained in the methanolic leaves extract was the highest amongst others. Therefore, the methanolic leaves extract of *E. milii* had higher potential to be used as a new medicine in the treatment of gout.

Abstract

The aggregation of silver nanoparticles (AgNPs) is a serious problem in their applications. This article describes the synthesis of AgNPs using $AgNO_3$ as a metal precursor and *Murdannia loriformis* extract (MLE) as a reducing agent. The effect of MLE concentration, $AgNO_3$ concentration, reaction time, and pH on the synthesis of AgNPs was studied using the absorbance of the surface plasmon resonance (SPR) band. From the TEM image, highly scattered AgNPs with a spherical shape and an average particle size of around 12.60 nm ± 2.83 nm were observed for synthesized AgNPs at optimized conditions (pH 8, 100% MLE concentration, 2 mM of $AgNO_3$ and 24 hr reaction time). The stability of synthesized AgNPs was initially studied using a different initial concentration (5 and 10 mM) of the metal precursor. The aggregation process was evaluated by the zeta potential and UV-

vis spectra measurements and finally confirmed by TEM. For an antibacterial performance, the disk diffusion method was applied. It was observed that the synthesized AgNPs showed enhanced antibacterial activity depicting the inhibition zone between 18.27 and 22.09 mm reported against *Escherichia coli* (*E. coli*) compared to *Staphylococcus aureus* (*S aureus)*, which has an inhibition zone between 9.11 and 10.99 mm. The significance of this study showed that the AgNPs synthesized in this process were found to have efficient antibacterial activity against bacteria *E. coli*. Additionally, the increasing metal precursor concentrations exhibited a reduction in the stability of AgNPs.

Abstrak

Penggumpalan nanopartikel perak (AgNPs) adalah masalah serius dalam aplikasinya. Artikel ini menerangkan sintesis AgNPs menggunakan $AgNO_3$ sebagai prekursor logam dan ekstrak *Murdannia loriformis* (MLE) sebagai agen penurunan. Kesan kepekatan MLE, kepekatan $AgNO_3$, masa tindak balas, dan pH ke atas sintesis AgNPs telah dikaji menggunakan penyerapan jalur resonans plasmon permukaan (SPR). Daripada imej TEM, AgNPs yang tersebar adalah dalam bentuk sfera dan saiz zarah purata sekitar 12.60 nm ± 2.83 nm di sintesis pada keadaan optimum (pH 8, 100% kepekatan MLE, 2 mM $AgNO_3$ dan 24 jam masa tindak balas). Kestabilan AgNPs pada mulanya dikaji menggunakan kepekatan awal prekursor logam yang berbeza (5 dan 10 mM). Proses penggumpalan dinilai oleh potensi Zeta dan ukuran spektrum UV/vis dan akhirnya disahkan oleh TEM. Untuk prestasi antibakteria, penyebaran cakera dilaksanakan. Diperhatikan bahawa AgNPs menunjukkan aktiviti antibakteria yang dipertingkatkan yang menggambarkan zon perencatan antara 18.27 dan 22.09 mm yang dilaporkan terhadap *Escherichia coli* (*E. coli*) berbanding *Staphylococcus aureus* (*S aureus*), yang mempunyai zon perencatan antara 9.11 dan 10.99 mm. Kepentingan kajian ini menunjukkan bahawa AgNPs yang disintesis dalam proses ini didapati mempunyai aktiviti antibakteria yang cekap terhadap bakteria *E. coli*. Di samping itu, didapati bahawa peningkatan kepekatan prekursor logam menunjukkan pengurangan kestabilan AgNPs.

Kata kunci: *Murdannia loriformis*, nanopartikel perak, kestabilan, *Escherichia coli, Staphylococcus aureus*

Introduction

This article describes the synthesis, stability and antibacterial study of AgNPs synthesized using $AgNO_3$ as a metal precursor and *Murdannia loriformis* extract (MLE) as a reducing agent. *Murdannia loriformis* (Hassk.) (*M. loriformis*) is an Indian plant that belongs to the Commelinaceae family. The plant species are found throughout the forests and grassy slopes of Asia, especially in China and Thailand [1]. This plant is gaining popularity in Malaysia due to its therapeutic potential for conditions such as psoriasis and dermatitis [2]. *M. loriformis* is one of Thailand's most popular folk medicines for cancer and diabetes patients. It is thought to slow cancer progression as well as provide symptomatic relief from contemporary therapy [3]. *M. loriformis* is also a traditional Chinese remedy for detoxifying respiratory tract problems [4]. *M. loriformis* is known as “Beijing grass,” or “Angel grass” in English, “Rumput Cina,” “Rumput Beijing,” and Rumput Siti Khatijah in Malay and “Ya Pak King” in Thailand (Figure 1). The phytochemical analysis of *M. loriformis* found that the plant's extract contains phenolics, flavonoids, condensed tannin, carbohydrates, protein, and plant membrane lipids [2, 5, 6]. Several scientific reports support the traditional use of *M. loriformis* in treating different ailments. From the kinds of literature, *M. loriformis* extract possesses numerous pharmacological properties, including antioxidant, antimutagenicity, anticancer, anti-inflammatory, immunomodulatory effects, antipyretic, analgesic, antimicrobial, antibacterial, and gastroprotective activity, which support its traditional use [2]. Due to the phytochemicals and properties of *M. loriformis*, this plant is selected as a potential reducing agent for synthesis of AgNPs.

The scientific world has recently given special attention to the use of bioresources in nanotechnology due to their eco-friendly properties, availability, and low cost, and *M. loriformis* has a promising future in this regard [7]. Nanomaterials have piqued the interest of the scientific community due to their unique properties and diverse biomedical and environmental remediation applications [7–11]. Nanomaterials, such as silver nanoparticles (AgNPs), have numerous possible applications, such as medical diagnostics, imaging, medication delivery,

identification of biological samples, solar cells, catalysis, photovoltaics, and digital data storage [12]. The most famous application of AgNPs is their usage in environmental cleaning. Due to the use of benign phytochemicals and the elimination of dangerous molecules that would have been employed in chemical synthesis, the green synthesis of nanoparticles has earned considerable favor [13]. This technique utilizes bio-extracts as reducing agents, making them relatively less expensive, quicker, and easier than alternative processes. Controlling the size, shape, and structure of AgNPs is crucial due to the close correlation between these features and their optical, electrical, and catalytic properties [14].

Figure 1. Murdannia loriformis plant

In this study, AgNPs were synthesized using silver nitrate as a metal precursor and *Murdannia loriformis* extract (MLE) as a reducing agent. The stability of synthesized AgNPs was investigated and characterized by a variety of characterization techniques. Then, the antibacterial properties were studied against *Escherichia coli* (*E. coli*) and *Staphylococcus aureus* (*S. aureus*) using the disc diffusion method.

Materials and Methods

Materials

Silver nitrate, 99.8%, and sodium hydroxide, 99%, were purchased from QReC. Sulphuric acid, 95-97%, was acquired from Supelco. The aerial part of *Murdannia loriformis* was acquired from EES Biotech Sdn Bhd, Penang, then dried and ground into a fine powder. The powder was then added to 200 mL of deionized water in a 250 mL beaker and heated at 70 °C for 1 hour. Using Whatman No. 1 filter paper, the extracts were filtered and stored at 4 °C for future use. This solution was considered as 100% *Murdannia loriformis* extract (MLE). The *Escherichia coli* ATCC 25922 PK/5 and *Staphylococcus aureus* subsp. aureus ATCC 29213 PK/5 were purchased from Oxoid. The chemicals were used without further purification.

Identification of phytoconstituent in MLE

The phytochemical screening test was conducted using standard procedures Sofowora, 1993; Trease and Evans, 1989; Harborne, 1973 to identify the chemical compounds in the MLE [15]. Table 1 summarizes the experimental for the selected screening test for this study. Carbohydrates content was determined using the calculation method suggested by Guide to Nutrition Labelling and Claims (2010) [16]. The protein content was determined using the Kjeldahl method, protein content was determined as $N \times 6.25$. The average nitrogen (N) content of proteins was found to be about 16 percent, which led to the use of the calculation N x 6.25 (1/0.16 = 6.25) to convert nitrogen content into protein content. The functional group in compounds was determined using a Nicolet FTIR spectrophotometer (Thermoscientific Nicolet 6700, USA). A small amount of powdered *Murdannia loriformis* was respectively placed directly on the germanium piece of the infrared spectrometer with constant pressure applied, and data of infrared absorbance, collected over the wave number ranged from 500 to 4000 cm^{-1} and computerized for analyses by using the Omnic software (version 5.2). The reference spectra were acquired from the cleaned blank crystal prior to the presentation of each sample replicate.

Synthesis of AgNPs: Effect of Variable Parameters

The preparation of AgNPs was observed by the appearance of the characteristic of surface plasmon resonance (SPR) due to the combined vibration of free electrons of AgNPs in resonance with the light wave. The optimization studies were carried out for the formation AgNPs in order to find the optimized condition using MLE as a reducing agent and $AgNO_3$ as the metal precursor. As to ensure the results of the experiments were reproducible, the experiments were run in triplicates. The formation of AgNPs at different pH, MLE concentrations, $AgNO_3$ concentration, temperature, and reaction time were analyzed using a

UV-Vis spectrophotometer.

Table 1. Screening test for identification of phytochemicals in MLE

Test	Experimental	Explanation
Tannin	About 0.5 g of the dried powdered samples were boiled in 20 ml of water in a test tube and then filtered. A few drops of 0.1% ferric chloride were added.	Brownish green or a blue-black colouration indicates the presence of tannins.
Flavonoids	NaOH (2 mL, 10%) was added to MLE, and the solution turned to yellowish colour. Dilute HCl was added to the mixture.	The yellowish colour will turn colourless if flavonoids are present.
Saponins	A small portion of the crude sample was dissolved in 1 mL of ethanol and then diluted with distilled water. The mixture was placed in a shaker for 15 minutes.	A layer of foam (around 1 cm) is formed if saponins are present in the mixture.
Sterols	Chloroform solution of the extract when shaken with concentrated sulphuric acid.	The red colour of the solution indicates the presence of sterols.
Terpenoids	This test is known as the Salkowski test. Chloroform (2 mL) was added to 5 mL of MLE. Then, 3 mL of concentrated H_2SO_4 was added carefully into the mixture.	A reddish-brown layer formed on the surface of the mixture indicates the presence of terpenoids.

Effect of pH

The effect of pH on the synthesis of AgNPs was studied. At this stage, 1 mL of 2 mM of $AgNO_3$ as the metal precursor and 9 mL of 100% MLE as reductant were kept constant. The pH of the solution was adjusted to pH 2, 4, 6, 8, and 10 using 0.1 M of NaOH and H_2SO_4, respectively.

Effect of $AgNO_3$ as metal precursor

The effect of metal precursor concentration on the synthesis of AgNPs was examined using 1 mL of varied $AgNO_3$ concentrations from 1 mM to 15 mM. In this part, 9 mL of 100% MLE was used as a reductant at constant pH 8 and room temperature.

Effect of contact time

The effect of contact time on the synthesis of AgNPs was set at different time intervals, which were 20, 40, and 60 min. In this experiment, 1 mL of 2 mM of $AgNO_3$ as a metal precursor, 9 mL of 100% MLE as a reductant, and pH 8 were kept constant.

Effect of MLE concentration as reductant

In order to optimize the amount of extract as a reductant for the synthesis of AgNPs, 100% MLE concentration (10 g in 200 mL solution) was prepared, and the solution was diluted to 25, 50, and 75%, respectively. In this experiment, 1 mL of 2 mM of $AgNO_3$ as a metal precursor and 9 mL of reductant was kept constant at pH 8.

Characterization of AgNPs

Characterization of AgNPs was carried out using various characterization techniques. Information about optical properties, surface, morphology, particle size, shape, crystal structure, and chemical composition related to the sample was unveiled.

The optical characteristics of the samples were determined using Lambda 35 Perkin Elmer UV-vis spectroscopy with a 10 mm quartz sample cuvette optical path length. The synthesized AgNPs were placed in a sample cuvette and then scanned in a sample chamber. The range of the scan was 400 to 800 nm. The increase in the relative intensity of the SPR peaks

indicates a growing concentration of AgNPs in the system. The shape, size, and average size distribution were determined utilizing Phillips CM12 TEM with Docu version 3.2 image processing, High-Resolution Transmission Electron Microscope (HRTEM) 200 kV with Field Emission TECNAI G20S-TWIN, FEI, and Malvern Zetasizer, respectively. By enabling a high-energy electron to pass through the sample during the TEM measurement, an image with atomic resolution is produced. In the meantime, HRTEM gives crystallographic information about samples by measuring the interplanar spacing (d-spacing) and grain boundaries with atomic resolution.

The X-ray diffraction (XRD) investigation was carried out using a Philips FW1710 and Cu K radiation. The development of diffraction patterns is analysed and identified by comparing the diffracted beams to the reference database stored in the International Centre for Diffraction Data (ICDD) library. The diffracted patterns reveal whether the sample materials are pure or contaminated. Thermo Scientific (Nicolet 6700) FTIR spectrometer was used to analyse functional groups that exist in AgNPs in the range of 500-4000 cm^{-1}. FTIR spectroscopy is used to determine whether biomolecules in MLE are involved in AgNP production.

The criteria of stability of AgNPs are measured when the values of zeta potential range from higher than +30 mV to lower than -30 mV. Surface zeta potentials were measured using the laser zeta meter (Zeta Sizer- Nano Zs). Colloidal AgNPs (5 mL) was diluted with double distilled water (50 mL) using NaCl as suspending electrolyte solution (2 $x10^{-2}$ M NaCl). The pH was then adjusted to the required value. The samples were shaken for 30 minutes. After shaking, the equilibrium pH was recorded, and the zeta potential of the AgNPs was measured. A zeta potential was used to determine the surface potential of the AgNPs. The chemical composition of the samples has been obtained with EDX using a Hitachi S3700N SEM instrument equipped with a Bruker Quantax EDX system**.**

The preparation of AgNPs was observed by the appearance of the characteristic of surface plasmon resonance (SPR) due to the combined vibration of free electrons of AgNPs in resonance with the light wave. The formation of AgNPs at different $AgNO_3$ concentrations from 1 mM to 15 mM was analyzed using a UV-Vis spectrophotometer. To study the stability of synthesized AgNPs, the formation of AgNPs was further investigated using 2, 5, and 10 mM of initial concentration of metal precursor at longer reaction time (1 week and 1 month) and characterized using UV-vis, TEM, and Zeta potential.

Antibacterial test

The production of fresh germs is required for antimicrobial experimentation. Fresh culture is used to cultivate microorganisms that were present 24 hours prior. The linear culture was employed to create a new culture. A single colony was extracted from the cultures and dissolved in the culture's nutrient broth after the loop had been sterilized by heat and cooled. After the culture medium containing the bacteria had been transferred, the tubes holding the normal saline were thoroughly mixed with a vortex for 24 hours until the suspension turbidity was equal to 0.5 McFarland. This opacity is equal to 1.5 x 10^8 CFU/mL. Two bacterial species, namely *E. coli* (ATCC No. 25922) (EC) and *S. aureus* (ATCC No. 29213) (SA), were procured from Next Gene Scientific Sdn. Bhd as Culti-loops. Each bacterial strain was activated on Mueller Hilton Agar, constant at 37 °C for 18 hours. Then 30 µL of the broth was transferred to nutrient agar and incubated at 37 °C for another 24 hours; cell concentration was 10^8 cfu/mL. The effects of antibacterial were studied using the disc diffusion technique. The microbiological suspension of single-colonies of bacteria was generated in accordance with the standard at 0.5 McFarland's to study the antibacterial impact of the disc diffusion technique. On agar nutrition, several bacteria were cultivated independently. 10 mL of different concentrations of AgNPs (2, 5, and 10 mM) and negative controls (MLE) were put onto the disc using the sampler. The plates were then incubated in an oven set to 37°C. Additionally, there was no microbial cloud formation after 24 hours.

Results and Discussion

Three approaches were used to identify phytoconstituents in MLE: phytochemical screening

and carbohydrate and protein content testing. To identify the chemical components found in the MLE, a phytochemical screening test was performed. Table 2 displays the phytochemical screening results, which revealed the presence of flavonoids and sterols but no alkaloids, terpenoids, or saponins.

Table 2. Phytochemical compounds from the screening test

Chemical Compound	Presence	Description
Alkaloids	--	Alkaloids are absent
Terpenoids	--	Terpenoids are absent
Flavonoids	++	Flavonoids are present
Saponins	--	Saponins are absent
Sterols	++	Sterols are present

Carbohydrates content was determined using the calculation method suggested by Guide to Nutrition Labelling and Claims (2010) [16]. The protein content was determined using the Kjeldahl method. The total carbohydrates and protein content in the MLE were found to be 67.20% and 8.90%, respectively. FTIR spectroscopic analysis was then applied to characterize MLE and the synthesized MLE-mediated AgNPs (Figure 2). The FTIR spectrum of AgNPs showed a strong peak at 3257-3371 cm^{-1}, which is a characteristic of the -OH stretching modes in the hydroxyl functional groups. Distinct peaks at 1632-1638 cm^{-1} were observed, in which the second peak is related to the hydroxyl functional groups of alcohols and phenolic compounds that might exist in MLE.

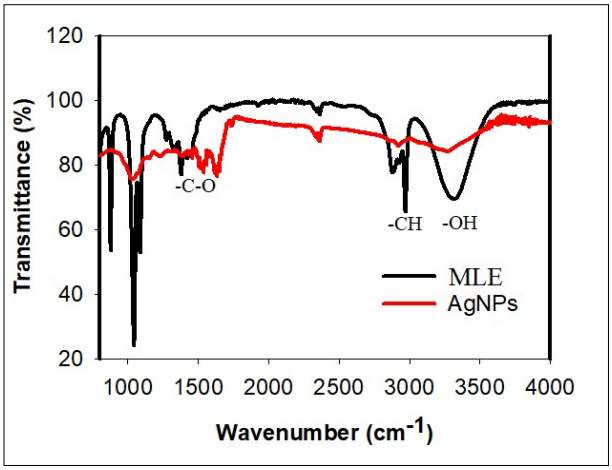

Figure2. FTIR spectra for MLE and MLE-mediated AgNPs

The distinct band within 1632-1645 cm^{-1} could be linked to the aromatic compounds of carbon and carbon double bonds. The sharp band at 1032-1051 cm^{-1} indicates the presence of the -C-O group, and the absorption bands at 1714-1732 and 1635-1655 cm^{-1} correspond to the presence of the carbonyl group within the extract. The observed peaks in the range of 1075-1079 cm^{-1} can be related to the combination of alcohols and phenols. The band at 2923 - 2913 cm^{-1} indicates -CH stretching vibrations. Most of the absorption bands that appeared in the IR spectrum of the aqueous MLE could also be observed in the IR spectra of synthesized AgNPs. This shows that the phytoconstituents biomolecules protect the AgNPs from aggregation. The synthesis of AgNPs by MLE as source of biomolecules was done by some metabolite's functional groups such as alcohols. Similar findings have also been reported in other studies [17].

Synthesis of AgNPs: Optimization studies

AgNPs were formed as a result of the reduction of Ag^+ by MLE. The presence of a band indicative of Surface Plasmon Resonance (SPR) around 410-455 nm validated the development of AgNPs. The AgNPs have free electrons, which cause the SPR absorption band to form as a result of the coupled vibration of AgNPs' free electrons in resonance with light waves. Reaction time, pH, precursor concentration, MLE concentration, and temperature were among the synthesis parameters studied. The findings are organized under the following headings.

Effect of pH

The influence of pH on the formation of AgNPs has been investigated using a pH range of 2-10 and was plotted in Figure 3(a). From Figure 3(b), it can be seen that the intensity of the SPR peak increases when it increases pH from pH 2 to pH 10. In view of the results obtained, the formation of AgNPs is favourable under basic conditions. The addition of NaOH does not bring negative consequences on the formation of AgNPs. Alas, the SPR peak of synthesized AgNPs is higher than in acidic form. However, with the addition of acid solution, the SPR peaks show lower and broader absorbance compared to pH 8 and 10. It can be observed that the SPR peaks for acidic conditions (pH 2) appear at a relatively short wavelength of around 401 nm, while the SPR peaks are shifted towards a longer wavelength (red shift) at 423 nm in the case of the basic medium as shown in Figure 3 (c). The red shift in a basic medium indicates relatively large AgNPs sizes compared with the cases of neutral and very acidic conditions (pH 2).

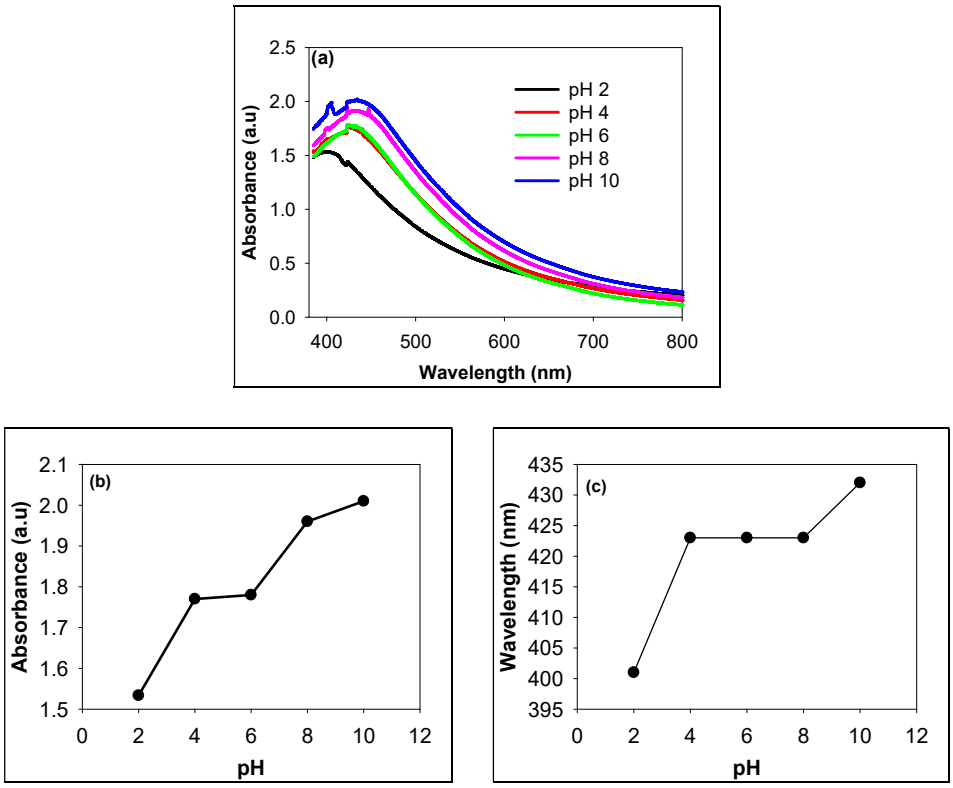

Figure 3. Effect of pH on SPR peak of synthesized AgNPs

Effect of concentration of MLE

Figure 4(a) shows the SPR peak for the effect of MLE concentration as a reducing agent in the formation of synthesized AgNPs. As seen in Figure 4(b), the intensity of SPR peak at 423 nm increases when the initial concentration of MLE increases from 25% to 100%. The

increases in SPR peak with increasing concentrations of MLE can be explained by the increase in the amount of active ingredient in a higher concentration of MLE. At low concentrations of MLE (25% and 50%), the synthesized AgNPs do not have enough reducing agents for synthesizing AgNPs and fail to stabilize the high surface energy of AgNPs. Similar findings have also been reported in other studies [10].

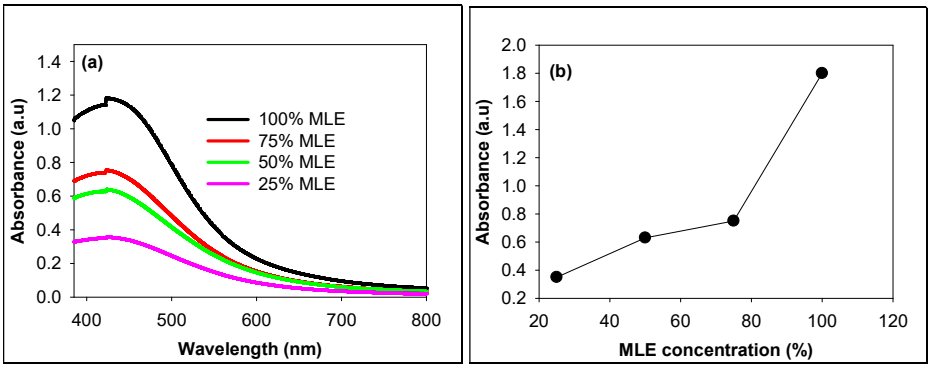

Figure 4. Effect of MLE concentration on SPR peak of synthesized AgNPs

Effect of reaction time

The effect of reaction time on the SPR peak of synthesized AgNPs is shown in Figure 5(a). The intensity of the SPR peak increases with increasing the reaction time from 20 mins to 60 mins, as shown in Figure 5(b). It was noted that with an increase in contact time, the SPR peak becomes sharper. Formation of AgNPs started within 20 mins and increased up to 60 mins. For the stability study, the SPR peak was evaluated for 24-hour, 1-week, and 1-month contact time, as shown in the same spectra in Figure 5(a). However, the SPR peaks in Figure 5 (b) show higher and sharper absorbance compared to the initial reaction time (20-60 mins). It can be observed that the SPR peaks are shifted towards a longer wavelength (red shift) at 479 nm - 482 nm, as shown in Figure 5(c). The redshift at longer contact times indicates relatively larger size AgNPs were obtained. This is due to unstable AgNPs produced and cause agglomeration after a longer contact time.

Effect of concentration silver nitrate

Figure 6 (a) shows the SPR peak for the effect of different concentrations of silver nitrate as a metal precursor from 1 to 15 mM at 1 h reaction time. It can be seen that the intensity of the SPR peak of synthesized AgNPs appears to increase with increasing silver nitrate concentration until it reaches a maximum SPR peak at 430 nm for 5 mM, as shown in Figure 6 (b) – (c). However, the after the SPR peak decreased for higher concentration. No significant SPR peak for 1, 2, and 4 mM of silver nitrate, indicating that low concentrations of Ag^{+} are not enough to induce the formation of AgNPs. For 10 mM and 15 mM silver nitrate concentration, the SPR peaks decreased with increasing silver nitrate concentration due to the agglomeration of AgNPs at high concentrations of the metal precursor.

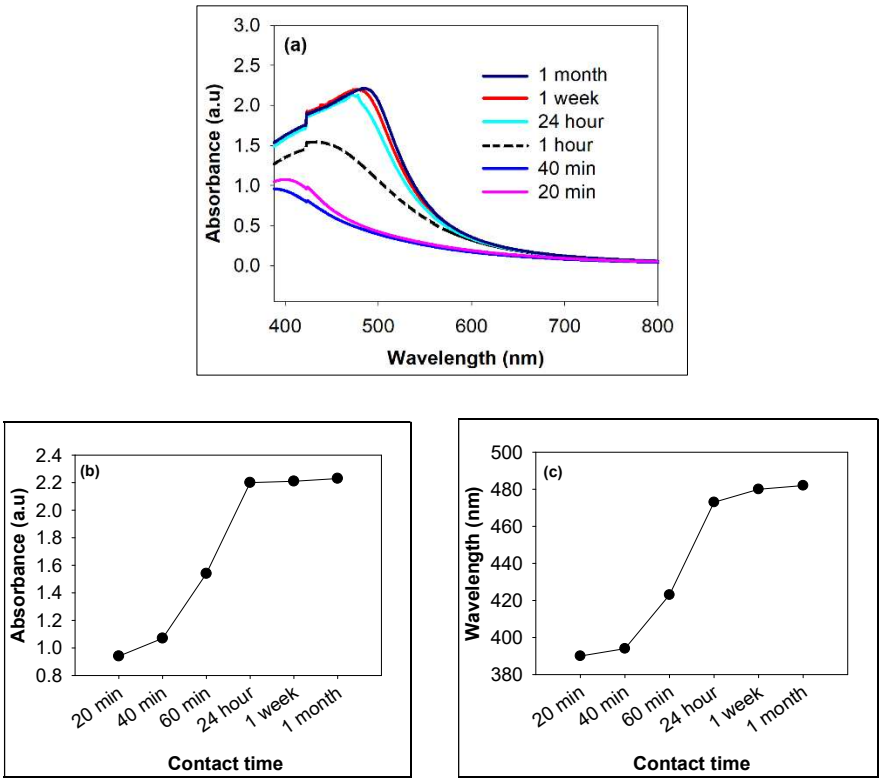

Figure 5. Effect of contact time

Characterization of AgNPs

AgNPs were synthesized at selected parameters, and the optimum condition was further characterized to evaluate their features, such as size, shape, crystallinity, morphology, form, elemental composition, and surface chemistry.

Transmission electron microscopic (TEM) analysis

Figure 7(a-c) show the TEM, HRTEM, and size distribution (histogram) of synthesized AgNPs, respectively. From Figure 7(a), the shape of the colloidal AgNPs was quasi-spherical, and the particles were observed to be evenly distributed. Figure 7(b) shows the HRTEM image of a single AgNP; from the HRTEM, it can also be seen that AgNPs are capped with the phytoconstituents, which is likely to be MLE as a reducing as well as capping agent. The lattice spacing of 0.23 nm was calculated for the HRTEM of a single AgNP, which is associated with (111) plane of AgNPs and with a diameter of 16.16 nm. This indicates the success in the use of MLE not only as a reductant, as it was intended but also as a capping agent to avoid agglomeration of the particles. From Figure 7 (c), the range of particle size of the AgNPs, as calculated from the histogram, was between 8.25 and 19.34 nm with an average particle size of 12.60 nm ± 2.83 nm. Similar findings have also been reported in other studies about the plant extract capped the AgNPs [17, 18].

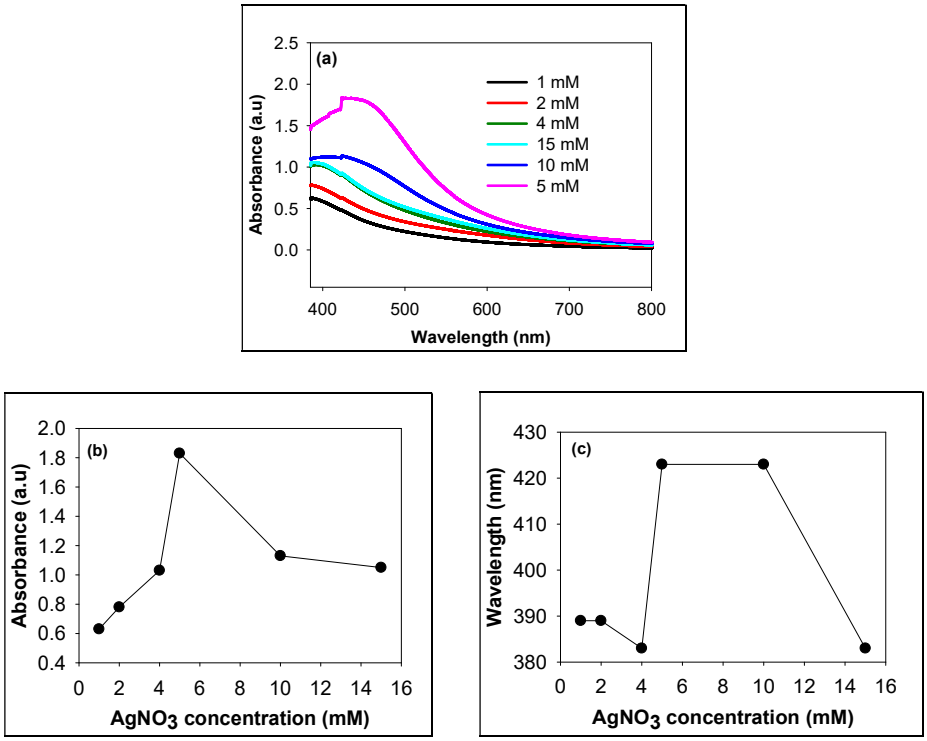

Figure 6. Effect of concentration of metal precursor

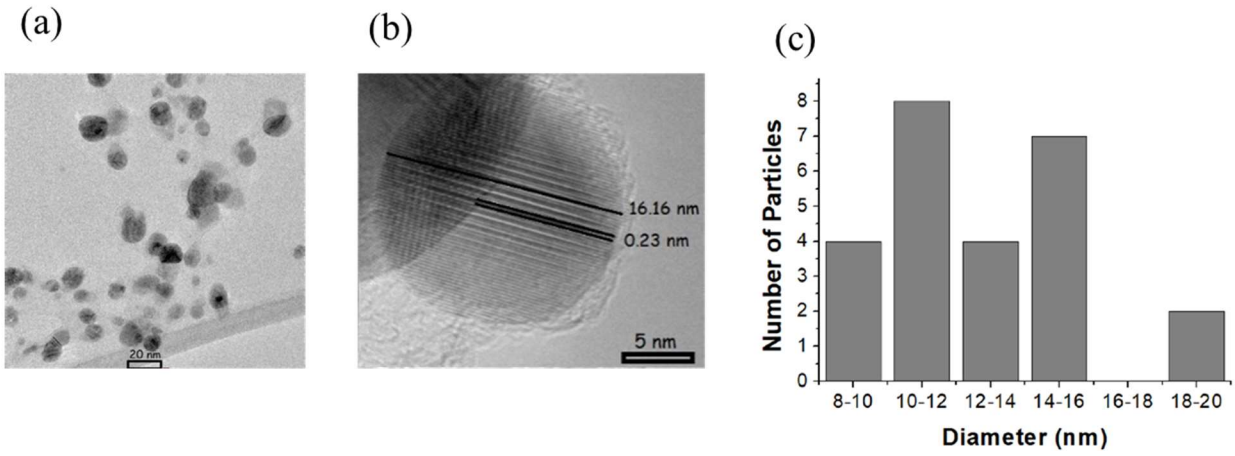

Figure 7. (a) TEM image, (b) HRTEM, and (c) histogram for the size distribution of 2 mM MLE-mediated AgNPs

The crystallinity of Synthesized AgNPs

Figure 8 shows the XRD pattern that proved the crystallinity of the synthesized AgNPs. The freeze-dried MLE-mediated AgNPs' XRD peaks matched the FCC structure of silver at 2 of 38.08°, 44.16°, 64.40°, and 76.85°, corresponding to the (111), (200), (220), and (311) planes, respectively. The (111) plane is found to be more intense than other planes, indicating that growth is concentrated along the (111) plane. The same pattern was also reported in other studies [19, 20].

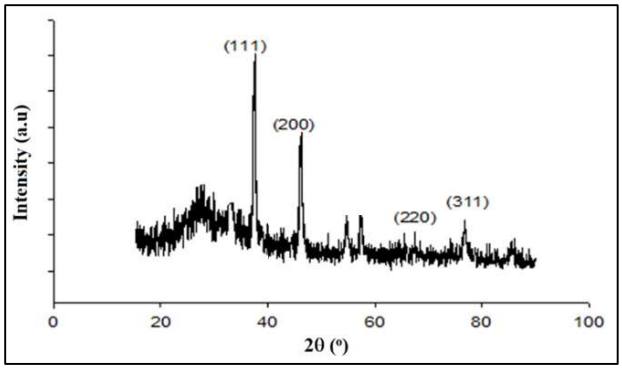

Figure 8. XRD pattern for MLE-mediated AgNPs

Particle size distribution and zeta potential

The Malvern Zetasizer was used to determine the particle size distribution and the zeta potential. Figure 9(a) depicts the hydrodynamic diameter size for synthesized AgNPs prepared using a different initial concentration of metal precursor of 1, 2, 5, and 10 mM. From

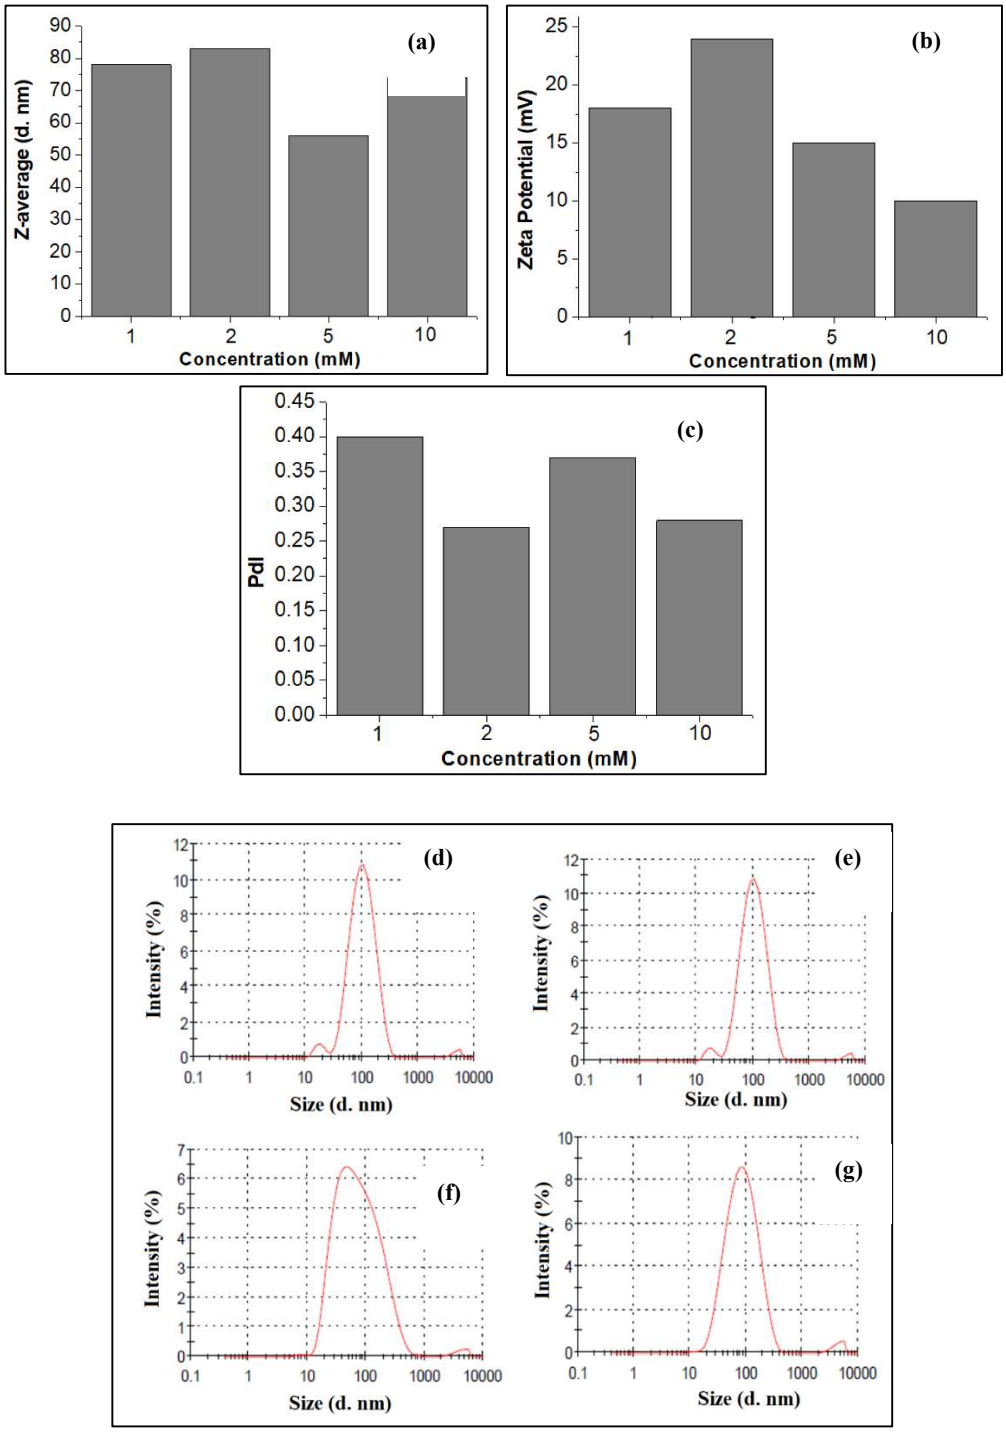
Figure 9(a), it can be seen that the smallest hydrodynamic diameter size of 55.25 nm for synthesized AgNPs prepared at 5 mM and the biggest size of 86.09 nm at 2 mM of initial metal precursor concentration. The increases in the hydrodynamic size of synthesized AgNPs at 2 mM initial concentration might be explained by the optimum amount of the active ingredient in MLE reacted with metal precursor at 2 mM. However, with the increasing initial concentration of metal precursor to 5 mM and 10 mM, the amount of active ingredient is not enough to reduce and stabilize the synthesized AgNPs at high concentrations.

The results obtained were supported by the zeta potential value of synthesized AgNPs at a different initial concentration, as shown in

Figure 9(b). The results showed that synthesized AgNPs prepared using 2 mM have the highest zeta potential value of 23.61 mV. The high potential value could be attributed to the capping action of MLE phytoconstituents, resulting in well-dispersed synthesized AgNPs at 2 mM concentration. The zeta potential for 5 mM and 10 mM of synthesized AgNPs was decreased to 15.80 and 9.75 mV, respectively. It is known that colloids with high zeta potential (negative or positive) are electrically stable, while colloids with low zeta potential tend to coagulate or flocculate [11].

The PDI of the synthesized AgNPs (Figure 9(c)) was in the range between 0.27 and 0.40, showing that the synthesized AgNPs are monodispersed (for monodispersed systems, the PDI should be 0.01 - 0.7 [14]. Colloids with a high zeta potential (negative or positive) are electrically stable, whereas colloids with a low zeta potential coagulate or flocculate [21]. The difference in size between HRTEM and particle sizer measurements could be attributed to the particle sizer assessing the hydrodynamic size of the AgNPs (size of the dispersed AgNPs solvated along with the phytoconstituents of MLE as capping and stabilizing agents).

Figure (d) shows the particle size analysis for synthesized AgNPs prepared at an optimum concentration of 2 mM of initial metal precursor concentration. The particle size analyzer detected two particle size ranges (1-10 nm and 10 - >100 nm). This finding implies that the AgNPs produced are polydispersed particles. Smaller particles (1-10 nm) have a lower peak intensity, whereas larger particles (10 -100) have a greater intensity with a Z-average of 86.09 nm. Small particles may arise in the proximity of larger ones. According to Yin et al., small particles surrounding large particles are most likely generated via second-round nucleation. The larger AgNPs were produced by accelerated crystal development, but their varied sizes of AgNPs may occur due to their formation at different times [22].



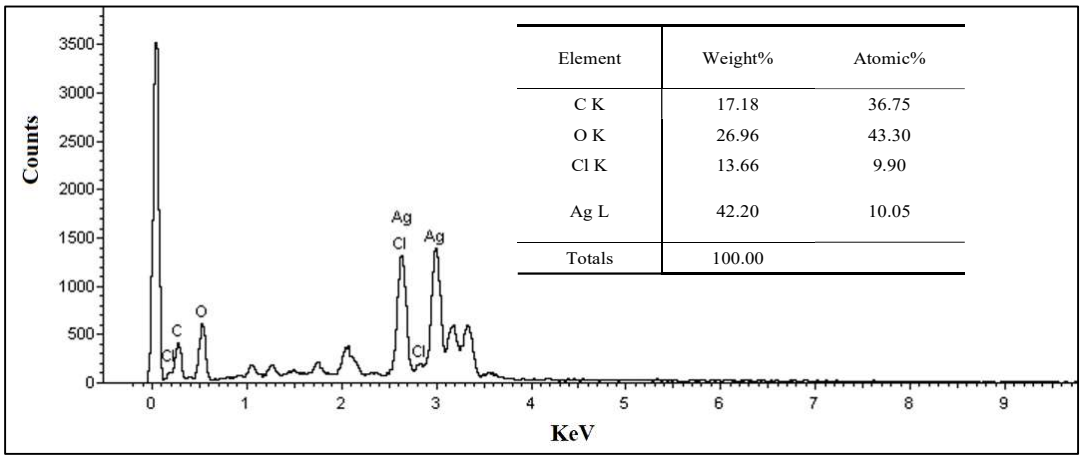


Figure 9. (a) Hydrodynamic size of synthesized AgNPs (b) Zeta potential of synthesized AgNPs (c) Polydispersity index of synthesized AgNPs. Particle size analysis of synthesized AgNPs at (d) 1 mM, (e) 2 mM, (f) 5 mM, and (g) 10 mM initial concentration

Chemical composition analysis

The chemical composition of the synthesized AgNPs was determined by energy-dispersive X-ray spectroscopy (EDX), as shown in Figure 10. It can be seen that the EDX spectrum consisted of Ag, C, O, and Cl. The EDX data of synthesized AgNPs shows a peak at around 2.6 keV; another intense peak appears at 3 keV for silver (42.20 wt%).

Element	Weight%	Atomic%
C K	17.18	36.75
O K	26.96	43.30
Cl K	13.66	9.90
Ag L	42.20	10.05
Totals	100.00	

Figure 10. EDX of synthesized AgNPs

Stability study of AgNPs

After 24 hours, the AgNPs' stability was checked. The synthesized AgNPs created using 2 mM $AgNO_3$ as the metal precursor was shown to be as stable as when they were originally formed. This is seen in Figure 11(a). Even after a 24 h reaction period, the colour of the colloidal AgNPs solution changed from pale yellow to dark brown without any sedimentation. It was thought that the phytoconstituents in the MLE were effective in giving the MLE-mediated AgNPs stability. AgNPs are coated by the phytoconstituents in MLE, which prevents aggregation and provides stability for a while. MLE have large concentrations of protein and carbohydrates, which may be what prevents AgNPs that are mediated by MLE from agglomerating.

However, when the concentration of metal precursor increased to 5 mM and 10 mM, the stability of AgNPs decreased significantly, as shown in Figure 11 (b-c). The color of the solution was dark brown, but after 24 h, the precipitation of AgNPs occurred due to the instability of the MLE-mediated AgNPs. Agglomeration of AgNPs shows the larger size of nanoparticles.

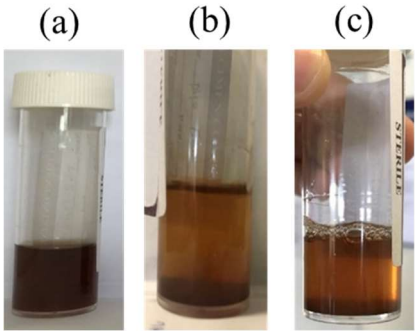

Figure 11. Colour changes of MLE-mediated AgNPs at different concentrations of silver nitrate as metal precursor; (a) 2 mM, (b) 5 mM, and (c) 10 mM

The TEM images were displayed in Figure 12(a) through (c) at various concentrations. Using 5 and 10 mM of $AgNO_3$ as the metal precursor, the synthesized AgNPs are clearly shown from the TEM pictures that the particles of AgNPs are agglomerated and form larger particles at high concentrations.

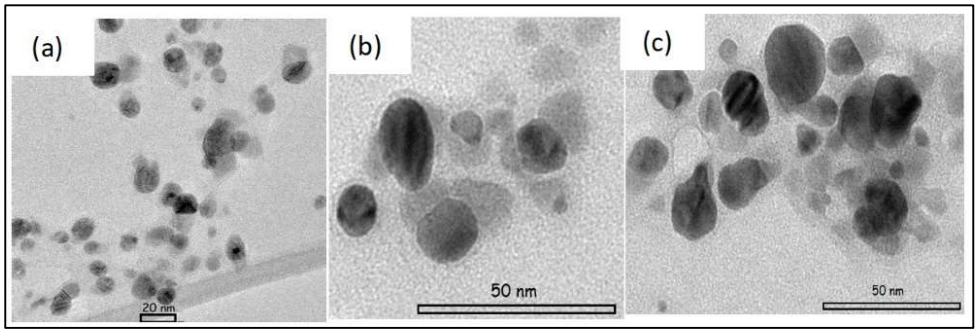

Figure 12. TEM images of MLE-mediated AgNPs at different concentrations; (a) 2 mM, (b) 5 mM, and (c) 10 mM

Figure 13 shows the SPR peak for different concentrations of silver nitrate as a metal precursor (2 mM, 5 mM, and 10 mM) after 24 h reaction time. It can be seen that the intensity of the SPR peak of AgNPs using 2 mM of $AgNO_3$ is higher than SPR for 5 mM and 10 mM concentrations. It also clearly showed the red shift in peak values from 439 nm to 434 nm and 396 nm for 5 mM and 10 mM, respectively. The red shift of the SPR peak indicated the formation of larger AgNPs.

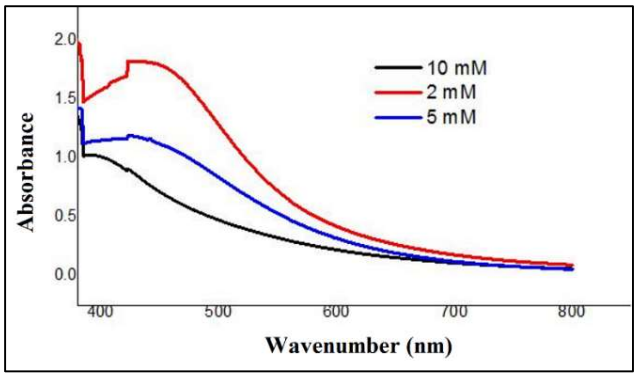

Figure 13. SPR peak from UV-vis of AgNPs at different concentrations after 24 hours

Zeta potential is a useful tool for predicting the stability of AgNPs in solution and understanding their surface. Zeta potential measurement is a technique for determining the surface charge of NPs in a colloidal solution. Figure 14 shows the Zeta potential of AgNPs at different concentrations (2, 5, and 10 mM). From the zeta potential value, it showed that the stability of AgNPs at high concentrations suffers from stability.

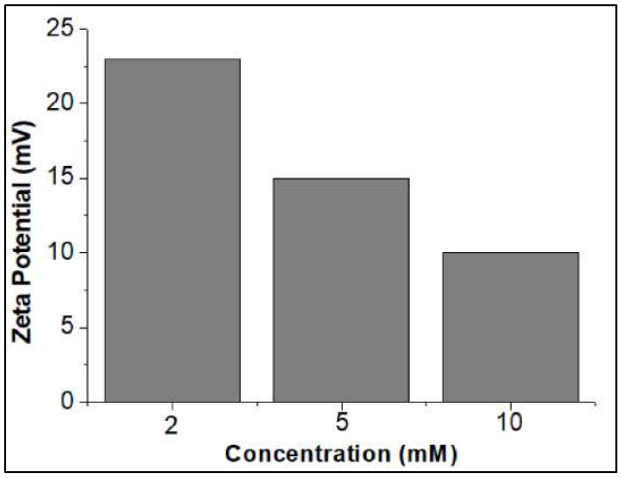

Figure 14. Zeta potential of AgNPs at different concentrations after 24 hours

This section's conclusion clearly shows that using 5 and 10 mM of $AgNO_3$ lowered the stability of synthesized AgNPs. Adopting the idea demonstrated the size distribution's heterogeneous nature [24]. Additionally, it might be because the biomolecules in the MLE were insufficiently powerful to maintain the high concentration of AgNPs. The production of precipitation for AgNPs created by increasing the concentration of metal precursor was also demonstrated in earlier research [25, 26].

According to the data above, the stability of AgNPs produced by MLE reduced as metal precursor concentration increased. AgNPs must be prepared as a homogeneous mixture with various organic, inorganic, and polymeric components for the majority of real-world applications. To study the impact of polymer on the stability and toxicity of high concentrations of AgNPs, two different polymers were evaluated as stabilizing agents for high concentrations of AgNPs (5 mM and 10 mM).

Antibacterial studies of AgNPs

The antibacterial efficacy of synthesized AgNPs was tested against Gram-positive (*Staphylococcus aureus*) and Gram-negative (*Escherichia coli*) pathogens. Each pathogen strain was purchased from Next Gene Scientific Sdn Bhd. Antimicrobial tests were then conducted according to the American Society for Testing and Materials (ASTM) standard method E2783-11. Biosynthesized AgNPs showed significant antimicrobial activity against both the pathogenic bacteria, i.e., *E. coli* and *S. aureus*. The mean diameter of the inhibitory zone (mm) around each well was measured and tabulated in Table 3 result shows *Murdannia loriformis* extract didn't exhibit any significant antibacterial activity against test pathogens even at high concentrations, which might be due to the active constituents responsible for the antibacterial activity is not present in aqueous leaf extract, or the concentrations are very low. *E. coli* (Gram-negative bacteria) and *S. aureus* (Gram-positive bacteria) were sensitive to synthesized AgNPs. The most sensitive is *E. coli,* around 18.27-22.09 mm, while *S. aureus,* around 9.95-10.99 mm in diameter, is related to concentration bacteria 30 µL. It was also observed that the maximum zone of inhibition increases with increasing concentration of AgNPs, where *E. coli* (Gram-negative) exhibited a higher zone of inhibition as compared to *S. aureus* (Gram-positive) (Figure 15). From the observation, different concentrations of MLE-mediated AgNPs did not bring much difference in antibacterial properties against both bacteria.

This might be due to the rigid peptidoglycan layer on the Gram-positive bacterial cell wall compared to Gram-negative bacteria preventing the AgNPs from penetrating, resulting lower zone of inhibition. The exact mechanism behind the antibacterial activity of AgNPs is not very clear, but many proposals have been

put forward for the same. The most accepted hypothesis are i) the formation of pits on the outer membrane progressively release the lipopolysaccharides and membrane proteins, ii) cells treated with AgNPs lead to increase conductivity resulting in leakage of the intracellular molecules, and iii) AgNPs interrupts the ATP metabolism and DNA replication preferentially by targeting the sulfur and phosphorous rich macromolecules resulting programmed cell death.

Table 3 Antibacterial activity of synthesized AgNPs against test bacterial pathogens.

Test	**Zone of Inhibition (mm)**				
Concentration (mM)/ Bacteria	MLE	1	2	5	10
E.coli	0	18.27± 1.37	19.55± 1.81	21.78± 1.51	22.09± 0.44
S.aureus	0	10.99± 0.42	9.11±0.28	9.18±0.18	9.95± 0.26

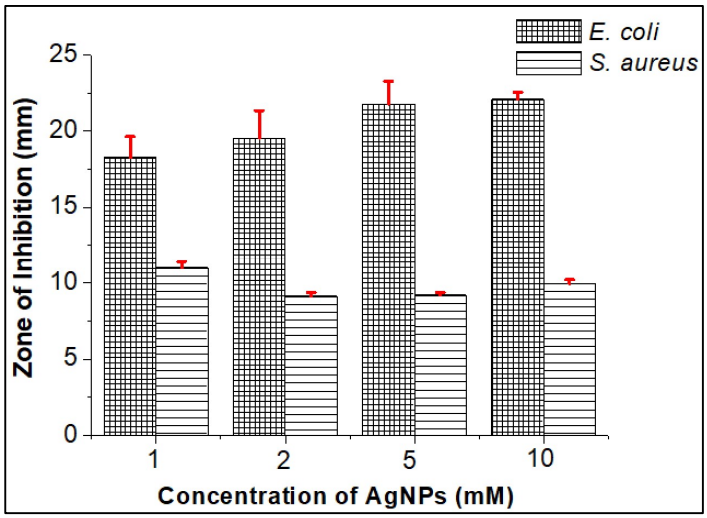

Figure 15. Antibacterial activity means the zone of inhibition (mm) of synthesized AgNPs against pathogenic bacterial strains

Conclusion

AgNPs were successfully synthesized via biological method using MLE as a reducing agent and silver nitrate as the metal precursor. Phytochemical identification revealed that the MLE showed a high concentration of protein and carbohydrate as primary metabolites and the presence of flavonoids and sterols as secondary metabolites, which displayed dual performance of reducing agents, as well as capping agent/stabilizers. TEM images verified the formation of the well-dispersed and quasi-spherical shape of AgNPs with a size range between 8.25 nm and 19.34 nm with an average size of 12.60 nm ± 2.83 nm at the optimized condition of 0.05 g/L (devoted as 100%) concentration of MLE, 2 mM of metal concentration, pH of 10 and 24 hr reaction time at room temperature. At optimized conditions, the AgNPs were highly crystalline in nature with FCC geometry, identified with XRD analysis. The stability of AgNPs synthesized at optimized conditions was confirmed by UV-vis spectral and zeta potential analysis. The synthesized AgNPs were seen to be as stable as when they were first made based on SPR peak in UV-Vis plot as well as did not show any precipitation or colour change in the colloidal AgNPs solution. The stability of synthesized AgNPs can be obtained by phytoconstituents in MLE coat these AgNPs or form an

organic matrix to embed them, thus preventing their aggregation and providing stability for a prolonged period of time. The zeta potential value of 23.61 mV also supports this conclusion. However, the stability of AgNPs decreased when the concentration of metal precursor increased. From the TEM image, the AgNPs were agglomerated when the concentration of $AgNO_3$ increased from 2 mM to 5 mM and 10 mM. Moreover, the Zeta potential values were decreased from 23.63 mV to 15.80 mV, and 9.75 mV as the stability of AgNPs decreased when 5 mM and 10 mM of initial concentration of metal precursors were used. The antibacterial study shows that the maximum zone of inhibition increases with increasing concentration of AgNPs where *E. coli* (Gram-negative) exhibited a higher zone of inhibition as compared to *S. aureus* (Gram-positive) with the value of maximum zone of inhibition around 18.27-22.09 mm for E. coli while S. aureus around 9.95-10.99 mm in diameter related to concentration bacteria of 30 µL. More extensive analysis is required for appropriate synthesis parameters and adequate concentration selection for use in biomedical applications and antibacterial control systems.

Abstract

Demand for authenticating and distinguishing the provenance of bee honey among consumers is continuously rising. Considering vast variations in prices attributable to different geographical origins, suitable indication on labeling of honey products is important for consumer protection. Since concentrations of trace metals can be closely related to geographical origin, the use of spectroscopy and chemometric techniques for ascertaining the validity of such claim may prove relevant. In this study, multi-trace metals in stingless bee honey of *Heterotrigona itama* species, from different regions and seasons (rainy and dry) in Peninsular Malaysia (Kedah, Johor, Selangor and Pahang) were determined *via* inductively coupled plasma-optical emission spectrometry (ICP-OES). Principal component analysis (PCA) was then applied to recognize the distribution patterns. Subsequently, linear discriminant analysis (LDA) was applied to perform further classification. With the use of LDA, cross-validation was found as 95.8% and 89.6% during rainy and dry seasons, respectively. Combination of ICP-OES data with PCA and LDA techniques has provided accurate classification of the Malaysian stingless bee honey samples according to their respective origins. This study provided some elemental information on distribution of stingless bee honey samples at spatial and temporal levels, and could be used as a reference for their provenance establishment and authenticity.

Abstrak

Permintaan untuk mengesahkan dan membezakan asal usul madu lebah di kalangan pengguna terus meningkat. Mengambil kira variasi besar harga byang disebabkan oleh asal geografi yang berbeza, petunjuk yang sesuai pada pelabelan produk madu adalah penting untuk perlindungan pengguna. Oleh kerana kepekatan logam surih berkait rapat dengan asal geografi, penggunaan teknik spektroskopi dan kemometrik untuk menentukan kesahihan tuntutan tersebut mungkin terbukti relevan. Dalam kajian ini, logam pelbagai surih dalam madu lebah tanpa sengatan dari spesies *Heterotrigona itama*, dari pelbagai rantau dan musim (hujan dan kering) di Semenanjung Malaysia (Kedah, Johor, Selangor dan Pahang) ditentukan melalui plasma gandingan teraruh-spektrometri pancaran optik (ICP-OES). Analisis komponen utama (PCA) kemudian digunakan untuk mengenal corak taburan. Seterusnya, analisis diskriminan linear (LDA) telah digunakan untuk melaksanakan klasifikasi lanjutan. Dengan penggunaan LDA, pengesahan silang masing-masing adalah 95.8% dan 89.6% pada musim hujan dan kering. Gabungan data ICP-OES dengan teknik PCA dan LDA telah memberikan klasifikasi tepat sampel madu lebah tanpa sengatan Malaysia mengikut asal usul masing-masing. Kajian ini memberikan beberapa maklumat unsur mengenai taburan sampel madu lebah tanpa sengatan pada tahap spasial dan temporal, dan dapat digunakan sebagai rujukan untuk asal usul dan keasliannya.

Kata kunci: madu, lebah tanpa sengatan, asal usul, ketulenan, spektroskopi, kemometrik

Introduction

Honey is the oldest natural sweetening agent with various nutritional and therapeutic values [1]. Being a natural product, composition of honey is diverse, ranging from sugars, flavor compounds, amino acids, enzymes, flavonoids, gluconic acid, lactone, nitrogenous compounds, proteins, vitamins (vitamin B6, thiamine, niacin, riboflavin and pantothenic acid) [2 - 5] phenols, pigments as well as multi-trace metals [2, 6, 7]. Modern researchers have reported several honey biological activities such as antioxidant activity [8], decreases factors of cardiovascular risk [9] and improve resistance against pathogenic organisms [10].

To date, consumer demands for genuine honey of high qualities are continuously increasing. Since the beginning of honey trade, negative perceptions concerning processed honey products (adulteration) are also growing. Honey adulteration is the major problem influencing the overall perception of honey in terms of quality, price and human health (potential genotoxic, cytotoxic and carcinogenic effects of hydroxymethylfurfural) [11]. According to [1], two major factors related to honey authenticity; (i) origin of the honey (geographical and botanical origins) and (ii) mode of honey production (harvesting and processing techniques). Since years ago, internationally, the Codex Alimentarius have developed the authenticity standard of honey by providing the essentials of identity and quality of honey requirements for human consumption. This standard can be applied to all types of honey produced by bees and it covers all types of honey conditions [12].

Recently in Malaysia, Department of Standards Malaysia have developed a standard for *Kelulut* (Stingless bee) honey (MS 2683:2017) in 2017 [13]. In this Malaysian standard, it covered the quality requirements, sampling methods, sample preparation, hygiene, packaging as well as labeling of stingless bee honey for direct human consumption. Besides being great pollinators in ecosystem, stingless bees able to modify floral nectars into distinctive aroma and flavor of honey [14] that is favorable by local consumers.

Honey produced by stingless bee species especially by Meliponinae is appreciated by consumers worldwide [14] including Malaysia. Meliponinae was reported to have distinct characteristics compared to other bee species such as absence of sting, short foraging distance and build hives in horizontal position to store nectar and pollen [15, 16]. Due to the insufficient knowledge of Malaysian stingless bee honey composition, there is a shortage of identity of its geographical origin especially related to the present of multi-trace metals signature. As reported by [2], multi-trace metals content is important as it much dependent on the soil and the environment of plants where the stingless bees collect nectar in the production of honey. In addition, anthropogenic activities such as agricultural practices and industrial can also influence the presence of multi-trace metals in honey [17]. Atanassova et al. [18] reported that during different vegetation season, honeys could exhibit different multi-trace metals concentrations even though it comes from same geographical region, same beehive and same locality.

The assessment of multi-trace metals concentrations can be useful in discriminating honey based on their geographical origin [19]. Few authors have begun to apply analytical approaches such as flame atomic absorption spectroscopy (FAAS) [20, 21], graphite furnace atomic absorption spectrometry (GFAAS) [22], inductively coupled plasma-mass spectrometry (ICP-MS) and inductively coupled plasma-atomic emission spectrometry (ICP-AES) [23] and inductively coupled plasma-optical emission spectrometry (ICP-OES) [24, 25] to determine the

presence of multi-trace metals in honey samples.

In Malaysia, studies on multi-trace metals analysis have been performed by Moniruzzaman et al. [22] and Chua et al. in 2012 [23] on various type of Malaysian bee honey but none of the studies reported on the honey provenance establishment of stingless bee species. Shadan et al. [24] reported for the first time on the provenance establishment of stingless bee honey from five districts of Johor region (Segamat, Muar, Batu Pahat, Kota Tinggi and Johor Bahru). Their study focuses on the provenance establishment of the honeys using chemometric techniques namely principal component analysis (PCA) and linear discriminant analysis (LDA). The multi-trace metals profile detected the present of Ag, Al, As, B, Ba, Be, Cd, Co, Cr, Cu, Fe, Mg, Mn, Mo, Ni, Pb, Sb, Se, Sn and Zn. Despite its natural occurrence in most regions of Malaysia, there is still a shortage of studies on the geographical origin of stingless bee honey. The identity and quality standards of the honey are difficult to ascertain.

The incorporation of chemometric techniques into spectroscopy methods is an effective method for identifying minor and major compounds in honey that can serve as unique signatures for its botanical or geographical origin [26]. Therefore, the aims of our study were: (i) to determine eighteen multi-trace metals in stingless bee (*Heterotrigona itama*) honey samples collected from four regions of Peninsular Malaysia, namely Kedah, Johor, Selangor, and Pahang during two different seasons (rainy and dry); and (ii) to classify stingless bee honey samples by regions of each season based on their multi-trace metal concentrations using ICP-OES in combination with PCA and LDA techniques.

Materials and Methods

Instrument and apparatus

The analysis was performed using ICP-OES, Perkin Elmer (PE 4300 DV) model (Shelton, USA), located at the Department of Chemistry, Petaling Jaya, Selangor. The operating conditions for determining multi-trace metals in stingless bee honey samples were as follows: radio frequency power (0.7-1.5 kW; 1.2-1.3 kW for axial), Ar plasma gas flow (radial: 10.5-15 L/min; axial: 15 L/min), Ar auxiliary gas flow rate (1.5 L/min) and viewing height (5-12 mm).

Reagents

Analytical grade HNO_3 (65% v/v) was purchased from Merck KGaA, (Darmstadt, Germany). Ultra-pure water (resistivity, 18.2 MΩ cm^{-1}) was produced from a Milli-Q water purification system (Millipore, Bedford, MA, USA) and was used throughout the preparation of solutions. Multi-element standard solution was obtained from Agilent Technologies (Santa Clara, USA).

Sample collection, preparation and analysis

Honey samples from stingless bees (*Heterotrigona itama*) were harvested in November 2016 and February 2017, respectively, during rainy and less rainy seasons. At the beginning of this study, we decided to collect stingless bee honey samples throughout Peninsular Malaysia, but because of the limited number of beekeepers registered with the Malaysian Agricultural Research and Development Institute (MARDI), we are focusing only on the registered beekeepers from selected districts in this study. A total of thirty-two stingless bee honey samples were collected from the northern (Kedah: Padang Terap, Kulim, Yan and Baling), southern (Johor: Segamat, Johor Bahru, Pontian and Mersing), western (Selangor: Sabak Bernam, Klang, Kuala Selangor and Hulu Selangor) and eastern (Pahang: Jerantut, Rompin, Temerloh and Kuantan) regions of Peninsular Malaysia.

The honey samples were harvested directly from beekeepers during rainy and less rainy seasons, with the mean maximum temperature being 27.9℃ and 35.6℃, respectively. All the stingless bee honey samples were harvested without any treatment and kept in separate amber glass bottles at 12℃. To minimize the final acidity of honey samples after preparation, the acid mineralization method was performed, as suggested by Chua et al. [23] with a few modifications. Approximately 1 g of each honey sample was digested and mineralized using 65% concentrated HNO_3 (10 mL) by heating the mixture till near to dryness. The mixture was then made up to a volume of 50 mL with deionized water (DI), filtered and kept in a glass bottle at 12℃ prior to analysis. Using the same sample preparation procedure, a blank control sample that contained 10 mL of HNO_3 (65% v/v) was used in the preparation of calibration and quality control samples. The varying concentrations of working solutions and quality control samples were freshly prepared *via* serial dilution from a stock solution containing 100 mg/L of multi-elements in HNO_3.

Chemometric approach dataset

The data set consisted of thirty-two stingless bee honey samples separated by geographical origins and eighteen multi-trace metals. The samples which came from the sixteen districts of the four regions were divided as follows:

1. Northern region: Padang Terap (PT), Kulim (KM), Yan (YN) and Baling (BG)
2. Southern region: Segamat (ST), Johor Bahru (JB), Pontian (PN) and Mersing (MG)

3. Western region: Sabak Bernam (SB), Klang (KL), Kuala Selangor (KS) and Hulu Selangor (HS)
4. Eastern region: Jerantut (JT), Rompin (RN), Temerloh (TH) and Kuantan (KN)

Upon completion of data entry in Microsoft Excel® spreadsheet (Microsoft Corporation, Washington, USA) and IBM® SPSS statistics 20.0 software, the data were exported into Minitab® 17 software (Minitab Inc., State College, PA).

Principal component analysis (PCA) and linear discriminant analysis (LDA)

For studying the organization of the overall dataset, PCA was utilized following the steps proposed by Shlens [27] viz. standardization of dataset, calculation of covariance matrix, obtaining the principal components (PCs) and data translation into components. Being the supervised statistical method, LDA categorically clusters objects into user-defined groups/clusters by calculating linear discriminant function to create a model that would enable correct classification of objects within a given dataset. For validating the developed model for a given dataset, the "leave-one-out" technique cross-validation approach was utilized.

Results and Discussion

Analytical parameters and method accuracy

Thirty-two stingless bee honey samples were analyzed using ICP-OES to determine their multi-trace metal concentrations (3 replicates). The limits of detection (LOD) and limit of quantitation (LOQ) for ICP-OES were estimated from blank analysis (7 replicates). The LOD and LOQ were calculated as 3SDblank/slope and 10SDblank/slope, respectively. The proposed method with matrix matching calibration used in this study is shown in Table 1.

Table 1. Wavelength, R^2, regression equation, LODs, LOQs and % RSD for multi-trace metals determination in stingless bee honey using ICP-OES

Metals	Wavelength (nm)	Coefficient of Determination (R^2)	Equation	Limit of Detection (mg/L)	Limit of Quantitation (mg/L)	Relative Standard Deviation (%)

Note: Silver (Ag), aluminum (Al), arsenic (As), barium (Ba), beryllium (Be), cadmium (Cd), cobalt (Co), chromium (Cr), copper (Cu), manganese (Mn), nickel (Ni), lead (Pb), selenium (Se), thallium (Th), thorium (Th), uranium (U), vanadium (V) and zinc (Zn).

Multi-trace metals concentrations in stingless bee honey samples

The preliminary findings for multi-trace metals analysis presented in this study demonstrated the potential for provenance establishment of Malaysian stingless bee honey samples. Concurrently, a total of eighteen multi-trace metals were determined after digestion process using ICP-OES. For these metals, some trace metals cannot be detected in some types of honey samples and some exhibited low or high concentration based on certain areas and regions. It may be because of the differences in soil composition, floral type, floral density, nectar or pollen [28 - 30]. Study by Pohl [31] suggested another factor which may contribute to the diversified trace metals content such as beekeeping practices, environmental pollution and honey processing. In an industrial area, toxic trace metals have been reported to be presented high concentrations in honeys [32]. According to Fatima et al. [33], the composition of Malaysian stingless bee honey from Trigona species varies according to geographical or botanical origin, as well as fruit or flower season. Therefore, these trace metals may give useful information in order to validate the geographical origin (provenance) of stingless bee honey samples.

Table 2 shows the most abundant metals (Al and Zn) obtained in stingless bee honey from four regions of Peninsular Malaysia. Bees are exposed to Al from various sources of their foraging activities for nectar as this element is reported to be abundant in Earth's crust [34]. In this study, the highest concentration of Al in stingless bee honey samples of rainy and dry seasons were 0.666 and 0.477 mg/L, respectively. The Al values obtained in this study was slightly similar to the study by Chua et al. [23] as they reported the range of Al concentration was between 0.708 to 1.872 mg/L in various type of honey from Malaysia. Previous research by Altun et al. [35] on honey samples from South and East regions of Turkey using ICP-MS found the highest concentration was 0.96 mg/L. In addition, Di Bella et al. [36] reported the highest concentration of Al was 5.67 mg/L in all honeys from Sicily and Calabria, Italy whereas Czipa et al. [37] found 4.39 mg/L of Al in Hungary honeys. According to Oroian et al. [38], due to neurological and cancer effects, Al is not essential to be consumed in high dosage.

The recommended daily consumption of Zn was 7.5 mg/kg and 13.5 mg/kg for children and adults, respectively [39]. In this study, the lowest and the highest Zn concentrations were less than 1 mg/L in all honeys. Since the highest concentration of Zn in this study was 0.549 mg/L, it showed Zn level was within the acceptable limits. Honeys from Hatay, Turkey also showed lower Zn concentration (0.237 mg/L) [35]. Conversely, other studies obtained high Zn concentration values in Anatolia honey (1.1-12.7 mg/L) [21] and Eastern Solvakia honey (1.3 mg/L) [17]. Chua et al. [23] reported Zn concentration of forest Malaysian honeys between 2.353 to 18.112 mg/L which is higher compared to our study.

Table 3 shows the low concentrations metals present in stingless bee honey. The content of Cr and Ni in this study (<1 mg/L) attributed to the uncontaminated environment as the main sources of livelihood is agriculture and not heavily industrialized. The Cr concentrations of our honey samples are similar to the Cr concentrations of Turkey honey (0.0024-0.0379 mg/L) [21], Eastern Solvakia honey (0.0268-0.0433 mg/L) [17] and Hatay honey (0.1-0.54 mg/L) [40]. In contrast, various type of honey samples from Malaysia possessed high Cr concentration of the range 1.8-3.8 mg/L as discussed by Chua et al. [23]. In this study, the highest concentration of Ni during rainy and dry seasons was 2.939 and 0.0406 mg/L, respectively whereas Chua et al. [23] obtained 0.084 mg/L of Ni from Malaysian forest honey sample. The mean Ni concentration of Argentine honey was 0.03 mg/L [41].

Copper (Cu) is an important element in eukaryotes aerobic respiration [42] and vital in formation of haemoglobin as well as in production of melanin for skin, hair and eyes pigmentation [38]. The mean range concentration of Cu in this study (0.015-0.128 mg/L) was slightly similar to the mean range (0.046-0.236 mg/L) of various honey samples as reported by Chua et al. [23]. The maximum and minimum concentration values for Mn exhibited 0.031 and 0.795 mg/L, respectively. These results showed lower values compared to results from Chua et al. [23]. However, our study was higher than Irish honey samples (0.004 mg/L) [43].

Selenium (Se) is a nutritious element for humans and it plays an important role in reproduction process, DNA synthesis and protection against infection [35]. In this study, the highest Se concentration determined in stingless bee honeys was 0.023 mg/L which was lower than Se concentration of Malaysian Tualang honey produced by sting bees (17.202 mg/L) [23]. However, our result exhibited slightly higher compared to Argentine honeys [41] and honeys from North East of Romania [38].

SD = standard deviation (n = 12). One-way ANOVA with Tukey's HSD post hoc test with significant value of 0.05 was used for determining the mean differences in the concentrations of multi-trace metals in stingless bee honey samples among the different regions. *The mean difference is significant at the 0.05 level.

Table 4 shows heavy metals concentrations obtained from Malaysian stingless bee honey samples. Excess heavy metals such as As, Cd, Co and Pb cause an excessive production of reactive oxygen species (ROS) causing oxidative stress [44]. According to Bogdanov et al. [45], Cd and Pb are considered as bio-indicators for contamination of honey. Pollutants from industries might contaminate soil and air. Cd is an element that passed from soil to plants and nectar whereas Pb contamination correlates with air pollution [17]. The lowest and the highest concentrations of As, Cd, Co and Pb were <1 mg/L in all stingless bee honey samples. The honey samples of this study are harvested directly from beekeepers that are located mostly far from the main road and the factories area. Moreover, our data for As, Cd, and Pb concentrations were within the recommended limits as stated in Malaysia Food Act 1983 (Regulation 38) and Food and Agriculture Organization (FAO) and World Health Organization (WHO) [46].

[c]FAO and WHO	General limit for food		1		2

SD = standard deviation (n = 12); ND = not detected. One-way ANOVA with Tukey HSD post hoc test with significant value of 0.05 was used for determining the mean differences in the concentrations of multi-trace metals in stingless bee honey samples among the different regions. *The mean difference is significant at the 0.05 level. [a,b,c] Results are expressed in mg/kg [22, 46].

Trace metals concentrations of stingless bee honey samples from four regions of Peninsular Malaysia were shown in Table 5. In this study, the concentrations obtained for Ag and U were lower to those found by Chua et al. [23]. Additionally, Be and V metals have been determined in stingless bee honey samples but absent in various honey samples from Malaysia [23]. The presence of rare earth elements (REE), such as Ce, Dy, Er, La, Ho, Sm and Th are associated with the used of fertilizers to increase plants productivity [47]. From the results obtained, both rainy and dry seasons possessed low concentration of Th metal.

Table 5. Trace metals in stingless bee honey samples from four regions of Peninsular Malaysia

SD = standard deviation (n = 12); ND = not detected. One-way ANOVA with Tukey's HSD post hoc test with significant value of 0.05 was used for determining the mean differences in the concentrations of multi-trace metals in stingless bee honey samples among the different regions. * The mean difference is significant at the 0.05 level.

The data from multi-trace metal concentrations suggested that stingless bee honey samples from four regions of Peninsular Malaysia indicate the honey good quality. Different geographical regions are probably related to the variations in the multi-trace metal concentrations. Increases in anthropogenic activities such as agricultural practice, industries, traffic, coal mining and burning contribute to the accumulation of hazardous multi-trace metals in the ecosystem and become part of the regional environmental compartments [17, 24, 48, 49]. Atanassova et al. [18] reported that during different vegetation seasons, honey could exhibit different multi-trace metal concentrations even though it comes from the same geographical region, same beehive, and same locality.

Principal component analysis (PCA)

For better illustration, PCA was performed on eighteen multi-trace metals to study the overall organization of data for all stingless bee honey samples from the different geographical origins. In this study, it is possible to separate honey samples by their multi-trace metals distribution. The starting part of PCA calculations was the matrix of data with dimensions ($n \times p$), where n is the number of cases (rows) and p is the number of variables (columns). In the matrix, rows represented the honey samples geographical origins and the column represented the multi-trace metals in stingless bee honey samples. As a result of PCA analysis, thirteen and fourteen new variables were obtained, which were represented by eigenvalues for rainy and dry seasons, respectively.

The significance of a factor is explained by its eigenvalue. The factor with the highest eigenvalue is considered the most important. As a result, eigenvalues of 1 or greater are considered significant [50]. The results for the rainy season, as demonstrated in Figure 1(a), showed the first three principal components (PC1-3), with eigenvalues > 1, had 68.7% of the total variability among the thirteen variables in the original data, where in PC1, PC2 and PC3 contributed to 39.5%, 17.0% and 12.2%, respectively. Based on the eigenvalue criterion, PCs with eigenvalues of greater than 1 are considered important [51]. The first PC was principally correlated (loading > 0.30) with five trace metals (Al, Cd, Co, Ni and Zn) that were detected at low concentrations in stingless bee honey samples. While copper, manganese and lead metals were the dominant contents in PC2 and metal content of As, Th, U and V loaded highly in PC3.

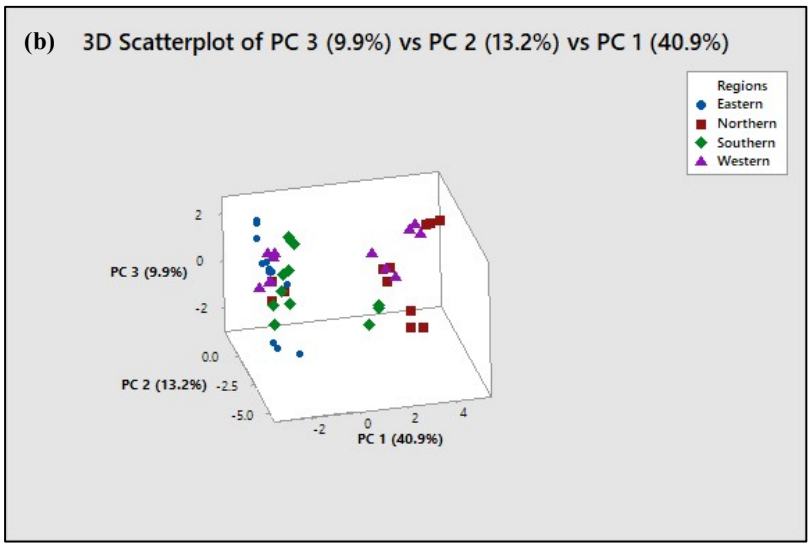

Figure 1. A three-dimensional PCA plot (PC1, PC2 and PC3) for the concentration of eighteen multi-trace metals during (a) rainy and (b) dry seasons

As shown in Figure 1(b), during the dry season, the first three principal components (PC1-3), with eigenvalues greater than one, had 64% of the total variability, where PC1, PC2 and PC3 accounted for 40.9%, 13.2% and 9.9%, respectively. The results showed that a three-factor model could explain 64% of the total variance. The first three PCs (loading plot > 0.3) showed that the Be, Co, Se, Th, U, and V metals have high weights in PC1; Ba, Cd, Mn, and Tl metals loaded high in PC2; and the dominating content in PC3 were Al, As, Cu, and Ni metals. The variability of these multi-trace metal concentrations could be a result of geographical variation. The distribution of stingless bee honey varies between rainy and dry seasons. During the rainy season, as shown in Figure 1(a), the northern, southern, and western regions are close to each other, indicating similarity in multi-trace metal compositions. The eastern region, on the other hand, is separated from the other three regions. As shown in Figure 1(b), the distribution pattern was different during the dry season. This study discovered a relationship between multi-trace metal compositions and the seasons.

As studied by Biluca et al. [52] and Pucholobek et al. [53], Mn metal exhibited the highest concentration in stingless bee honey produced in Brazil through PCA, indicating that geographical origin may influence the concentration of metals in honey. In this study too, Mn is evidently present in high concentrations in the stingless bee honey samples in Peninsular Malaysia during both the rainy and dry seasons. The fact that specific studies focusing on the distributions of Mn across the different locations in Peninsular Malaysia remain unreported, suitable attempt to elucidate such a matter proves necessary.

Linear discriminant analysis (LDA)

LDA simplifies the observation and interpretation of information on graphical representations [51]. The classification results obtained using LDA technique is shown in Figure 2(a) and (b). An accuracy of 95.8% (rainy season) and 89.6% (dry season) success rate in honey samples regions classifications were achieved by the cross-validation (leave-one-out) LDA technique, in order to evaluate the performance of developed classification models. A neat and no neat separation between regions can be observed during rainy and dry seasons, respectively. Although no neat separation was obtained during dry season, however, all the stingless bee honey sample was confirmed to be harvested from the beekeepers of selected districts of four regions.

A study by Nomikos and MacGregor [54], explained that, with highly correlated variables, only few PCs are needed to explain the significant in the data set. Additionally, by using cross-validation technique, the number of PCs to retain can also be determined. The power of PCA technique can be observed by plotting the scores of PCs, in which the objects will exhibit measurement similarities to form clusters and moreover, an isolated object (outlier) can be seen clearly. As shown in Figure 1(a) and (b), an exploratory PCA was run on the entire data set to get a sense of the data distribution for each region.

During both rainy and less rainy seasons, overlapping regions for stingless bee honey were observed, with a minor clustering for their geographical origins. Therefore, in this study, by considering three PCs, rainy and less rainy seasons represented 68.7% and 64.0% of the variations, respectively. Further classification by the LDA technique exhibited an improvement in percent of classification to 95.8% (rainy) and 89.6% (less rainy). The selection techniques allowed a reduction from eighteen trace metal concentrations to only ten. The presence of Al, As, Cd, Co, Cu, Mn, Ni, Th, U, and V in both rainy and less rainy seasons appears to provide suitable chemical signatures of the Malaysian stingless bee hone's geographical origins. This percentage can be considered satisfactory as the number of stingless bee honey samples was small. A previous study by Shadan et al. [24] reported 70.2% of variations using the first three PCs and improved to 96.2% using the LDA technique. Their study was similar to our study, but they only examined five districts in the southern region (Johor) of Peninsular Malaysia during the less rainy season in February to July 2016. The composition of stingless bee honey varies according to geographical or botanical origin, as well as fruit or flower season [33].

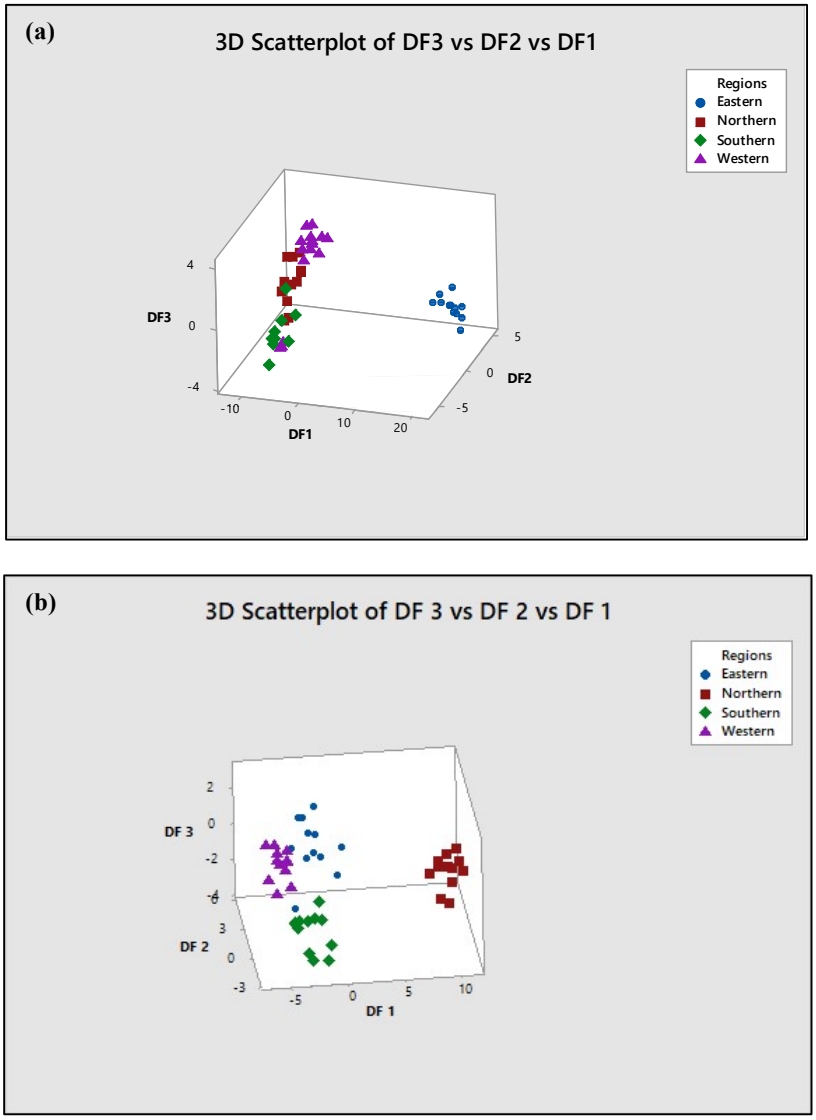

Figure 2. A three-dimensional LDA plot (DF1, DF2 and DF3) after removal of outliers and (b) dry season

Conclusion

This study filled some information gaps on multi-trace metals in *Heterotrigona itama* stingless bee honey from four regions of Peninsular Malaysia, namely Kedah, Johor, Selangor, and Pahang. For the first time, discussion on eighteen multi-trace metals (Ag, Al, As, Ba, Be, Cd, Co, Cr, Cu, Mn, Ni, Pb, Se, Th, Tl, U, V and Zn) concentrations of stingless bee honey sample collected from Padang Terap, Kulim, Yan and Baling (Kedah), Pontian and Mersing (Johor), Sabak Bernam, Klang, Kuala Selangor and Hulu Selangor (Selangor) as well as Jerantut, Rompin, Temerloh and Kuantan (Pahang) were made. Cross-validation results were excellent during the rainy and less rainy seasons, with 95.8% and 89.6%, respectively. It could be attributed to regional differences in the composition of multi-trace metals. This study supported the possibility of assigning a relationship between multi-trace metal compositions and their geographical origins, following the integration of such data with chemometric techniques like PCA and LDA. Further research should concentrate on bioavailability studies to estimate the degree of intake that is suitable for the human digestive system as metals show varied absorption interactions.

Abstract

Carbon fibre is widely used in industry, but its high cost limits its use. Interestingly, lignin has the potential to serve as a carbon fibre precursor with properties similar to those of polyacrylonitrile (PAN) and pitch-based precursors. Oil palm frond (OPF), lignocellulosic biomass composed of cellulose, hemicellulose and lignin, is an attractive source of biomass for lignin extraction. This study proposes lignin extraction from OPF using a deep eutectic solvent (DES). DESs are eutectic mixtures of hydrogen bond acceptors (HBAs) and donors (HBDs) with much lower melting points than their constituents. This study used choline chloride (ChCl) and glycerol as HBA and HBD because they are easy to prepare, have low toxicity and are biodegradable and ecologically benign. Lignin extraction from OPF was conducted in a batch reactor at different reaction temperatures (130 °C–170 °C) and reaction times (3–6 h) using a 1:3 molar ratio of ChCl:Glycerol. The results show that DES can extract lignin with low particulate matter content (4.53%) at a higher reaction temperature (170 °C) and longer reaction time (6 h). However, extracted lignin with low ash and volatile matter contents was obtained at a lower reaction temperature (130 °C) and shorter reaction time (3 h). The carbon content of the extracted lignin was significantly influenced by the reaction temperature and reaction time, with a lower reaction temperature and moderate reaction time capable of producing lignin with a carbon content of >50%

Keywords: carbon fibre, lignin, deep eutectic solvent, oil palm biomass

Abstrak

Gentian karbon digunakan secara meluas dalam industri, walaupun penggunaannya dihadkan oleh kos prekursor yang mahal. Lignin mempunyai potensi sebagai prekursor untuk gentian karbon dengan sifat yang setanding dengan poliakrilonitril dan prekursor berasaskan pitch. Pelepah kelapa sawit, sejenis biojisim lignoselulosa yang mengandungi selulosa, hemiselulosa, dan lignin merupakan sumber biojisim yang menarik untuk pengekstrakan lignin. Penyelidikan ini mencadangkan pengekstrakan lignin daripada pelepah kelapa sawit menggunakan pelarut eutektik dalam (DES). DES ialah campuran eutektik yang terdiri daripada penerima ikatan hidrogen (HBA) dan penderma ikatan hidrogen (HBD) dan mempunyai takat lebur yang jauh lebih rendah daripada

juzuk masing-masing. Kajian ini menggunakan kolin klorida dan gliserol sebagai HBA dan HBD kerana ia mudah disediakan, mempunyai ketoksikan yang rendah, boleh terbiodegradasi, dan tidak berbahaya dari segi ekologi. Pengekstrakan lignin daripada pelepah kelapa sawit dijalankan dengan menggunakan reaktor kelompok pada suhu tindak balas (130 °C–170 °C) dan masa tindak balas (3–6 jam) yang berbeza bersama dengan kolin klorida dan gliserol pada nisbah molar 1:3. Kajian ini membuktikan bahawa DES mampu mengekstrak lignin dengan bahan zarah yang rendah (4.53%) pada suhu tindak balas yang lebih tinggi (170 °C) dan masa tindak balas yang lebih lama (6 jam). Walaubagaimanapun, lignin dengan kandungan abu dan bahan meruap yang rendah diperolehi pada suhu tindak balas yang rendah (130 °C) dan masa tindak balas yang singkat (3 jam). Kandungan karbon di dalam lignin yang diekstrak dipengaruhi oleh suhu tindak balas dan masa tindak balas, dengan suhu tindak balas yang lebih rendah dan masa tindak balas sederhana mampu menghasilkan lignin dengan kandungan karbon lebih daripada 50%.

Kata kunci: gentian carbon, lignin, pelarut eutektik dalam, biojisim kelapa sawit

Introduction

The exceptional mechanical, electrical and thermal properties of carbon fibre have led to its widespread use in various fields, including military and aerospace engineering, construction and medicine [1]. The global market for carbon fibre is predicted to quadruple in a decade, reaching over $3 billion and exceeding 100,000 tonnes [2]. However, the rapid growth of industrial applications of carbon fibre hinges on the material's affordability without compromising its physical properties. The high cost of carbon fibre is directly proportional to the cost and yield of the precursor from which it is derived. A large proportion of carbon fibre is manufactured using wet and solution-spun PAN, an expensive precursor that accounts for 51% of the price of carbon fibre. Significant research is being conducted on the synthesis of low-cost carbon fibre because of the growing demand for the commercialisation of carbon fibre in various sectors.

Lignin, an aromatic polymer found in nature, has recently attracted considerable attention because of its low price, high carbon content and bio-renewability. Lignin is a promising replacement for petroleum-based PAN for producing carbon fibres because of its high carbon content (60%–65%) [3]. In addition to cellulose and hemicellulose, lignin is a key component of lignocellulosic biomasses. Lignin is a by-product of the paper industry that cannot be recycled; its decomposition produces furans and dioxins, which deplete atmospheric oxygen [4]. Lignin's aromatic compounds, availability of phenolic and aliphatic hydroxyl groups, high carbon content, thermal stability and abundance make it a superior choice for synthesising carbon fibres compared with cellulose and other renewable carbon sources.

According to Chen et al. [5], lignin valorisation necessitates the effective extraction of lignin with properties amenable to further processing. Condensed lignin and/or pseudo-lignin resulting from traditional pretreatment methods, such as dilute acid and steam explosion, are unusable for further processing. Research into lignin valorisation has led to the development of pretreatment technologies that utilise ionic liquids and organic solvents derived from biomass. DESs are ionic solvents composed of HBA and HBD, which combine to form a eutectic with a significantly lower melting point than its constituents [6]. Most DESs are produced by reacting ChCl (as HBA) with HBDs, such as amines, carboxylic acids and polyols. DES has been suggested as a promising solvent for processing lignocellulosic biomass, especially for lignin valorisation [7–9].

Currently, lignocellulosic treatments are used to produce high-quality cellulose. Nonetheless, the separation of lignin from a native structure has received less attention, making it difficult to obtain homogeneous lignin with the requisite structure and molecular weight [10]. Recent studies have shown that ChCl and acid-based DES effectively extract lignin from lignocellulosic biomass. Lignin extracted from biomass using DES has distinct structural characteristics, such as a lack of ether linkages and a low molecular weight distribution [8, 11]. Hydrogen bonds in DES molecules are crucial for lignin extraction. Di Marino et al. [12] hypothesised that increasing the amount of water in the biomass could improve the solubilisation ability of DES for biomass by increasing the formation of hydrogen bonds between the DES and components of the biomass.

Lignin is extracted from various natural sources using several methods, each yielding lignin with its unique structure and physicochemical properties. Therefore, one of the most challenging and critical processes in biological refining is lignin extraction from lignocellulosic materials. Currently, the most common lignin are sulphate lignin, soda lignin, and kraft lignin [13]. However, the high sulphur and ash content of sulphate lignin render it unsuitable for further processing and usage. Although lignin-derived alkali pulping does not contain sulphur, the extraction method has many disadvantages, including a low-extraction yield, excessive alkali consumption and environmental contamination [14, 15]. Furthermore, reaction parameters, such as reaction time, temperature, solvent concentration and biomass/solvent ratio, substantially affect the extraction yield and structural characteristics of lignin produced by organic solvent-based extraction.

Lignin extracted using DES treatments was discovered to have a high yield, high purity and low molecular weight, which would be advantageous for biomass valorisation [9]. It is known to have unique structural properties; however, these properties have not been studied or addressed. Therefore, the fundamental properties of lignin must be examined to establish its potential as a carbon precursor. The Oak Ridge National Laboratory (ORNL) established a set of criteria to assess the viability of lignin as a carbon fibre precursor, as shown in Table 1 [16].

Table 1. Lignin specification as carbon fibre precursor [13]

Criteria	Value (wt.%)
Lignin Purity	99%
Ash Content	<0.1
Volatile Matter	<5.0
Particulate Matter	100% removal for matter >1μm in diameter

Materials and Methods

Synthesis of DES

The DESs were prepared by mixing ChCl and glycerol in a 1:3 molar ratio and heating to 100 °C with constant stirring. In our previous study, DES with a molar ratio of 1:3 produced the highest lignin yield from OPF. Heating and stirring were repeated until a clear, homogeneous and stable liquid were obtained. The DESs were then cooled and stored at room temperature for 24 h. DES synthesis was successful if the solution was colourless and remained liquid after 24 h.

Preparation of OPF

The biomass was dried overnight at 45 °C before being cooled to room temperature. 500g of the samples were ground and sieved to sizes between 250–500 μm. Solid-liquid extraction with 3L ethanol was used to remove extractives from the samples. The extracted samples were collected after 6 h and washed with ethanol before being oven-dried overnight at 45 °C.

Experimental works

The OPF was mixed with DESs at a solid loading ratio of 1:10 and subjected to various reaction times and temperatures in a 100-mL batch reactor. The reaction parameters used in these experiments are listed in Table 2. The mixture was immediately immersed in an ice bath after completion of the reaction to quench the reaction. The solution fraction (SF) and solid residue (SR) fractions were separated by centrifugation at 4000 rpm for 15 min. SR was washed with 95% ethanol until the liquid was clear. Subsequently, the SF was combined with an ethanol-washing liquid to form SF1. Deionised water was added to SF1 in a 1:2 volume ratio of ethanol to water to precipitate lignin. After 15-min centrifugation at 4000 rpm, the precipitated lignin was successfully separated from the SF1. The lignin precipitate was washed twice with deionised water to remove solvent impurities and obtain extracted lignin. Lignin was then dried for 24 h at 40 °C.

Table 2. Reaction parameter for experimental work

Abbreviation	Reaction Time (hours)	Reaction Temperature (°C)
DESL-01	3	130
DESL-02		150
DESL-03		170
DESL-04	4	130
DESL-05		150
DESL-06		170
DESL-07	5	130
DESL-08		150
DESL-09		170
DESL-10	6	130
DESL-11		150
DESL-12		170

Particulate matter content analysis

The particulate matter content was determined using the method described by Luo [17]. Approximately 0.25 g of DES-L was dissolved in 100 mL of a 5% NaOH solution. The flask was then immersed in a water bath at 100 °C for 60 min. The sample was filtered to separate insoluble particles. The percentage of insoluble matter was calculated using Equation 1 based on the residual solid mass and mass of the original sample.

$$\text{Particulate Matter} = \left(\frac{m_2}{M_1}\right) \times 100\% \quad (1)$$

where m_2 is the mass of residual solid (g) and M_1 is the mass of the lignin sample (g).

Ash content analysis

The ash content was determined using TAPPI Standard Test Method T 413 om-93. Approximately 0.05 g of DES-L was combusted at 900 °C in a muffle furnace. As shown in Equation 2, the ash content was calculated by dividing the weight fraction of residual ash by the initial weight of the sample.

$$\text{Ash Content} = \left(\frac{m_2}{M_1}\right) \times 100\% \quad (2)$$

where m_2 is the mass of residual ash (g) and M_1 is the mass of the lignin sample (g).

Volatile matter content analysis

The volatile matter content of the DES-L was determined according to the method outlined by Luo [17]. Approximately 0.25 g of DES-L was heated for 6 h at 250 °C in a muffle furnace. The volatile matter content was calculated based on the weight loss of the DES-L relative to the weight of the initial sample (Equation 3).

$$\text{Ash Content} = \left(\frac{M_1 - m_2}{M_1}\right) \times 100\% \quad (3)$$

where m_2 is the mass of the residual lignin sample (g) and M_1 is the mass of the lignin sample (g).

Carbon content analysis

The carbon content of the DES-L was determined using a CHNS/O analyser.

Results and Discussion

Carbon content

The carbon content of the precursor is essential. The low carbon content in the precursor indicated a high content of non-carbon elements in the sample, which resulted in higher weight losses during carbonisation and higher production costs [18]. High-quality carbon fibre requires a carbon content of at least 92 wt% after carbonisations.

The carbon content of lignin extracted at different temperatures (130 °C–170 °C) and reaction times (3–6 h) are shown in Figure 1. The highest carbon content

was 54.1% at 150 °C for 3 h. In contrast, the lowest carbon content attained was 31.5% at 130 °C for 3 h. The carbon content varies with reaction temperature and time, with no discernible trend. The ORNL does not specify the carbon content requirements for lignin as a carbon fibre precursor. However, it is widely accepted that the carbon content of the extracted lignin must be >50% to produce significant carbon fibre yields [19]. As a result, it was concluded that the reaction time and temperature affect the carbon content of the extracted lignin.

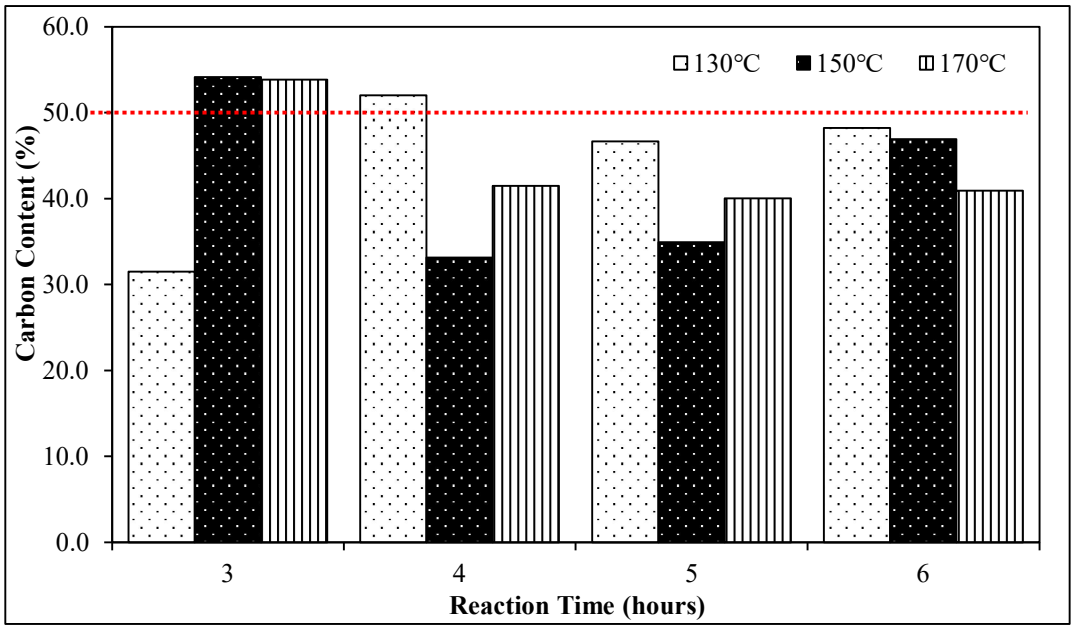

Figure 1. Carbon content (%) at different temperatures (130 °C–170 °C) and reaction times (3–6 h) and a solid loading ratio of 1:10

In this study, only the DESL-02 (150 °C and 3 h), DESL-03 (170 °C and 3 h), and DES-L04 (130 °C and 4 h) samples yielded lignin with a carbon content of >50%. The obtained lignin had a lower carbon content than the previously reported lignin at various reaction temperatures and times. For example, coniferyl alcohol, a common precursor of lignin in softwood, contains approximately 72% carbon.

While sinapyl alcohol, a common lignin monomer found in hardwood, contains 63% carbon, PAN, the most important precursor material used in the industrial production of carbon fibre, contains 68% carbon [17]. The required carbon content differed according to different studies. Previous studies showed that the required carbon content varies. For example, Souto et al. [19] suggested that the carbon content must be >50%, whereas Bengtsson et al. [3] concluded that the carbon content of extracted lignin must be >60% to produce carbon fibres with a high yield after conversion. According to Nunes and Pardini [20], the carbon content of lignin varies depending on the type of biomass, with kraft and sugarcane lignin containing 62% and 58% carbon, respectively.

Alvarez-Vasco et al. [9] demonstrated that lignin extraction with DES results from breaking ether bonds in the lignin carbohydrate complex (LCC), thereby improving lignin solubility in DES. It has been proposed that the breakage of ether bonds and the solvent properties of DES significantly influence the depolymerisation of lignin, facilitating its separation from lignocellulosic biomass. Lignin is more soluble in DES because of the increased cleavage of β-O-4 linkages.

The glycerol-based DES used in this study has a moderate acid-base catalysis mechanism that is advantageous for cleaving labile ether bonds, thus improving lignin solubility in DES. The effectiveness of acid-based DES for lignin extraction has been investigated, and the enhanced hydrogen bond interaction between acidic DES and LCC has been shown to facilitate lignin extraction [21]. However, the increased lignin solubility in DES results in more carbon loss to the liquid fraction and a faster depolymerisation rate at higher temperatures [22]. The carbon content of the recovered lignin decreased as the temperature increased because of the increase in the lignin carbon loss to the liquid fraction.

Nevertheless, recognising that the reaction time significantly affects the carbon content of the extracted lignin is critical. The reaction temperature determined the effect of reaction time on the carbon content. In this study, a shorter reaction time of 3 h and a moderate reaction temperature of 150 °C were optimal for extracting lignin from OPF with higher carbon content. According to Zhang et al. [23], the higher the carbon content of lignin, the more aromatic the structures in the lignin monomers. However, the structure of lignin is extremely complex, with heterogeneous molecular weights, numerous functional groups and varying amounts of monolignols (p-coumaryl alcohol, coniferyl alcohol and sinapyl alcohol) linked by various interunit chemical bonds. As a result, the reduced aromatic structure of the extracted lignin accounts for the lower carbon content observed in this study.

Our previous study found that the presence of phenolic compounds in extracted lignin was lower (0.07–0.15 g/mmol) than previously reported in the literature. Consequently, the extracted lignin had less aromatic compounds and reactivity. Lignin is extracted using DES by ether connection cleavage, specifically β-O-4 bonds, which are the weakest links in the lignin unit. However, in this study, DES treatment produced lignin with reduced aromatic structures, resulting in a carbon content of 31.5%–54.1% at different reaction temperatures and times.

Ash content

Ash is the residue left over by high-temperature combustion at 900 °C. Lignin must have low inorganic content as a carbon fibre precursor. The ash content should be <0.1 wt% to ensure that the carbon fibre has minimal defects and imperfections. The lignin source and extraction method heavily influenced the ash content of the extracted lignin. Figure 2 illustrates the effect of temperature (130 °C–170 °C) and reaction time (3–6 h) on ash content.

In this study, the lignin ash content was 9.1%–15.7% with increased reaction times (3–6 h) and temperatures (130 °C–170°C), producing higher lignin ash content. As a result, lignin with low ash content can be produced at a lower reaction temperature (130 °C) and in a shorter reaction time (3 h). The increased condensation of ash caused the high ash content with other by-products as the reaction time and temperature increased.

The ash content determined in this study did not meet the ORNL standard of <0.1%, which makes it a suitable precursor for carbon fibre production [16]. The ash content must be low to avoid a negative impact on the tensile qualities of the manufactured carbon fibre, which is detrimental to the mechanical properties of the carbon fibre produced [3].

The biomass source and extraction method determine the ash content of the extracted lignin. Herbaceous biomass contains significantly more ash than wood, typically containing <1% ash. Calcium, potassium and magnesium are the most abundant elements in wood ash, whereas sodium and silicon are in smaller quantities. However, the source and quantity of minerals in the extracted lignin were significantly more dependent on the extraction method than on plant species. Alkaline pulping processes, such as kraft, produce lignin with high ash content (43.6%), whereas autohydrolysis (1.2%) and organosolv (0.1%) produce lignin with low ash content [24].

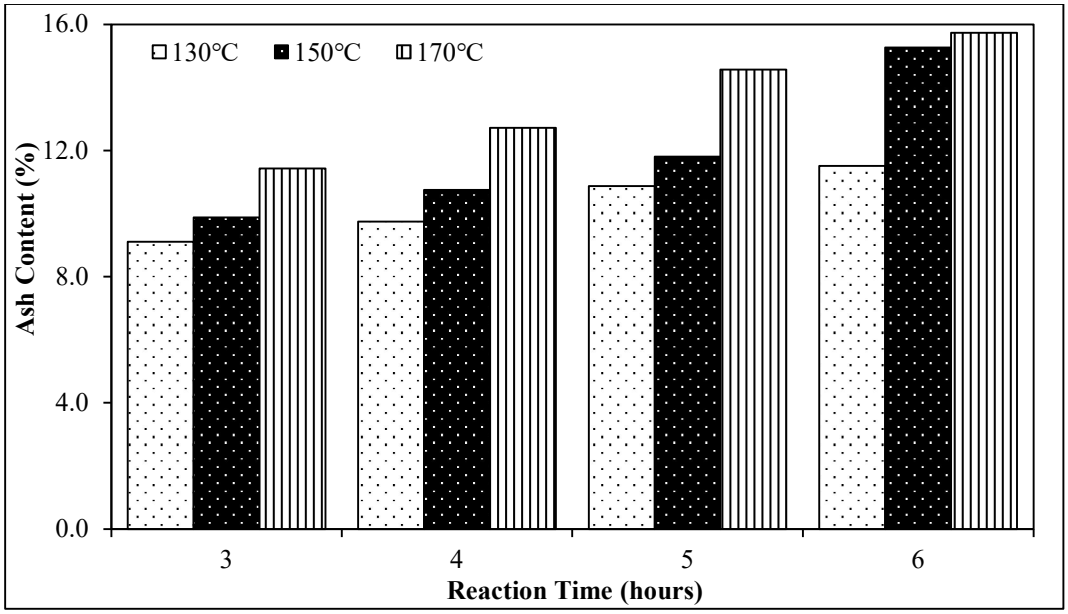

Figure 2. Ash content (%) at different temperatures (130–170 °C), reaction times (3–6 h) and a solid loading ratio of 1:10

Volatile matter content

Volatile matter refers to the portion of a sample that can readily volatilise at high temperatures under typical conditions. This volatile substance typically consists of combustible and non-combustible gases. The volatile matter content of the extracted lignin must be evaluated because it can alter the carbon fibre structures through evaporation, especially during carbonisation at high heating rates. Carbonisation significantly modifies the surface and porosity of carbon fibres by releasing volatile components, resulting in surface flaws and defects. Therefore, low volatile matter content is desired to reduce the flaws in manufactured carbon fibre [25].

As demonstrated in Table 1, the volatile matter content must be <5% for a precursor to be viable for carbon fibre production. Figure 3 depicts the volatile matter content of lignin extracted at various reaction temperatures (130 °C–170 °C) and reaction times (3–6 h). The volatile matter content of lignin ranged was 3.4%–9.4%.

The volatile matter content increased with reaction time (3–6 h) at all temperatures. For example, at 130 °C, the volatile matter content increased linearly from 3.4% to 4.7% between 3 h and 6 h. Additionally, at 150 °C, the volatile matter content varied between 5.3% and 8.8%. Higher reaction temperatures produce lignin with larger amounts of volatile compounds. The increase in volatile matter content with increasing temperature is attributable to the decreased bond strength of lignin at higher temperatures, which produces volatile macromolecules [26]. Low temperatures and shorter reaction times made lignin more thermally resistant to volatilisation, as evidenced by its lower volatile matter content at 130 °C and 3 h.

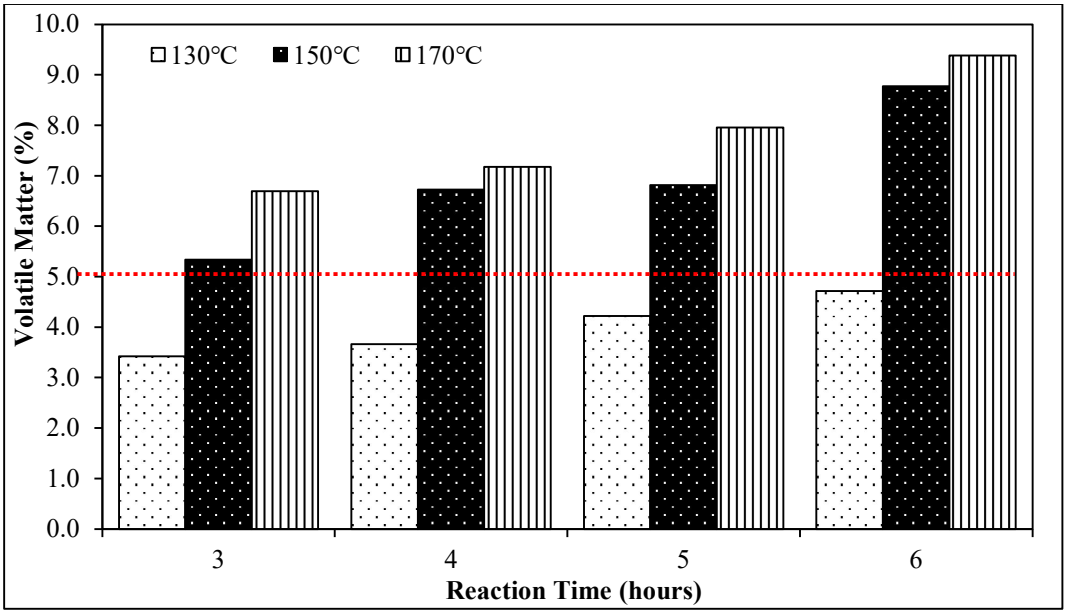

Figure 3. Volatile matter content (%) at different temperatures (130–170 °C), reaction times (3–6 h) and a solid loading ratio of 1:10

In addition, the volatile matter content of lignin extracted at 130 °C for all reaction times (3–6 h) met the ORNL requirement that it should contain <5% volatile matter to be suitable as a carbon fibre precursor. Higher temperatures (150 °C–170 °C) produce lignin with a volatile matter content of >5% [16]. Thus, we can conclude that temperature is important in determining the amount of volatile matter in lignin extracted using DES.

Furthermore, the volatile matter content reported in this study was significantly lower than those reported in previous studies [24,27]. The extraction conditions, solvent type and biomass source, affected the volatile matter content of lignin. According to Omar et al. [25] and Atnaw et al. [28], OPF has high volatile matter contents of 82.4% and 85.1%, respectively. The high volatile matter content of the OPF is attributable to the higher volatile matter content of the lignin recovered in this study.

It is possible that the high inorganic content of lignin, as reflected by its high ash content, could have influenced the volatile matter content. As a result of their catalytic effect on lignin decomposition, the inorganic matter may promote the formation of volatile matter [29]. As depicted in Figure 2, the volatile matter and ash contents exhibited a similar trend, which explains the results obtained for the volatile matter content.

Particulate matter content

As a precursor to carbon fibre, lignin must be devoid of solid particles of >1 µm in size. Particulate matter is the amount of solid particles entrapped in lignin. Natural particles, such as sand, clay and cellulose, are the most prevalent causes of structural defects in carbon fibre. The mechanical properties of carbon fibres, such as modulus and tensile strength, are reduced by high particulate matter content, increasing the breaking point of the fibre [16]. Figure 4 shows the effect of temperature (130 °C–170 °C) and reaction time (3–6 h) on the particulate matter content of DES-L.

Particulate matter content decreased with increasing temperature and reaction time. The highest particulate matter content of 15.5% was obtained after 3 h at 130 °C, whereas the lowest particulate matter content (4.5%) was obtained at 6 h and 170 °C. These findings exceed the ORNL's requirement of 100% removal of particulate matter of >1 µm in diameter.

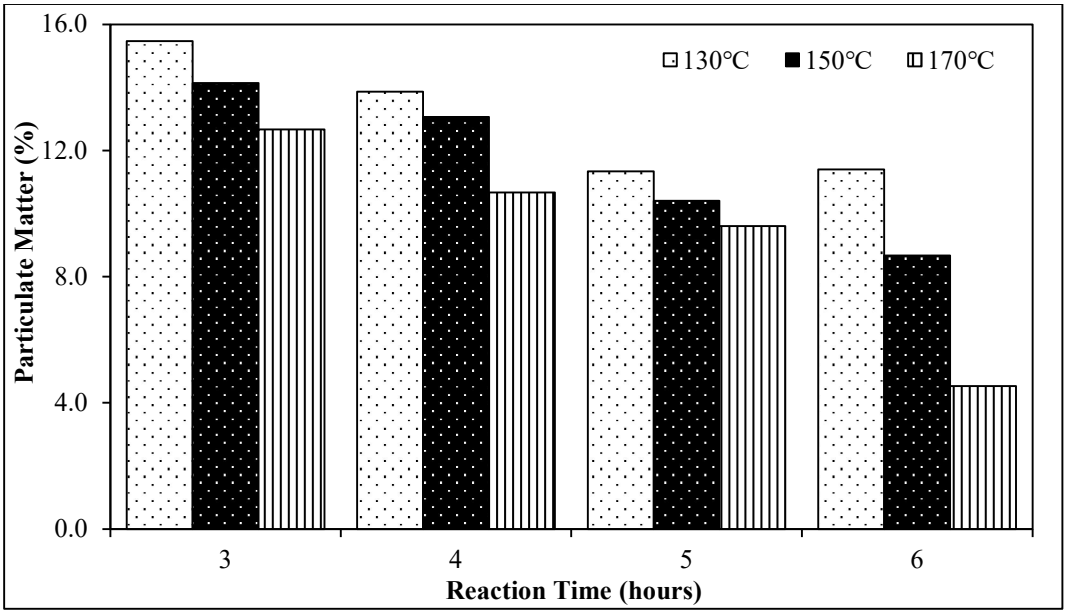

Figure 4. Particulate matter content (%) at different temperatures (130–170 °C), reaction times (3–6 h) and a solid loading ratio of 1:10

The incomplete breakdown of cellulose increases the number of high-molecular-weight compounds in the SR, which explains why lignin extracted using the DES system has a high particulate matter content. Furthermore, owing to the partial breakdown of cellulose, particles and pollutants increased the amount of particulate matter in the lignin. The incomplete removal of extractives during OPF solid-liquid extraction may also contribute to the high particle matter content. The results show that low particulate matter lignin can be obtained at higher temperatures and longer reaction times.

Conclusion

Investigating the fundamental properties of lignin extracted from OPF using DES is critical to assess its viability as a carbon fibre precursor. This study found that reaction temperature and time affect the properties of lignin. The particulate matter content was low at high temperatures (170 °C) and long reaction times (6 h). However, a lower temperature and shorter reaction time are appropriate for lignin extraction with a low ash and volatile matter content. The highest carbon content (54.1%) was obtained at 150 °C for 3 h. The low carbon content of lignin obtained in this study was attributable to the enhanced cleavage of ether linkages by glycerol-based DES, which improved lignin solubility in the solvent and, thus, increased carbon loss into the liquid fraction. Thus, this study establishes the viability of using DES as solvents for effective lignin cleavage and efficient lignin separation from LCC linkages. The viability of the extracted lignin as a carbon fibre precursor should also be examined further by determining other fundamental properties, such as purity, molecular weight and glass transition temperature.

Abstract

Systematic investigations are essential in establishing the current water quality because numerous industrial and anthropogenic sources are responsible for polluting the ecosystem along Peninsular Malaysia's east coast. Since aquatic stocks play a significant role in the daily diets of the surrounding populations, the present study used the ICP-MS technique to measure the levels of three natural radionuclides ^{232}Th, ^{238}U and ^{40}K in three fish species collected from three locations along the east coast of Peninsular Malaysia. The activity concentration ranges from 23.13 ± 1.70 to 43.31 ± 2.10 Bq kg^{-1}for ^{40}K, 0.06 ± 0.01 to 0.33 ± 0.05 Bq kg^{-1} for ^{232}Th and 0.11 ± 0.08 to 0.48 ± 0.10 Bq kg^{-1} for ^{238}U. The determined activity concentration of radionuclides was used to estimate the annual effective dose and cancer risk. The findings showed that the predicted yearly effective doses (μSv year^{-1}) for ^{232}Th, ^{238}U and ^{40}K were 1.67, 0.70, and 11.92 correspondingly, which were much lower than the UNSCEAR recommendation and considered to be safe. Based on the estimated annual effective dose and a life expectancy of 70 years, the cancer risk factor for adults is predicted to be 3.00×10^{-5}. Compared to the UNSCEAR cancer risk factor of 8.4×10^{-3} and ICRP cancer risk factor of 3.5×10^{-3}, this value is much lower. According to the current study, the dose that locals consume from eating fish is safe for human consumption, relatively minimal, and does not impair human health.

Keywords: Bioaccumulation, natural radionuclide. activity concentration, ingestion dose, cancer risk

Abstrak

Penyiasatan sistematik adalah penting dalam menentukan kualiti air semasa kerana banyak sumber perindustrian dan antropogenik bertanggungjawab dalam mencemarkan ekosistem di sepanjang pantai timur Semenanjung Malaysia. Memandangkan stok akuatik memainkan peranan penting dalam diet harian populasi sekitar, kajian ini menggunakan teknik ICP-MS untuk mengukur tahap tiga radionuklid semula jadi ^{232}Th, ^{238}U dan ^{40}K dalam tiga spesies ikan yang dikumpulkan dari tiga lokasi di sepanjang pantai

timur Semenanjung Malaysia. Kepekatan aktiviti berkisar antara 23.13 ± 1.70 hingga 43.31 ± 2.10 Bq kg^{-1}untuk ^{40}K, 0.06 ± 0.01 hingga 0.33 ± 0.05 Bq kg^{-1} untuk ^{232}Th dan 0.11 ± 0.08 hingga 0.48 ± 0.10 Bq kg^{-1} bagi ^{238}U. Kepekatan aktiviti radionuklid yang ditentukan telah digunakan untuk menganggarkan dos berkesan tahunan dan risiko kanser. Penemuan menunjukkan bahawa dos berkesan tahunan yang diramalkan (μSv $tahun^{-1}$) untuk ^{232}Th, ^{238}U dan ^{40}K adalah masing-masing 1.67, 0.70, dan 11.92, yang jauh lebih rendah daripada pengesyoran UNSCEAR. Berdasarkan anggaran dos berkesan tahunan dan jangka hayat 70 tahun, faktor risiko kanser untuk orang dewasa diramalkan ialah 3.00×10^{-5}. Berbanding dengan faktor risiko kanser UNSCEAR sebanyak 8.4×10^{-3} dan faktor risiko kanser ICRP sebanyak 3.5×10^{-3}, nilai ini jauh lebih rendah dan selamat. Menurut kajian semasa, dos yang diambil oleh penduduk tempatan daripada memakan ikan adalah selamat untuk dimakan manusia, agak minimum, dan tidak menjejaskan kesihatan manusia.

Kata kunci: Bioakumulasi, radionuklid semula jadi. kepekatan aktiviti, dos pengambilan, risiko kanser

Introduction

Radionuclides in the water may contribute to internal exposure more frequently by ingestion, despite the fact that people are constantly exposed to external radiation from cosmic and terrestrial sources. ^{232}Th and ^{238}U are two prominent examples of radioactive elements that spontaneously decay and release energy, subatomic particles, and the remainder, or smaller offspring nuclei than the original [1]. The majority of the radioactive decay in the natural decay ^{232}Th and ^{238}U are gamma emitters, which are a significant source of external exposures [2]. However, some of their decay products, such as ^{222}Rn, are alpha emitters, while others, such as ^{214}Bi are beta emitters, with ^{40}K potentially producing more internal exposure routes from environmental sources. These levels can be increased by anthropogenic activities, which are subsequently enhanced by artificial radioactive sources released into the environment [2–4].

By nature of undersea earthquakes, underwater volcanic activity, weathering and mineral recycling of terrestrial rocks, and movement of the seabed, seawater naturally includes radioactivity [5]. The ^{226}Ra (^{238}U), ^{228}Ra (^{232}Th) decay series radionuclides are consequently transferred to water through leaching action as a result of extensive contact with a variety of minerals and geological materials, such as igneous rocks and ores, which frequently contain high concentrations of natural radionuclides [6]. It is known that human activities, such as the burning of fossil fuels in coal-fired power plants, the extraction of natural gas and oil, the mining and processing of ores, and the manufacturing of these fuels, enhance naturally occurring radioactivity in aquatic ecosystems. The reprocessing of spent nuclear fuel, underwater nuclear device testing, nuclear power plant leak accidents, and the post-nuclear disposal of hazardous and radioactive material are further anthropogenic contributors [1, 7-9].

Because uranium and thorium radionuclides enter the human body predominantly through food intake and only to a much lesser extent through respiration, the breakdown sequence of these radionuclides is crucial [10]. In the meantime, ^{40}K is significant since it is a marine environment radionuclide with a long half-life (1.25 × 109 years) [11]. Even though radionuclides in the ocean exhibit complex behaviours (for example, uranium is quite soluble in sea water while thorium is almost completely insoluble, radium and radon are soluble in water), they can spread throughout the marine ecosystem in a number of ways, including by becoming dissolved in the seawater, attached to plankton suspended in the seawater, attached to sediment on the seabed, and through contaminated marine organisms, such as fish, shellfish, and other seafood [12]. Therefore, a deeper understanding of the concentration of radionuclide activity in various reference organisms is crucial to estimating radiological risk to the environment [13].

Due to their high toxicity and the cumulative behaviour of these creatures, the dissolution of radionuclides into seawater adversely affects the biological balance of the environment and the activity of aquatic organisms [14]. For evaluating radiological effects on human health and marine environment, radionuclide concentrations in seawater and marine life are crucial inputs [15]. It is common knowledge that marine creatures naturally accumulate radionuclides, and that they can offer valuable data for radio-ecological and radiological

research [16, 17]. Fish and seafood are significant sources of protein for many developing nations and are significant dietary sources in many regions of the world [18]. In terms of total consumption and protein content per capita, Malaysia is regarded as one of Southeast Asia's top seafood eaters [19].

The distribution of radioactivity in seafood varies depending on feeding habits and origin areas [3, 5, 22]. Since the consumption of marine fish is among the highest in the world, it is relevant to note that the information on the radionuclide balance in sea fish is of correspondingly larger value [20, 22]. Human uptake is obviously influenced by food habits. The literature that is currently accessible still lacks information on the bioaccumulation and distribution of natural radionuclides in sea fish and sea water. Given the importance of this information, the current study's objectives are to assess the activity concentrations of ^{232}Th, ^{238}U and ^{40}K in edible marine life caught along Peninsular Malaysia's east coast, as well as the ingestion dose, and the risk of cancer for the local population. This information could be used to inform public health policies and recommendations related to seafood consumption and environmental protection in the region.

Materials and Methods

Samples and sampling location

The east coasts of Peninsular Malaysia were chosen to gather fresh samples of three different species of fish: *Rastrelliger, Megalaspis cordyla*, and *Decapterus maraudsi*. Nine samples total, ranging in mass from 125 to 260 g, were collected for each location, three samples from each species. These study locations were selected because of their biodiversity and fish farming methods, which serve as important sources of seafood for Peninsular Malaysia. The samples were taken between March 2016 and February 2017, from coastal locations of Tanjung Lumpur (3.759865° N, 103.315066° E) in Pahang, Kerteh (4.5079° N, 103.4430° E) in Terengganu, and Chendering (5.2666° N, 103.1656° E) in Terengganu, all of which are bordered by several fishing communities. In each situation, there are multiple gas-fired power plants close by, including the 324 MW Petronas power plant in Pahang, the 1136 MW Sultan Ismail power plant in Terengganu, and the 808 MW Paka power station in Terengganu. These are also well known for a few offshore sectors such as petrochemical and metal refining sectors.

Sample treatment

To separate the head, stomach contents, gills, and tissues of the fish flesh, the fish samples were first rinsed in distilled water. Fish samples of known weight were cleaned with distilled water and dried in an oven at 80 °C to stabilise the weight. This dry sample was ground into fine granules of about 500 m. The following step involved combining 0.1 g of sample with 4.0 mL of nitric acid and 6.0 mL of hydrochloric acid. A clear solution was created by digesting the mixture in a microwave for 55 minutes. Following filtering, distilled water was added until the volume of the sample solution reached 100 mL, at which point its radionuclide concentration was evaluated using ICP-MS technique. To prevent potential contamination from digestion processes, 5 standards and 1 blank solution were run using the same reagents in each case. Control sample were used in this study and treated in the same way as the fish samples from the East Coast of Peninsular Malaysia, except that they not come from the study area and therefore serve as a comparison group.

Sample analysis

An Induced Coupling Mass-Plasma Spectrometer (ICP-MS) that was calibrated using the SRM standard MA-A-2 (TM) Fish Flesh Homogenate was used to analyse samples that had been produced in solution form [21, 22]. ICP-MS is the combination of a mass spectrometer and an ICP (Induced Coupled Plasma) high temperature source. The atoms of the elements in the sample are changed into ions by the ICP source. A mass spectrometer is then used to separate and find these ions [23]. As shown in Table 2, ICP-MS generated radionuclide weights (w), which were used to calculate the concentration of radionuclide activity (A).

Determination of radionuclide activity concentration, annual effective dose and cancer risk

The concentration of radionuclide activity, A (Bq kg^{-1}) was determined using Equation (1) below

$$A = \frac{\lambda \theta N_A}{M} \times \frac{w}{W} \quad (1)$$

Where λ is the decay constant of the radionuclide, θ is the abundance of radionuclides in the universe, N_A (mol^{-1}) is the Avogadro constant, M (g mol^{-1}) is the molecular weight of the radionuclide. W (g) is the sample weight and w (mg kg^{-1}) are the natural radionuclide content in the sample obtained from ICP-MS [21, 22]. The values of w dan A for the three radionuclides are shown in Table 2.

From ^{232}Th, ^{238}U dan ^{40}K activities, the annual effective dose, D (µSv year^{-1}) is calculated using Equation 2 below

$$D = I \times A \times E \quad (2)$$

Where I (kg tahun^{-1}) is the annual fish intake rate of 57.3 kg year^{-1} [24], A (Bq kg^{-1}) is the concentration of radionuclide activity and E (µSv Bq^{-1}) is the factor conversion of radionuclide activity to dose for adults (> 17 years) [25]. Assuming that an individual's life expectancy is 70 years, R is estimated from Equation 3 below

$$R = D \times 70 \times (5 \times 10^{-8}) \quad (3)$$

Where, 5×10^{-8} (µSv^{-1}) is a cancer risk factor for low doses [26]. This research focused on the population for the age category> 17 (adults) because adults are the main consumers of Malaysian fish [22, 24]. The annual effective dose of D (µSv year^{-1}) and cancer risk R, are as in Table 3.

Results and Discussion

Activity concentrations of ^{232}Th, ^{238}U and ^{40}K

ICP-MS showed average natural radionuclide content of ^{232}Th (^{228}Ra), ^{238}U (^{226}Ra) and ^{40}K in the samples. From these, calculations were performed using Equation (1) to estimate the concentration of radionuclide activity. ^{232}Th (^{228}Ra) concentrations in marine environment is substantially lower than that of ^{238}U (^{226}Ra) when it comes to natural radionuclides. The findings are consistent with uranium's solubility in water and thorium's low solubility [4, 27], which are somewhat counterbalanced by thorium's higher abundance in the earth's crust. The dry weight basis activity concentrations of the examined radionuclides in fish, along with their uncertainties, are reported in Table 1. In turn, it may be anticipated that the accumulation of thorium in marine fish will be somewhat lower than that of the uranium chain nuclides.

For all three study sites, the current analysis reveals higher quantities of ^{238}U than ^{232}Th in the fish. Between the three research locations, there is also a significant difference ($p < 0.05$) in the concentrations of ^{238}U and ^{232}Th in the fish samples, according to statistical analysis (ANOVA). In addition, the spread of ^{232}Th, ^{238}U and ^{40}K in aquatic ecosystems can occur through solid suspension which in turn involves other aquatic components such as plankton and coral reefs. The chemical nature of the water, the physiology of the fish including the feeding behaviour and digestion of food by the fish can also affect the number of radionuclides accumulated in the body of the fish [2 - 4, 23]. *Megalaspis cordyla* had the lowest mean activity of ^{238}U among fin fishes, at 0.11 ± 0.08 Bq kg^{-1}, and the highest was 0.48 ± 0.10 Bq kg^{-1} (*Rastrelliger*). The small differences in ^{238}U uptake by the studied fishes may be explained by biological factors unique to each fish, including feeding habits, particulate ingestion with food (in the case of *Rastrelliger*, which has a varied diet regardless of the prey species, such as macroplankton and fish larvae), physiological behaviour, and the radionuclide distribution within the marine compartments [28].

When levels in other places are compared, Table 2 demonstrates that the current values of ^{238}U accord with those that have been previously reported from the same sites [5] and from the Indian coastal seas [29], but less so than the data from the Aleutian Islands [28] and Nigeria [30]. The outcomes in each of these situations are far worse than what is now observed. In contrast, Rosli et al. 2018 [22] reported average activity ranges for ^{232}Th and ^{238}U in the soft tissue of fish collected from the Terengganu coast in Malaysia of 0.30 to 0.51 Bq kg^{-1} and 1.07 to 1.15 Bq kg^{-1}, respectively. Compared to ^{238}U in fish, the mean activity of ^{232}Th in fishes ranging from 0.06 ± 0.01 Bq kg^{-1} (*Megalaspis cordyla*) to 0.33 ± 0.05 Bq kg^{-1} (*Decapterus maraudsi*). This finding

confirms that thorium is insoluble in water and that uranium is soluble in it [4]. The outcomes are comparable to those of a prior study done on various fish species in the same study settings [3]. However, no significant differences were found for the ^{232}Th activity in the literature (Table 2), with the exception of the Ondo area of Nigeria [30], regardless of fish species or study sites.

According to Table 1, the average activity concentration of ^{40}K was often higher than that of ^{232}Th and ^{238}U activities. This is to be expected as this radionuclide is widely distributed in marine environments and is involved in the metabolism of species living there [31]. The fin fishes measured at this time have similar mean ^{40}K activity, ranging from 23.13 ± 1.70 Bq kg^{-1} 1 (*Megalaspis cordyla*) to 43.31 ± 2.10 Bq kg^{-1} (*Megalaspis cordyla*). The significantly higher findings for ^{40}K are consistent with expectations given that the potassium-rich fish bones make up a significant portion of the weight of each sample. Due to its great natural abundance, the discovery of 40K in every sample was anticipated [32]. The current ^{40}K results are consistent with previous fish investigations conducted at the same site (Tanjung Lumpur, Pahang), with values ranging from of 31.55 ± 2.20 Bq kg^{-1} to 32.10 ± 1.90 Bq kg^{-1} [5]. A quick review of the literature reveals a heterogeneous distribution of ^{40}K in various areas. For example, fish collected from the water near Vizag, India [33] had a relatively lower mean activity of ^{40}K, while fish from the coastal waters near oil producing regions in Nigeria [30], India [29], and the North Atlantic Ocean [11] had significantly higher concentrations.

Furthermore, it was discovered that the areas surrounding Tanjung Lumpur, Pahang, had the highest quantities of all detected radionuclides in fish samples. The diverse range of activity (such as housing, tourism, power plants, petroleum, chemical industries, etc.) in the Tanjung Lumpur area, as well as industrial and urbanisation effluents, may be contributing to an increase in radionuclide concentrations in the marine environment. These are just a few of the many potential causes. The range of results reported by earlier studies overlaps with the concentration of radioactive activity recorded in this investigation. This shows that the findings of this study are consistent with those of earlier research, as seen in Table 2.

Table 1. Arithmetic mean + SD of ^{226}Ra, ^{228}Ra and ^{40}K activity concentration (Bq kg^{-1}) and annual effective dose (μSv y^{-1}) due to the ingestion of collected fishes (d.w.)

Sample Code	Radionuclides	Mean Activity Concentration, *A* (Bq kg^{-1})			Grand Mean Activity Concentrations *A* (Bq kg^{-1})	Annual Effective Dose, *D* (μSv y^{-1})

Annual effective dose

Humans are exposed to radiation from natural sources on average at a rate of 2.4 mSv per $year^{-1}$ [2]. The average annual absorption dose for the radioactive series of uranium and thorium was 0.12 mSv $year^{-1}$ and 0.17 mSv $year^{-1}$, respectively, totalling 0.29 mSv $year^{-1}$ [2, 32]. Human exposure levels, however, differ based on geology, geography, and climate [2]. The presence of heavy metals and natural radioactivity has an impact on this level as well [34]. The effective dosage to humans is further increased by the anthropogenic radioactive content of fish and the absorption of radionuclides through diet [11].

The daily intake of ^{40}K was discovered to be significantly higher ($p < 0.001$) than that of the other radionuclides by ANOVA analysis. Intakes of ^{238}U (1.7%) and ^{232}Th (1.1%) are insignificant when compared to the radionuclide ^{40}K. (96.7 %). According to Table 3, ^{40}K was responsible for the greatest annual effective dosage of 11.92 Sv $year^{-1}$. However, the ^{40}K content in the body is tightly homeostatically regulated, meaning that it is not impacted by changes in radionuclide levels in the environment. Instead, the actively maintained amount is managed by the body to reach the typical range needed for system operation [33, 36, 37]. Adult males have roughly 3700 Bq of ^{40}K, which means that the amount of ^{40}K in the body is constant. This isotope administers a dose to soft tissue of 0.18 mSv $year^{-1}$ and to bone of 0.14 mSv $year^{-1}$ [34, 38].

Between the study locations, there are significant differences ($p < 0.05$) in the annual effective dose of ^{238}U and ^{232}Th. While ^{232}Th provided 1.67 µSv $year^{-1}$ and ^{238}U contributed 0.70 µSv $year^{-1}$ of the annual effective dosage, respectively. When compared to earlier studies [11, 13], the annual effective dosage brought on by the

ingestion of ^{232}Th and ^{238}U radionuclides is incredibly low. The findings of this study also demonstrated that the yearly effective dose average was lower than that stated by UNSCEAR (2.4 mSv year^{-1}) and ICRP (1.0 mSv year^{-1}) for annual effective doses originating from natural sources [2, 34]. According to the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) [2], the average global effective dose from ingesting uranium and thorium series nuclides is 120 µSv year^{-1}, while for ^{40}K it is 170 µSv year^{-1}, ignoring any substantial radiological concerns.

Table 3 shows that the risk of cancer, *R* for adults is based on the total dose of exposure. It is significantly lower than the UNSCEAR cancer risk factor of 8.4×10^{-3} (estimated from UNSCEAR total natural radiation dose of 2.4 mSv year^{-1}) and the cancer risk factor by ICRP of 3.5×10^{-3} (estimated from the recommended level of intake dose 1.0 mSv year^{-1}). Based on Table 3, the average population in one million adults eating sample fish in this study, only about 30 people are estimated to have a risk of death from cancer compared to 3500 people, as predicted by ICRP (1990) and $8^{40}0$ people, as predicted by UNSCEAR (2000) [2, 34, 38].

Cancer risk factor

Table 3. Annual effective dose, *D* and cancer risk factor, *R* due to the consumption of natural radionuclide from the marine fish

Sample	*D* (µSv year^{-1})				*R* ($\times 10^{-5}$)			
	^{232}Th	^{238}U	^{40}K	Total	^{232}Th	^{238}U	^{40}K	Total
FS	2.37	0.57	11.12	14.06	0.83	0.20	3.89	4.92
FC	0.92	0.41	12.76	14.09	0.32	0.14	4.47	4.93
FK	1.71	1.11	11.89	14.71	0.60	0.39	4.16	5.15
Average	1.67	0.70	11.92	14.29	0.59	0.25	4.17	3.00
World average	120	120	170	290	-	-	-	-

Conclusion

Present study shows the concentration of naturally occurring radioactive materials in the widely consumed fish collected from the coastal waters around Peninsular Malaysia. Activity concentrations of 0.06 – 0.33 Bq kg^{-1} for ^{232}Th, 0.11 – 0.48 Bq kg^{-1} for ^{238}U and 23.13 – 43.31 Bq kg^{-1} for ^{40}K in various fish samples agreed with the values previously reported by other researchers and UNSCEAR. The total annual effective dose obtained was in the range of 14.06 – 14.71 µSv year^{-1} and the average value of 14.29 µSv year^{-1}. The estimated cancer risk for adults from the annual effective dose is 3.00×10^{-5}. This value is significantly lower than the UNSCEAR cancer risk factor of 8.4×10^{-3} and the ICRP cancer risk factor of 3.5×10^{-3}. Therefore, it can be concluded that the fish in this study are radiologically safe for the use of nearby residents.

Abstract

This study aimed to investigate the influence of added chromium on the physical and chemical reduction behavior of molybdenum trioxide (MoO_3) in a carbon monoxide (CO) environment. The reduction behavior of the sample was evaluated by using temperature-programmed reduction (TPR), and the phases produced by the reduced samples were analyzed using X-ray diffraction spectroscopy (XRD) and field emission scanning electron microscopy (FESEM). The TPR study was conducted using two reduction modes: non-isothermal reduction at 700°C with 20 vol. % of CO in nitrogen (N_2), followed by isothermal reduction at 700°C for an additional 60 min. The TPR profile showed that the reduction of doped and undoped MoO_3 was preceded by two reduction stages ($MoO_3 \rightarrow Mo_4O_{11} \rightarrow MoO_2$), wherein, the reduction of doped MoO_3 starting at a lower temperature (380°C-500°C) than that of undoped MoO_3 (550°C). Additionally, based on XRD analysis, it was shown that the conversion of MoO_3 to MoO_2 under CO generated an intermediate product known as Mo_4O_{11}. It is discovered that, increasing the concentration of chromium doped to MoO_3 enhanced the reducibility of oxide due to the rapid production of MoO_2 phases at T: 380ºC. Further

heating under CO atmosphere, carbide species built up in the form of Mo_2C rather than metallic Mo which might be due to excess of CO exposure to the surface layer of oxide.

Keywords: reduction, molybdenum oxide, carbon monoxide, chromium

Abstrak

Kajian ini bertujuan untuk menyiasat pengaruh penambahan kromium terhadap sifat fizikal dan kimia semasa penurunan molibdenum trioksida (MoO_3) dalam persekitaran karbon monoksida (CO). Tingkah laku penurunan sampel dinilai menggunakan teknik suhu penurunan berprogram (TPR), dan fasa yang dihasilkan oleh sampel yang diturunkan dianalisis menggunakan pembelauan sinar-X (XRD) dan pancaran medan mikroskopi elektron pengimbasan (FESEM). Kajian TPR telah dijalankan menggunakan dua mod penurunan: penurunan bukan isoterma pada 700°C dengan 20 vol. % CO dalam nitrogen (N_2), diikuti dengan pengurangan isoterma pada 700°C selama 60 minit. Keputusan TPR menunjukkan bahawa penurunan MoO_3 terdop dan tidak terdop didahului oleh dua peringkat penurunan iaitu ($MoO_3 \rightarrow Mo_4O_{11} \rightarrow MoO_2$) dengan penurunan MoO_3 terdop bermula pada suhu yang lebih rendah (380°C-500°C) berbanding MoO_3 tidak terdop (550°C). Di samping itu, telah ditentukan bahawa penurunan MoO_3 kepada MoO_2 dengan CO telah menghasilkan produk perantaraan yang dipanggil Mo_4O_{11} berdasarkan analisis sampel yang diturunkan menggunakan XRD. Telah didapati bahawa, peningkatan kepekatan kromium yang didopkan kepada MoO_3 telah meningkatkan penurunan oksida dengan pembentukan fasa MoO_2 yang lebih cepat pada T: 380ºC. Pemanasan berpanjangan di dalam persekitaran CO menyebabkan pembentukan spesies karbida dalam bentuk Mo_2C dan bukannya logam Mo yang mungkin disebabkan oleh pendedahan berlebihan CO pada lapisan permukaan oksida.

Kata kunci: Penurunan, molibdenum oksida, karbon monoksida, kromium

Introduction

Molybdenum oxide (MoO_3) has a density of 4.692 g/cm^3 and a melting point of 1068K (795°C), making it a viable source of Mo for direct alloying steel making or the manufacture of ferromolybdenum processes [1]. Because it helps quenched and tempered steels to become harder and more resilient, molybdenum is a valuable alloying agent. It also makes the steel more durable at high temperatures [2]. Electrodes for heated glass furnaces, nuclear energy applications, missile and aeroplane parts, the manufacturing of tungsten, glass to metal sealing, and colloidal form as a lubricant additive are all uses for molybdenum. As a catalyst, it can also be used in the refining of petroleum [3]. Additionally, the reduction of suitable reacting agents, such as hydrogen and carbon monoxide, is a necessary step in the synthesis of metallic molybdenum [4]. Generally, the generation of volatile molybdenum species produced at high temperatures is minimized by using the two-stage flow scheme ($MoO_3 \rightarrow MoO_2$, $MoO_2 \rightarrow$ Mo). In a single-stage conversion of the molybdenum precursor, molybdenum must also be obtained through a separate method [5].

These days, hydrogen is used as a crucial reducing agent in the chemical sector. To produce pure molybdenum metal, the reduction process that uses hydrogen as a reducing agent goes through a two-step chemical reduction procedure [6]. MoO_3 is converted to MoO_2 in the first step of this reaction, which takes place at a lower temperature (450°C-650°C) [7]. MoO_2 is further reduced to metallic molybdenum during the second reduction step. The temperature range used for this technique is 1000°C-1100°C. Additionally, a critical step in the formation of metallic molybdenum is the reduction of MoO_3 to MoO_2. According to Wang et al. [8], MoO_3 is reduced to MoO_2 by using hydrogen as a reducing agent which consisting of two reduction processes, with the production of the intermediate phase Mo_4O_{11} occurring first before MoO_2.

Carbon can be used as a reducing agent to produce pure molybdenum as a choice. This technique comprises a high-temperature (600°C-1200°C) interaction between MoO_3 and carbon [9]. Additionally, the use of carbon in reduction is efficient because the reaction between metal oxide and carbon results in a gas that can be easily separated from the solid reaction product [10]. Carbon monoxide (CO), in addition to hydrogen and carbon, has started to be utilized as a reducing agent. However, just a few studies have investigated by using CO as a reducing agent to reduce MoO_3. Additionally, the use of

chromium as an adjuvant has been extensively studied by researchers to increase the catalyst low-temperature reducibility and catalytic activity [11]. When chromium is added as a precursor, gas sensing for carbon monoxide can be improved at a relatively low temperature, according to Habib et al. [12].

In this study, the reduction behavior and degree of reduction of the molybdenum species were examined in an atmosphere with 20 vol. % of CO in N_2. The goal of this study was to identify the appropriate way to increase the reducibility of MoO_3 by adding chromium, including the best reduction temperatures. In addition, the temperature-programmed reduction (TPR) method was used to characterize the chromium-doped MoO_3 and analyze its reduction behavior in comparison to undoped species.

Materials and Methods

Materials

Commercially pure MoO_3 powder and chromium (III) nitrate, $Cr(NO_3)_3$, which were provided by BDH Chemicals Ltd. and Sigma Aldrich Chemical, respectively, served as the starting ingredients. Moreover, the impregnation procedure used ethanol, C_2H_6O (99.5%) from Systerm® as the solvent. In addition, Linde provided the gas mixture with 20 vol. % of CO in N_2.

Catalyst preparation

An aqueous solution containing chromium cation additives was used to impregnate MoO_3 powder to prepare the chromium doped with molybdenum oxide. Chromium was added in amounts of (x = 3, 9, 15) mol % of the total metal cation. Then, all prepared samples were dissolved in a mixture of distilled water and ethanol at 40°C while stirred vigorously for 4 h at room temperature (24ºC) to form a viscous mixture. The impregnated samples were first oven dried at 110°C overnight before being calcined for 4 h in air at 400°C. The doped catalyst was denoted as x Cr-MoO_3, (x = 3, 9, 15%) while for undoped catalyst was denoted as MoO_3.

Temperature-programmed reduction

Using a Micromeritic Autochem 2920 Chemisorption Analyzer apparatus, the temperature-programmed reduction (TPR) method was used to analyze the total reduction of the undoped and doped MoO_3. With a flow rate of 20 mL min^{-1}, mixed gases containing 20 vol. % of CO and 80 vol. % of N_2 were fed into the micro reactor as the reducing gas (STP). Samples of 50 mg were heated at a rate of 10°C min^{-1} to 700°C. Then, an isothermal mode of reduction was used when temperature reached at 700°C and prolong the reaction from 30 min to 60 min. All analyses were identified by a thermal conductivity detector (TCD).

Characterizations

The physicochemical properties were characterized by X-Ray Diffraction (XRD), using the Cu Kα X-ray radiation source (40 kV, 40 mA) in the XRD Bruker AXS D8 (Advance type) to record the 2θ diffraction angle from 10° to 80° at wavelength (λ = 0.154 nm). Surface area and porosity were characterized by using Brunauer-Emmett-Teller (BET) utilizing the Micromeritics ASAP 2020 equipment. The samples underwent degassing at 200°C for 4 h, before treatment under liquid N_2 at -198ºC. Following that, the surface morphology of the reduced MoO_3 was studied using a Carl Zeiss Merlin field emission scanning electron microscope (FESEM).

Results and Discussion

XRD analysis of the structural properties of doped and undoped MoO_3

The XRD patterns of undoped and doped MoO_3 with various loadings of chromium were displayed after calcined at 400°C for 4 hours (Figure 1). It shows that undoped MoO_3 patterns largely existed as MoO_3 (JCPDS 05-0508) [4]. Nevertheless, the addition of chromium to MoO_3 had little effect on their mesoporous structure, as summarised in Table 1. About the display of chromium molybdenum oxide, $Cr_2(MoO_4)_3$, just a small difference in XRD patterns was noticed (JCPDS 77-5936). Moreover, the intensity of MoO_3 peaks decreased especially for MoO_3 with higher chromium loadings. The 2θ range of MoO_3 peaks showed many new $Cr_2(MoO_4)_3$ diffraction peaks at 15 mol % of chromium loading, which demonstrated that the impregnation of chromium on the MoO_3 was truly successful at range of 2θ = 20°-40°. The interference of chromium element which altered the lattice constant of

MoO_3, was primarily responsible for the evolution of diffraction peaks. This can be attributed to the differences in atomic radius of molybdenum and chromium, which can alter the lattice parameters and spacing. It was found that the difference in atomic size, electronic interaction, and magnetic spin relations between the solute and its solvent atoms (Cr-MoO_3) which all were contributed to the lattice distortions [13].

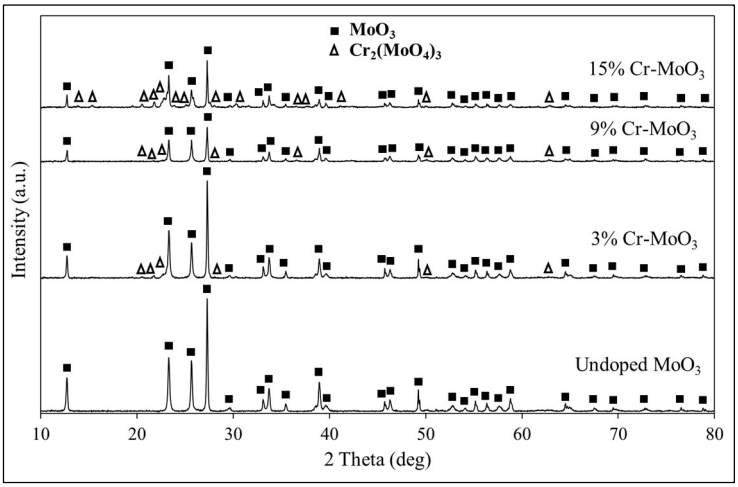

Figure 1. XRD patterns of undoped MoO_3 and chromium-doped of MoO_3 at various loadings after calcinations at 400 ºC for 4 h

BET analysis from the N_2 adsorption isotherm for structural properties

The analysis of N_2 adsorption-desorption isotherm at 77 K was used to identify the effect of the impregnation on the textural characteristics of MoO_3. Table 1 provides information about the textural properties of doped MoO_3 including BET surface area, total pore volume, and average pore size width. The surface area (BET), pore volume, and pore size of doped MoO_3 decreased as increasing the amount of chromium concentration of MoO_3 (6.85 m^2/g) > 3% Cr-MoO_3 (5.91 m^2/g) > 9% Cr-MoO_3 (3.28 m^2/g) > 15% Cr-MoO_3 (2.26 m^2/g). Decreasing of surface area of doped samples might be due to the ion-exchange that caused the low dispersion of Mo oxide after addition of chromium, which agreed with the decreasing of XRD peak intensity of MoO_3 at $2\theta = 27^o$ (Figure 1). Mesopore sizes decreased from 20.4 nm in undoped MoO_3 to 18.1 nm, 15.4 nm, and 14.3 nm with 3 mol %, 9 mol %, and 15 mol % of chromium addition, respectively. Besides, the cumulative pore volume (cm^3/g) in Table 1 demonstrated that the overall pore volume for undoped MoO_3 was 0.035 cm^3/g, and by increased the amount of chromium added had reduced the pore volume to 0.027 cm^3/g, 0.013 cm^3/g, and 0.008 cm^3/g, respectively. These demonstrated that the chromium layer present on the pore surfaces of MoO_3 had been the reason for the reduced pore size and pore volume of all doped MoO_3. Therefore, MoO_3 loaded with a higher percentage of chromium possessed smaller pore sizes and a decreased in pore volume. The decreasing of pore size and volume as increasing the addition of chromium concentration were due to the Cr salt filled in the pore of Mo oxide.

Table 1. BET analysis of chromium-doped of MoO_3 and undoped MoO_3

Catalyst	Surface Area (m^2/g)	Pore Size (nm)	Pore Volume (cm^3/g)
Undoped MoO_3	6.85	20.4	0.035
3% of Cr-MoO_3	5.91	18.1	0.027
9% of Cr-MoO_3	3.28	15.4	0.013
15% of Cr-MoO_3	2.26	14.3	0.008

TPR analysis of chemical properties

The TPR analysis was used to establish the reduction properties of each sample. The TPR profiles of prepared samples with x = 3, 9, 15 mol % of Cr-MoO_3 and undoped MoO_3 in a non-isothermal reduction under 20 vol. % of CO in N_2 and a continuation in an isothermal reduction mode at 700°C for 60 min are shown in Figure 2. Non-isothermal reduction at 700°C was added to the reduction system to prevent the production of alloy-fused mass, if the complete reduction to MoO_2 was not accomplished at a temperature below the melting point of MoO_3 (795°C) [6]. There were three reduction phases involved in the reduction of pure MoO_3 to Mo: Mo^{6+} to Mo^{5+}, Mo^{5+} to Mo^{4+}, and Mo^{4+} to Mo^0 [8]. By referring to the results obtained from the reduction of undoped and doped MoO_3 with chromium, the TPR profiles thus displayed nearly identical patterns by presenting two reduction peaks (denoted I and II), whereby the first peak owing to the reduction of MoO_3 to Mo_4O_{11} and the second peak represented the reduction of Mo_4O_{11} to MoO_2 [14].

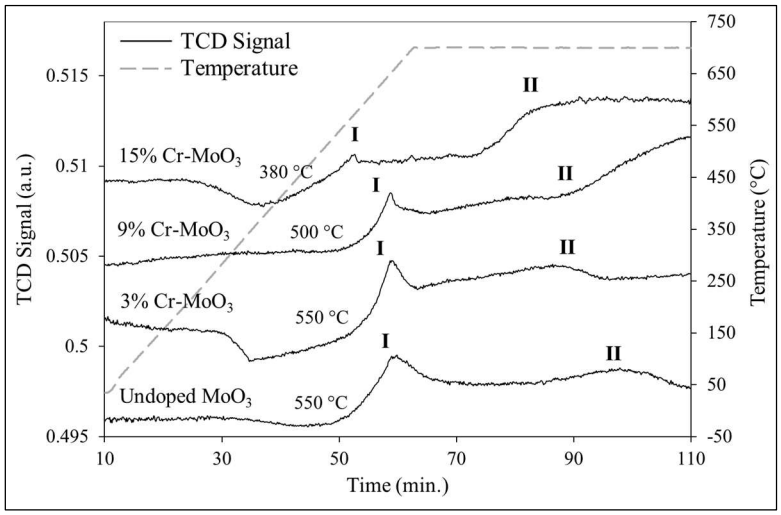

Figure 2. TPR profiles of undoped MoO_3 and chromium-doped of MoO_3

According to Dang et al. [5], the CO consumption peaks of undoped MoO_3 that began at roughly 550°C indicated that the initial phase of reduction was a Phase I as the production of Mo_4O_{11}. Due to sample modifications that took place 40 min after the isothermal reduction process began at 700°C, new peaks designated as Phase II were noticed. These peaks represented the second phase reduction of Mo_4O_{11} to MoO_2. Nonetheless, the addition of chromium to MoO_3 provided different information about the reducibility of MoO_3. The TPR results showed that the interaction between different loadings of chromium to MoO_3 decreased the reduction temperature and all peaks were shifted to a lower temperature. Besides, doping with chromium generated some amount of oxygen release and lowered the TPR reduction temperature [15].

However, TPR profile (Figure 2) also clearly shows two dominant peaks of doped MoO_3 designated as I and II. By adding 3 mol % of chromium, the reduction temperature of doped MoO_3 remained unchanged at early stage of reduction (I) as undoped MoO_3 at 550ºC. However, it was observed during the isothermal reaction, the reduction peak (II) appeared faster as compared to undoped MoO_3. Then, at 60 min and 90 min of reduction time, respectively showed the TPR profile for 9% of Cr-MoO_3 was designated as I and II. Peak I was observed at 650ºC represented the reduction of MoO_3 to Mo_4O_{11}, while peak II appeared after 20 min of isothermal reduction, which represented the complete reduction of MoO_2. At higher concentration of 15% of Cr-MoO_3, peak I and peak II shifted to a lower reduction (380°C and 10th min) as compared to undoped and lower Cr concentration. Besides, for the reduction of doped MoO_3 with 15 mol % of chromium, the TPR profile was

almost similar as it portrayed two peaks, whereby the first reduction peak was noted at about 380°C, which was lower than undoped MoO_3 (550°C), whereas the second peak began its formation at the 10th minute of isothermal reduction. As shown by the XRD analysis in Figure 4, increasing the isothermal reduction could lead to the synthesis of Mo_2C rather than metallic molybdenum [16].

It was evident that the addition of chromium to MoO_3 might have a major impact on the powder reduction by increasing the powder reducibility and oxygen storage capacity. Additionally, there were some changes in the coordination environment of molybdenum and the strength of Mo-O bonds because of the strong interaction between chromium ions and molybdenum ions in the samples [17]. In comparison to conventional Ni catalysts, Ni-Cr catalysts often exhibited substantially stronger anti-coking and anti-sintering capabilities, as well as much higher catalytic activity and stability. The smaller Ni particle size, the enhancing influence of Cr, and the increased sorption capacities for both H_2 and CO absorption are all thought to be the causes of the better catalytic performance [18] and indirectly causes the enhancement of reducibility of oxide. Next, to determine the changes in the samples, the residual obtained after TPR reduction was studied by recording the XRD pattern and examining the morphological change by using FESEM.

Crystallinity studies

The XRD profile of spent catalysts during non-isothermal reduction at 700ºC are shown in Figure 3. Major peaks of unreduced MoO_3 and the intermediary phase of Mo_4O_{11} (JCPDS 84-0687) were visible in the XRD patterns of reduced undoped MoO_3 (JCPDS 74-7383) [19]. The XRD pattern was also nearly identical to that of undoped MoO_3, with Mo_4O_{11} forming as an intermediate phase. Mo_4O_{11} was produced during the reduction of MoO_3 to MoO_2, according to Dang et al. [5]. This finding proved the formation of Mo_4O_{11} as predicted in TPR profile (Figure 2). Meanwhile, with the addition of 9 mol % of chromium, the MoO_3 phase almost disappeared and the Mo_4O_{11} phase was present as the dominant species. However, the addition of 9 mol % of chromium, showed a low intensity for the crystalline phase of Mo_4O_{11} due to the formation of $Cr_2(MoO_4)_3$ alloy (JCPDS 078-1654). Then, for the addition of 15 mol % of chromium, the patterns revealed that the reduction product was rather the same as the addition of 9 mol % of chromium with the major forms of Mo_4O_{11} and a few peaks of $Cr_2(MoO_4)_3$ alloy. However, no remaining unreduced MoO_3 peaks had been observed. Therefore, it had been discovered that adding more chromium might speed up reduction process of MoO_3.

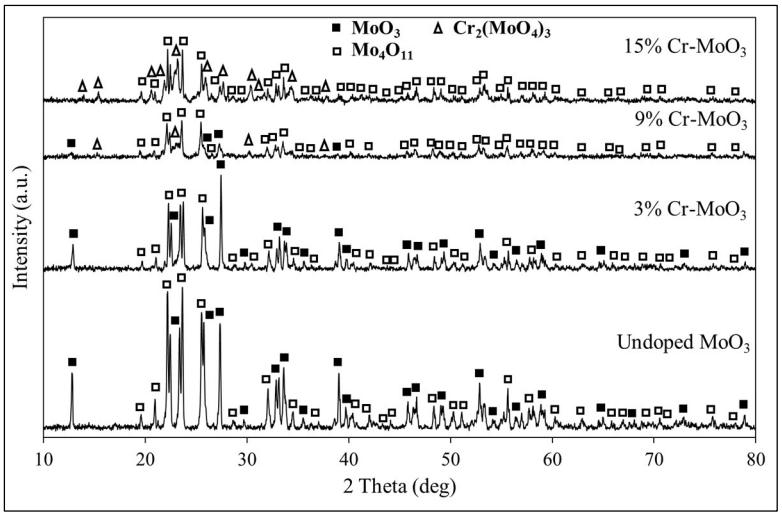

Figure 3. XRD patterns of 20 vol. % of CO in N_2 of non-isothermal reduction at 700°C

Figure 4 showed the XRD diffraction which carried out in isothermal mode for 60 min by using 20 vol. % of CO at 700°C to further reduce to MoO_2 phases. After 60 min of isothermal reduction, all samples had completely reduced to the MoO_2 phase (JCPDS 76-1807) [20]. In addition, the peaks that represented $Cr_2(MoO_4)_3$ alloy had completely disappeared in 9 mol % and 15 mol % of chromium-doped of MoO_3 samples after isothermal reduction. However, the increased addition of chromium showed that the low crystallinity of MoO_2 synthesis was affected by the formation of $Cr_2(MoO_4)_3$ alloy at range of $2\theta = 20°$-$40°$ (Figure 1) which enhanced the reduction performance of MoO_3. According to the formation of Mo_2C (JCPDS 071-0242) in 15 % of Cr-MoO_3 samples during isothermal reduction at 700°C for 60 min, carbide was formed when excessive CO was added to the MoO_2 phase. This finding was in agreement with Wang et al. [21] regarding the formation of Mo_2C.

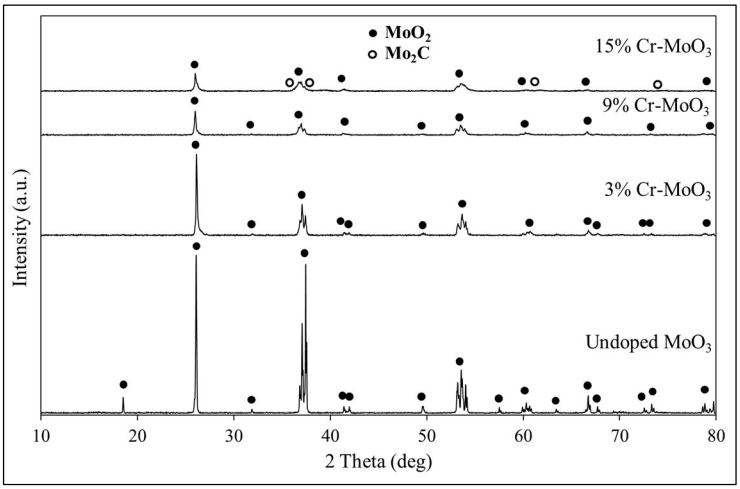

Figure 4. shows the XRD patterns of non-isothermal reduction in 20 vol. % of CO in N_2 up to 700°C and continued in isothermal mode at 700°C for 60 min

Apart from that, it can be concluded that the reduction step involved in the samples had been in the sequence of $MoO_3 \rightarrow Mo_4O_{11} \rightarrow MoO_2$ [8]. With the addition of chromium, the reducibility of MoO_3 was enhanced by changing the physiochemical properties of MoO_3, by the formation of $Cr_2(MoO_4)_3$ alloy which was confirmed by XRD analysis. As a result, it made the transition of MoO_3 to MoO_2 easier. The formation of Mo_2C instead of metallic molybdenum occurred when excessive CO was supplied to the MoO_2 phase, which was in line with the report by Alinda et al. [16] that the presence of excessive CO in the reduction process caused the formation of carbon on the external surface of Mo layer.

Morphological studies

Based on the TPR and XRD results, FESEM analysis was employed to identify new phases after the reduction process. The undoped MoO_3 morphology, according to Alinda et al. [4] is characterised by agglomerations of non-porous grains in vast numbers and with non-uniform sizes. However, as the reduction process continued, the resulting structures took on the appearance of a thin plate with an asymmetrical shape, demonstrating the rapid formation of MoO_2 phase from Mo_4O_{11} [4]. Figure 5 depicts the morphological change that occurred during the reduction of MoO_3 with various chromium loadings in 20 vol. % of CO in N_2 up to 700°C and proceeded with isothermal reduction for 60 min at 700°C.

The morphology of MoO_3 doped with 3 mol % of chromium is depicted in Figure 5(a). Figure 5(a) shows, no chromium particles had been observed on the MoO_3 surface. However, referring to BET results presented in Table 1, the surface areas eventually decreased. It revealed that the chromium added had successfully

penetrated the MoO_3 pores. After the reduction process, the MoO_2 phase with the plate-like particles and coated with small particles had been observed, as illustrated in Figure 5 (b). Other than that, as shown in Figure 5 (c) and Figure 5 (e), when the addition of chromium was increased to 9 mol % and 15 mol %, small particles had been observed on the surface of MoO_3. It seemed that the MoO_3 pores were filled with chromium and excessive chromium was attached to the surface of MoO_3, which was in agreement with the decreasing of surface area (BET) result. However, following a reduction, the MoO_2 phase developed plate-like particles with smaller particles dispersed on its surface, as depicted in Figure 5 (d) and Figure 5 (f). Another intriguing finding that can be seen in Figure 5 is the additional phase formation that occurred on the surface of the 15% of Cr-MoO_3 sample because of carbon deposition on MoO_2 surface rather than further Mo_2C production [1].

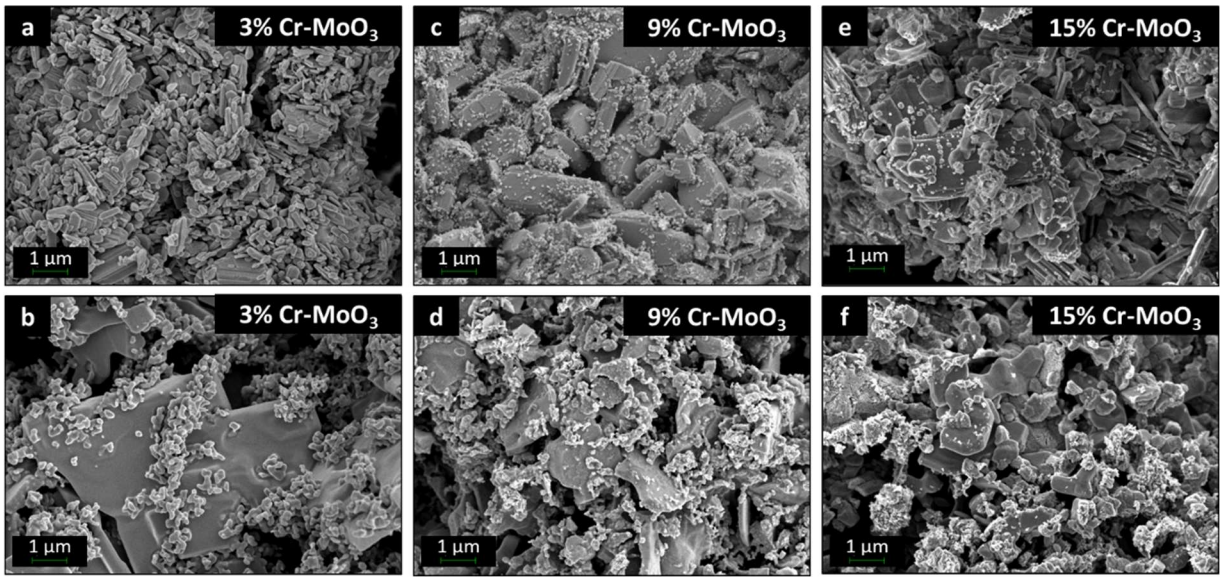

Figure 5. FESEM images before (top) and after (bottom) reduction in magnification 3,000X

Conclusion

Utilizing the TPR approach, the reduction behavior of chromium-doped and undoped MoO_3 was examined, compared, and characterized by XRD and FESEM analyses. The existence of $Cr_2(MoO_4)_3$ alloy on MoO_3 was demonstrated by the XRD data, which had the impact of accelerating the reduction process by reducing the temperature at which MoO_3 was reduced to the MoO_2 phase. As a result, adding chromium produced a two-step reduction process ($MoO_3 \rightarrow Mo_4O_{11} \rightarrow MoO_2$) that was comparable to MoO_3 that was not doped. Furthermore, better reducibility of Cr-MoO_3 was also due to the physicochemical changes on MoO_3 through the formation of successful intercalation of chromium onto the surface of MoO_3, which was further confirmed with the decreased in the surface area for chromium-doped MoO_3. However, excessive CO was added to the MoO_2 phase, Mo_2C would instead develop as opposed to metallic molybdenum.

Abstract

Cellulose, a promising source of renewable energy, is currently receiving a lot of interest due to its potential application in the production of bioenergy. The catalytic conversion of cellulose into value-added compounds like glucose, which is subsequently fermented into bioethanol or dehydrated into platform chemicals, avoids the heavy reliance on fossil fuel economy tremendously. In this study, the catalytic conversion of cellulose to glucose was conducted using a supported noble metal catalyst. The wet impregnation method was used to synthesize 4 wt.% palladium (Pd) supported on silica-alumina (SiO_2-AlO_3), which was then calcined at 500 °C. Prior to reaction work, Fourier- transform infrared spectroscopy, thermogravimetric analysis, Brunauer-Emmett-Teller method, and particle size analysis were conducted to characterize the catalyst. To investigate the effect of the catalyst on the yield of glucose from cellulose, the catalyst loading was varied from 0.04 to 0.10 g. The results demonstrated that up to 23.6% yield of glucose was produced at 200 °C for 3 h with the catalyst and cellulose loading of 0.06 g and 0.3 g, respectively. Additionally, under these conditions, cellulose conversion was at its highest (78.7%). This study shows that the supported noble metal catalyst has the potential to enhance the hydrolysis step for the conversion of cellulose to glucose.

Abstrak

Selulosa, sumber tenaga berpontesi yang boleh diperbaharui, kini menerima banyak perhatian kerana potensi aplikasinya dalam penghasilan biotenaga. Penukaran pemangkin selulosa kepada sebatian tambah nilai seperti glukosa, yang kemudiannya ditapai menjadi bioetanol atau dehidrasi menjadi bahan kimia platform, dapat membantu mengurangkan kebergantungan ekonomi kepada bahan api fosil. Di dalam kajian penyelidikan ini, penukaran pemangkin selulosa kepada glukosa telah dijalankan menggunakan mangkin logam adi yang disokong. Kaedah impregnasi basah digunakan untuk mensintesis 4 wt.% paladium (Pd) yang disokong pada silika-alumina (SiO_2-AlO_3), yang kemudiannya dikalsinasikan pada 500 °C. Sebelum memulakan kerja tindak balas, spektroskopi inframerah transformasi Fourier, analisis termogravimetri, kaedah Brunauer-Emmett-Teller, dan analisis saiz zarah

telah dijalankan untuk faktor pencirian mangkin. Untuk menyiasat kesan mangkin ke atas hasil glukosa daripada selulosa, pemuatan mangkin, berubah daripada 0.04-0.1g. Keputusan menunjukkan bahawa sehingga 23.6% glukosa dapat dihasilkan pada 200 °C selama 3 jam dengan mangkin dan pemuatan selulosa masing-masing, 0.06 g dan 0.3 g. Di samping itu, dalam keadaan ini ternyata penukaran selulosa berada pada tahap tertinggi, 78.7%. Kajian ini menunjukkan bahawa mangkin logam adi yang disokong berpotensi untuk meningkatkan langkah hidrolisis untuk penukaran selulosa kepada glukosa.

Introduction

The increasing carbon footprint, greenhouse gas emissions, environmental pollution, and ecosystem imbalance are the main issues around the world today. These issues demonstrate the impending necessity for renewable energy. Biomass, or organic material derived from plants and animals, is a viable alternative for non-renewable resources as a feedstock for fuels. Biomass typically contains cellulose, lignin, and hemicellulose that can be converted into high-value chemicals and biofuels.

Cellulose, the most abundant biomass on earth, has been studied widely since its discovery in the 19th century. It is a promising source of renewable energy, and currently, it is gaining a lot of attention due to its potential use in bioenergy production [1]. However, due to high crystallinity, cellulose faces several difficulties that prohibit its extensive utilization in the production of economically competitive biofuels. According to Li et al. [2], cellulose is less susceptible to enzymatic hydrolysis, less accessible, and less reactive at a higher degree of crystallinity. Hence, it is crucial to resolve the structure of cellulose for decomposition purposes to produce platform chemicals.

Glucose, which is a cellulose monomer unit, can be a promising starting compound to produce various value-added chemicals, such as levulinic acid (LA). The production of LA from glucose requires glucose to go through several processes, including rehydration and dehydration. Up to 56.8% of LA could be produced from glucose using a solid acid catalyst at 100 °C for 6 h [3]. Many high-value-added chemicals can be synthesized from LA, such as ethyl levulinate, succinic acid, and maleic anhydride. Ethyl levulinate acts as an oxygenated additive in fuels and is one of the examples of high-value organic chemicals produced from the esterification of LA with ethanol [4,5]. Meanwhile, succinic acid and maleic anhydride are well known to be useful in the food and textile industries, respectively.

Palladium (Pd), platinum (Pt), rhenium (Re), and gold (Au) are examples of noble metals with outstanding resistance to oxidation even at high temperatures. These metals have excellent catalytic properties and are widely employed, especially in the process of hydrogenation. Pt and Pd are well known for their efficiency in the hydrogenation of carbon-carbon multiple bonds (e.g., olefinic bonds, acetylenic triple bonds, and nitro compounds) compared to other metals, such as ruthenium [6]. Increasing the amount of Pt or Pd leads to an increase in the catalytic activity for the hydrogenation process.

Pt and Pd are known for their high cost and limited availability. Hence, the internal pores of silica (SiO_2) and alumina (Al_2O_3) support can be incorporated with tiny spheres of Pt or Pd rather than using the metals in their pure form as most of their atoms are wasted as only the surface of the atoms is involved in reactions [7]. Through the incorporation on the support, almost all expensive metal atoms are available on the particle surface where they can contribute to reactions, and none are wasted.

Heterogeneous catalysts, particularly metal catalysts (i.e., noble metal) incorporated on the support, are often employed in the conversion of cellulose to sugar alcohol via hydrogenation, in which high selectivity or yield of sugar alcohols can be achieved. Sorbitol with a selectivity of 69% was produced when the reaction was catalyzed by 1.5 wt.% Pt/SBA15 (fumed silica) [8]. Meanwhile, more than 40% of sugar alcohols (i.e., hexitols, ethylene glycol, 1,2-propanediol, and glycerol) were produced when 4 wt.% Pd/CNT (carbon nanotube)

was used as a catalyst [9]. Although supported noble metal catalysts are frequently used to produce sugar alcohols from cellulose via hydrogenation, the conversion of glucose from cellulose via hydrolysis must be considered as well. According to Kobayashi et al. [10], the hydrolysis of cellulose is the rate-determining step, and the noble metal catalysts enhance both the hydrolysis and hydrogenation steps. Once glucose is produced, the conversion of cellulose to sugar alcohols would be simpler. This concept is similar to that used to produce LA from cellulose. In this case, whether LA is produced in high yield depends on the production of glucose from cellulose. A recent study by Kamal et al. [11] discovered that by employing noble metal (i.e., Pd) supported on silica-alumina (SiO_2-Al_2O_3), up to 43.3% of LA was produced with cellulose conversion up to 73.9%. This shows that highly crystalline cellulose can be hydrolyzed to yield glucose, which can then be easier converted to other products, including 5-hydroxymethylfurfural (HMF), LA, and formic acid (FA) because the process only requires dehydration and rehydration. However, it is worth noting that studies on the use of noble metals incorporated into the support for the hydrolysis of cellulose are still lacking, although studies on the decomposition of cellulose to glucose using other heterogeneous catalysts have been widely established [12,13].

For example, in the study by Boonyakarn et al. [12], up to 11% of glucose was produced from cellulose, which eventually contributed to 8% yield of LA when 0.0025 M of chromium chloride ($CrCl_3$) catalyst was employed for 5 min at 220 °C. If the reaction period is prolonged, it is anticipated that the yield of LA will be higher than 8%. Joshi et al. [13] found that employing 2 wt.% of zirconium dioxide (ZrO_2) catalyst in the system produced up to more than 5% of glucose, contributing to the highest production of LA, which is above 80%. Hence, this research focused on the study of the effect of catalyst loading on the production of glucose from cellulose using noble metal (i.e., Pd) supported on SiO_2-Al_2O_3. As a result, the most suitable catalyst loading for the conversion of highly crystalline cellulose to glucose could be determined.

Materials and Methods

Materials

The catalyst was synthesized using palladium (II) nitrate ($Pd(NO_3)_2$) with 40% w/w of Pd and SiO_2-Al_2O_3 grade 135 (100%) purchased from Sigma Aldrich. Microcrystalline cellulose (extra pure, 100%) from Acros Organics served as the experimental work's substrate. As for standard reference calibration purposes, glucose (>99.9%), HMF (>98%), LA (>98%), FA (>98%), and furfural (>99.9%) were employed. All the chemicals were of analytical grade and used without further purification (unless otherwise stated), and distilled water was used for all the experiments.

Catalyst Preparation

First, 5 g of 4 wt.% Pd/SiO_2-Al_2O_3 catalyst was prepared using the wet impregnation method following the steps described in an earlier study [11]. The catalyst support, SiO_2-Al_2O_3, was weighed for approximately 4.8 g and spread on a petri dish before diluted palladium nitrate ($Pd(NO_3)_4$) was dropped onto the support using a syringe. A spatula was used to press $Pd(NO_3)_4$ until it was thoroughly mixed with SiO_2-Al_2O_3. Prior to calcination, the prepared catalyst was dried in an oven at 110 °C for 12 h to eliminate excess moisture. The catalyst was subsequently calcined for 5 h at 500 °C. The catalyst was kept in a parafilm-sealed vial and stored in a desiccator prior to analysis and experimental work.

Catalyst characterization

The prepared catalyst was characterized by Fourier-transform infrared spectroscopy (FTIR), thermogravimetric analysis (TGA), Brunauer-Emmett-Teller (BET) method, and particle size analysis. The TGA of the prepared catalyst was performed on a Mettler Toledo STARe software. The analysis was carried out from room temperature (30 °C) to 550 °C by employing a heating rate of 10 °C/min under the flow of 20 mL/min of high-purity air. The FTIR spectrum range was recorded from 4000 to 400 cm^{-1} on a Nicolet iS10 spectrometer with a spectral resolution of 8 cm^{-1} at room temperature and an accumulation of five scans in an open-beam air background. The surface area and pore volume of the prepared catalyst were determined by the BET method using a Micromeritics 3Flex surface characteristics analyzer, where the catalyst was

degassed at 150 °C for 12 h in nitrogen (N_2) prior to analysis. A Malvern Mastersizer 3000 particle size analyzer was used to conduct the particle size analysis.

Experimental procedure

The pre-reduction of the catalyst and the experimental work for the catalytic conversion of cellulose to glucose were carried out in a 20 mL stainless steel semi-batch reactor. For the pre-reduction of the catalyst, the catalyst and distilled water were loaded accordingly into the reactor. One bar of hydrogen (H_2) was inserted into the reactor. The timer and stirrer were set for 1 h and 1300 rpm, respectively, once the desired temperature of 150 °C was achieved. After 1 h, 0.3 g of cellulose was loaded into the reactor. The air inside the reactor was purged using N_2 three times. The stirrer (1100 rpm) and timer (30 min) were set accordingly once the reaction temperature reached 200 °C. The reaction was stopped by quenching the reactor into a water bath. The samples were collected, stored in a parafilm-sealed vial, and kept in a refrigerator prior to analysis. The experimental work was repeated for 60, 120, and 180 min.

A set of data, including the weight of the filter paper before drying and the weight of the filter paper with solid residue after drying overnight, was recorded to determine the conversion of cellulose to glucose. The samples were filtered using filter paper before being dried at 60 °C overnight. The weight of the filter paper containing solid residue was recorded, and it was consistently maintained around ± 0.005 g. The final weight of cellulose and the cellulose conversion were calculated using Equations 1 and 2, respectively.

$$\text{Weight}_{\text{final cellulose (solid residue)}}\,(a) = \text{Weight}_{\text{filter paper with solid residue after drying}} - \text{Weight}_{\text{filter paper before drying}} - \text{Weight}_{\text{catalyst}} \quad (1)$$

$$\text{Cellulose conversion}\,(\%) = [(a - \text{Weight}_{\text{initial cellulose}}) / \text{Weight}_{\text{initial cellulose}}] \times 100\% \quad (2)$$

Product analysis

Glucose was quantified using a high-performance liquid chromatography system consisting of Sugar SH1011 column (SHODEX, Japan) with ion exclusion mode (column's physical size: 8.0 mm I.D. × 300 mm) and a refractive index detector as the column and detector, respectively. The mobile phase was an aqueous solution of sulfuric acid (0.05 M) flowing at a rate of 0.5 mL/min with a column temperature of 40 °C.

Results and Discussion

Catalyst characterization: TGA

Thermogravimetric analysis of the catalyst was carried out before and after calcination to validate the decomposition of nitrate precursors in the catalyst. Based on the differential thermal gravimetric analysis (TGA/DTG) pattern in Figure 1, two weight losses were observed between the temperature of 50 and 120 °C and also 200 and 300 °C for the catalyst before calcination. The first weight loss (I) can be linked to the removal of absorbed water [14,15], whereas the second weight loss (II) can be attributed to the decomposition of nitrates and the elimination of organic compounds [16]. Furthermore, at temperatures above 350 °C, no weight loss was observed, implying that no decomposition took place. Therefore, the calcination temperature was set at 500 °C to ensure the decomposition of nitrate precursors. After calcination, the catalyst only exhibited one weight loss, which occurred between 50 and 100 °C (I), according to the TGA/DTG pattern in Figure 1. However, no weight loss was recorded at temperatures higher than 100 °C, demonstrating that nitrate had completely decomposed. Hence, the optimal calcination temperature for ensuring a precursor-free catalyst is 500 °C. This finding agrees with the FTIR analysis, where no nitrate peak was found in the catalyst after calcination.

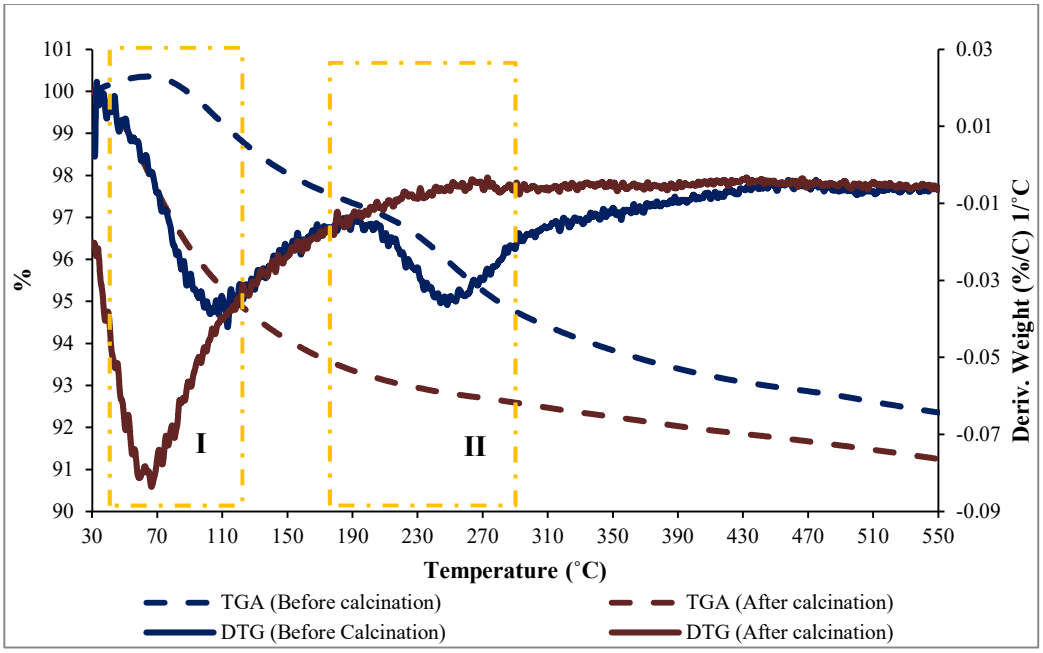

Figure 1. TGA and DTG of Pd/SiO_2-Al_2O_3 (before and after calcination)

Catalyst characterization: FTIR

The decomposition of the nitrate precursor in the synthesized catalyst was verified by FTIR. A comparison of the FTIR spectra of the catalyst before and after calcination is illustrated in Figure 2, and the functional groups present in this study are summarized in Table 1.

Table 1. Summary of the functional groups present in this study

Region	Wavelength (cm^{-1})	Peak Assignment
I	3600–3200	O-H stretching, strong, broad
II	2400–2300	C-O stretching
III	1700–1600	O-H bending
IV	1450–1300	NO_3^- (nitrate)
V	1200–1000	Si-O-Si

Based on Figure 2, the spectral range around 3600–3200 cm^{-1} (I) and 1700–1600 cm^{-1} (III) is attributed to the stretching and bending modes corresponding to water molecules by hydrogen bonding, respectively [17]. The C-O stretching band is due to the atmospheric carbon dioxide, an impurity where contamination occurred, which appeared in the spectral range of 2400-2300 cm^{-1} (II).

The spectral range around 1450–1300 cm^{-1} (IV) indicates the presence of nitrate precursor (NO_3^-) in the catalyst before calcination [18,19]. The NO_3^- bands disappeared from the catalyst after calcination, confirming the successful decomposition of nitrate under the calcination temperature of 500 °C. Hence, the optimum calcination temperature to remove nitrate precursor is 500 °C. In addition, the band assigned to Si-O-Si was observed in the spectral range of 1200–1000 cm^{-1} (V) [20]. This band proves the existence of the SiO_2 network in the catalyst.

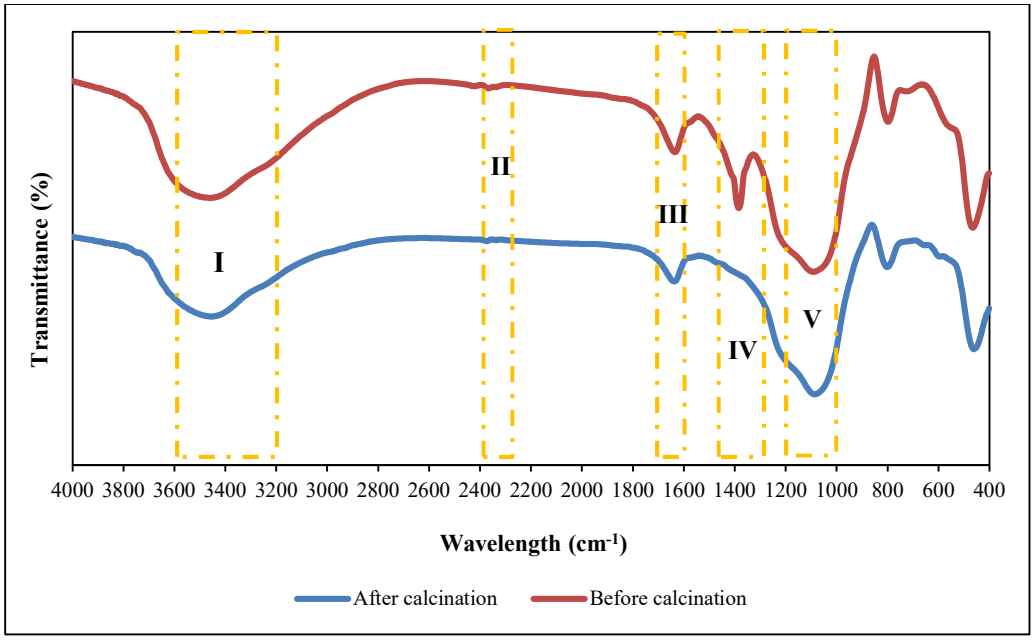

Figure 2. FTIR spectra of Pd/SiO_2-Al_2O_3 (before and after calcination)

Catalyst characterization: Surface area, pore volume, and particle size

Information on the surface area, pore size distribution, and particle size of the catalyst is essential, especially for catalytic reaction work. The BET surface area, pore volume, and particle size of the catalysts are presented in Table 2.

Table 2. BET surface area, pore volume, and particle size of the catalyst

Sample	Surface Area[a] (m^2/g)	Pore Volume[b] (cm^3/g)	Particle Size[c] (µm)
Pd/SiO_2-Al_2O_3 (before calcination)	501.9	0.2552	93.7
Pd/SiO_2-Al_2O_3 (after calcination)	485.6	0.2459	98.0

[a]: Surface area was obtained from the BET method
[b]: Pore volume was obtained from the BET method
[c]: Particle size was determined using a Malvern Mastersizer 3000 particle size analyzer

Based on Table 2, the surface area and pore volume of the catalyst decreased after the catalyst was calcined. The surface area and pore volume decreased after calcination by up to 16.2 m^2/g and 0.0093 cm^3/g, respectively. The decrease in surface area and pore volume is possibly due to the aggregation of the catalyst [21]. Even though calcination reduces the BET surface area and pore volume, it has the potential to secure the existence of a stable structure of the catalyst [22]. In addition, the catalyst has a higher surface area and pore volume than Wang et al. (329 m^2/g) [23], which are 485.6 m^2/g and 0.2459 cm^3/g, respectively.

The influence of surface area can be explained by the concept of collision theory, where the bigger the surface area, the greater the chances of the particle being exposed to each other [24]. Meanwhile, the information on pore size distribution is crucial for the catalyst's active sites [25]. According to Klinghoffer et al. [26], both properties greatly influence the catalytic activity and the reaction rate, whether they promote the reaction to be faster or otherwise.

Based on Table 2, the particle size of the catalyst increased as the surface area and the pore volume of the catalyst decreased after calcination. When the particle size of a catalyst is reduced, the surface area increases, and the shape changes, resulting in a larger number of reactive edge sites. This might be due to calcination, which results in increased crystallinity of the catalyst [27,17].

Effect of catalyst loading on the yield of glucose and conversion of cellulose

Figure 3 illustrates the effect of catalyst loading on the yield of glucose and cellulose conversion. Based on Figure 3, the highest conversion of cellulose and yield of glucose was 78.7% and 23.6%, respectively, when 0.06 g of catalyst was employed in the reaction. As catalyst loading increased from 0.04 to 0.06 g, the yield of glucose increased continuously increase. However, a further increase in catalyst loading from 0.08 to 0.10 g resulted in a decrease in the glucose yield and cellulose conversion. This finding was also observed in the study by Yan et al. [28]. This might be due to an unwanted side reaction from higher catalyst loading. Additionally, higher catalyst loading could make the reaction mixture more viscous, resulting in a slower reaction [29]. Therefore, the effect of mixing decreases and the mass transfer resistance in the mixture increases. Consequently, less cellulose is available for the reaction. Thus, no additional catalyst should be added when the amount of the catalyst has met the requirement of the reaction.

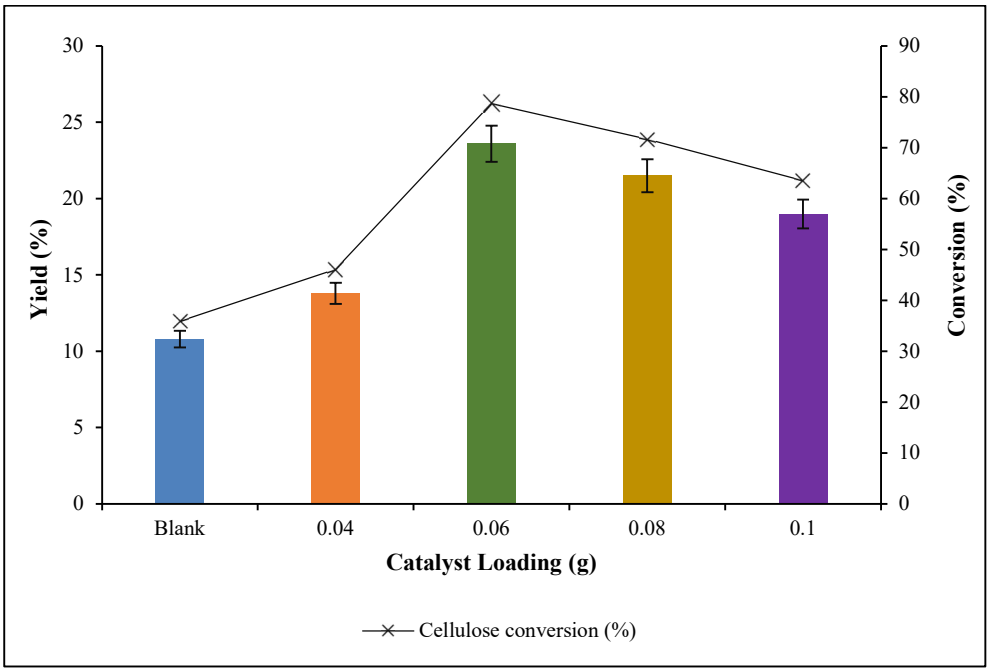

Figure 3. Effect of catalyst loading on the yield of glucose and cellulose conversion at 3 h. Note: a) Pre-reduction of catalyst conditions: 10 mL of distilled water, agitation speed of 1300 rpm, and 1 bar of H_2 for 1 h at 150 °C, b) reaction conditions: 0.3 g of cellulose, reaction temperature of 200 °C, agitation speed of 1100 rpm, and reaction time of 3 h

Besides, a reaction without the catalyst (blank) was conducted as a reference. Without the catalyst, the yield of glucose and conversion of cellulose were at their lowest levels of 10.8%, and 35.9%, respectively, as shown in Figure 3. This proves that in the presence of a catalyst, cellulose can be converted efficiently, and more glucose can be produced. The catalyst creates a distinct reaction pathway, reducing the activation energies of individual reaction stages and accelerating the process of reaching equilibrium by lowering the activation

energies of various reaction steps [30].

Conclusion

Several findings can be summarized from this study which are the TGA pattern demonstrates that the nitrate precursor in the catalyst can be decomposed at temperatures above 350 °C, the FTIR's diminishing peak at 1450–1300 cm^{-1} for the catalyst after calcination indicates that the nitrate precursor has been successfully removed at a calcination temperature of 500 °C, and the catalyst with higher surface area (485.6 m^2/g) and larger pore volume (0.2459 cm^3/g) contributed to the high yield of glucose and conversion of cellulose up to 23.6% and 78.7%, respectively. This proves that a supported noble metal catalyst with high surface area and large pore volume can provide a faster route in producing glucose from cellulose with high crystallinity.

Abstract

This study aimed to incorporate the nereistoxin, a compound that is the major metabolite of all nereistoxin analogue pesticides, including thiosultap-disodium into the previously reported analytical method developed for thiosultap-disodium residue analysis in the palm oil matrix. All steps that have been developed previously for the determination of thiosultap-disodium involving liquid-liquid extraction and subsequently determination using liquid chromatograph triple quadrupole mass spectrometer (LC-MS/MS) were followed, except the omission of matrix-matched calibration curve preparation and this was substituted with the use of spiked calibration curve technique due to its better performance in overcoming the matrix effect. The performance of the analytical method was evaluated in-house and found to be satisfactory. Recoveries of the nereistoxin residue spiked at 12, 30, and 50 ng g^{-1} were at 85-95% with a relative standard deviation of below 9%. Three months of monitoring of method intermediate precision by two analysts gave a relative standard deviation value of 3.6% to 8.3% for the same spiking levels. The limit of detection (LOD) and limit of quantification (LOQ) were first estimated using the standard deviation of the calibration curve at a 95% confidence level and subsequently evaluated by actual experimental work. The values found were 5.0 ng g^{-1} and 12.0 ng g^{-1}.

Keywords: nereistoxin, palm oil, method development, dimehypo, spiked calibration

Abstrak

Kajian ini bertujuan untuk menambahkan sebatian nereistoxin, iaitu sebatian metabolit utama bagi kesemua racun perosak dari kelas analog nereistoxin termasuk thiosultap-disodium ke dalam kaedah analisa sisabaki thiosultap-disodium dalam matriks minyak sawit yang dibangunkan sebelum ini. Kesemua langkah pengolahan sampel yang telah dibangunkan sebelum ini bagi penentuan thiosultap-disodium melibatkan pengekstrakan fasa cecair-cecair lalu penentuan menggunakan kromatografi cecair spektrometri jisim caturkutub ganda tiga masih diikut, kecuali langkah persediaan keluk kalibrasi padanan-matriks telah digantikan dengan penggunaan teknik keluk kalibrasi pemakuan memandangkan prestasinya yang lebih bagus dalam mengatasi kesan dari matriks. Prestasi kaedah analitikal ini telah dinilai secara dalaman di makmal sendiri dan didapati ianya memuaskan. Nilai

perolehan semula sisabaki nereistoxin yang telah dipakukan pada 12, 30 and 50 ng g^{-1}, masing-masing adalah dalam lingkungan 85-95 % dengan nilai piawai relatif di bawah 9%. Pemantauan selama tiga bulan bagi menentukan kepersisan perantaraan kaedah oleh dua orang penganalisa berbeza memberikan nilai piawai relatif 3.6% ke 8.3% untuk kepekatan pemakuan yang sama. Had pengesanan dan had kuantitatif telah dianggarkan pada permulaan menggunakan sisihan piawai yang diperolehi daripada keluk kalibrasi pada tahap keyakinan 95% lalu pengesahan dilakukan melalui kajian secara eksperimen. Nilai yang diperolehi adalah 5.0 ng g^{-1} dan 12.0 ng g^{-1}, masing-masing.

Kata kunci: nereistoxin, minyak sawit, pembangunan kaedah, dimehypo, kalibrasi pemakuan

Introduction

Thiosultap-disodium or in its trade name dimehypo is an insecticide known for its usage in oil palm plantations for controlling foliage pests [1-3]. Hence, a study was carried out to develop a method for determining the residue of this insecticide in crude palm oil (CPO) as a proactive step in monitoring the possible pesticide residues that may be present in the local CPO [4]. The method reported was simple and effective involving an aqueous-oil liquid-liquid extraction step and omitting the need for sample clean-up, thus it is cost-effective and time-saving.

Thiosultap-disodium is a compound classified under the group of nereistoxin analogue insecticides. Compounds under this category shared the common chemical structure of their parent compound of nereistoxin (Figure 1). Upon ingestion by insects, nereistoxin analogue insecticides tend to be metabolised into nereistoxin or its uncyclized dithiol and subsequently act as the nicotinic acetylcholine receptor or ion channel complex in the central nervous system thus killing the insects [5,6]. A few other nereistoxin analogue insecticides examples are thiocyclam and Cartap (Figure 1).

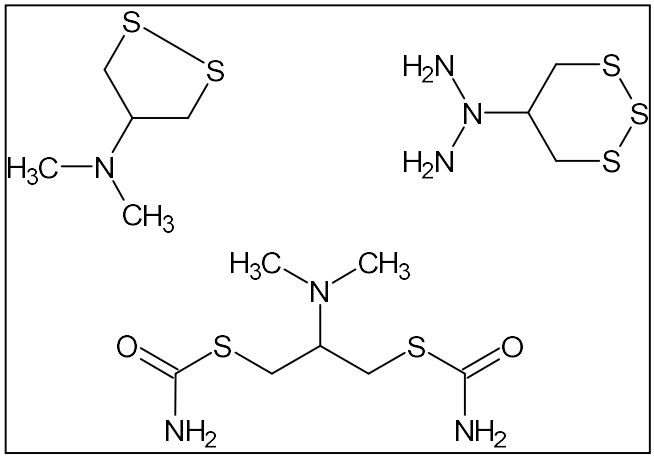

Figure 1. Chemical structure of nereistoxin (top left), thiocyclam (top right), and cartap (bottom)

Hence, it is obvious that the residue analysis method developed by Yeoh et.al. [4] in palm oil matrix for thiosultap-disodium alone is insufficient without the inclusion of determining the possible nereistoxin residue that might be present since the compound is likely to be formed as the primary metabolite in the action of the insecticide [7]. Therefore, this paper aims to re-examine the established workflow to incorporate nereistoxin as another compound of interest in order for the residue of both compounds can be determined in a single run. This article reports the performance of the analytical method to determine nereistoxin residue in palm oil matrix from the aspects of selectivity, linearity, recovery, and precision.

Materials and Methods

The performance of the previously developed analytical method for the thiosultap-disodium residue in handling the nereistoxin residue was evaluated through the analysis of control CPO samples spiked with the

nereistoxin standard. No major alteration was made to the previous method except for the inclusion of deuterated nereistoxin as an internal standard (IS).

Reagents and chemicals

All solvents used were at least of analytical reagent grade. Nereistoxin oxalate (96.1% purity) and nereistoxin oxalate D6 (99.5% purity) standard materials were obtained from Dr. Ehrenstorfer GmbH (Augsburg, Germany). Ultrapure water from Merck Millipore Direct Q® 8-UV-R water purification system (Darmstadt, Germany) was used throughout the experiments.

Blank crude palm oil (CPO) sample

CPO was obtained from a palm oil mill that processed fresh fruit bunches nearby Carey Island, Selangor, Malaysia with known records of pesticide applications. CPO obtained is considered blank upon confirmation with respective plantations in which no nereistoxin analogue insecticides have been used for at least the past 3 months before the harvesting. The CPO was filtered through anhydrous sodium sulphate (10% of blank oil weight) to ensure the sample used in method validation studies is dry and free from insoluble materials [8].

Standard solutions

Standard stock solutions of either native or isotopically labelled nereistoxin at the concentration of 100 µg mL^{-1} were prepared by dissolving 10.41 mg of nereistoxin and 10.05 mg of deuterated nereistoxin in 100 mL of methanol and stored in dark at -18°C. Working standard solutions of both compounds at 10 µg mL^{-1} were prepared by 10-fold dilution of the stock solution in methanol and stored in dark at -18°C. Prior to their use, all stocks or working standard solutions were kept for at least 1.5 h at ambient temperature.

Spiked calibration curve, linearity evaluation limit of detection (LOD) and quantification (LOQ)

Spiked calibration curves of 7 levels at 10, 20, 30, 50, 70, 90, and 100 ng g^{-1} were prepared by the addition of 5, 10, 15, 25, 35, 45, and 50 µL of nereistoxin working standard, respectively to 5 g portions of blank CPO in each level. An aliquot of 25 µL of the IS working standard was also added to each of the spiked CPO. The spiked samples obtained were then treated following the sample extraction procedures described in the later part of this section.

For linearity evaluation, it begins with the visual evaluation of the calibration curve in combination with the coefficient of determination, r^2 expression to see if a linear regression is an appropriate model for the curve. It was then followed by a residual plot that allows for graphical evaluation to observe the presence of any pattern as well as heteroscedasticity in the linear regression model.

LOD and LOQ methods were estimated from the calibration plotted curve followed by a recovery experiment that was performed at a spiking level close to LOQ for confirmation.

Recovery test samples preparation

300 g accurately weighed blank CPO was stirred in a dry and clean 500 mL beaker (tall form) with a controlled temperature at 60°C followed by the addition of 36 µl of nereistoxin stock solution (100 µg mL^{-1}). The mixture was then stirred continuously for another 40 min before the sub-sampling of spiked control samples. While stirring, 5 g of each of the control samples spiked with a nereistoxin standard at 12 ng g^{-1} of CPO were weighted. A total of 50 spiked control samples were obtained and stored in a freezer at -18°C in the dark. Samples were used in recovery and precision studies. The same procedures were repeated for the preparation of control samples spiked with nereistoxin at 30 ng g^{-1} and 50 ng g^{-1} of CPO.

Matrix effect evaluation

For matrix effect (% ME) evaluation, nereistoxin calibration curves at 6 concentration levels (10, 20, 30, 50, 70, and 100 ppb) prepared by three different techniques: neat solvent, matrix matched solution, and spiked calibration technique. The % of ME was calculated as follows:

$$\%ME = \left(1 - \frac{Slope\ of\ Calibration\ Curve\ Prepared\ in\ Solvent}{Slope\ of\ Calibration\ Curve\ Prepared\ in\ Matrix}\right) \times 100\% \quad (1)$$

Liquid chromatography triple quadrupole mass spectrometer (LC-MS/MS) analysis

LC-MS/MS analysis from Yeoh *et al.* [4] was performed on an AB Sciex QTRAP® 4500 (Foster City, CA; USA) triple quadrupole mass spectrometer coupled to an Eksigent Ekspert™ Ultra LC 100 system (Eksigent, Redwood City, CA, USA). Ionisation was in a positive mode at 5500 V and 550ºC with an electrospray probe. The Applied Biosystems Analyst 1.6 software was used to control the operation of the instrument and data acquisition or processing. Chromatography separation was achieved on a Phenomenex Kinetex® C18 100 Å 50 mm × 2.1 mm i.d., 2.6 µm particle size column, and coupled to a 2 mm × 2.1 mm i.d. Security Guard C18 column set at 40°C. The injection volume was 10 µl with a flow rate of 200 mL min^{-1}. The mobile phase is composed of methanol as the organic phase and an aqueous solution of ammonium acetate (10 mM, adjusted to pH 5.0). The following gradient elution profile was used; the initial conditions (95% aqueous phase) were maintained for 0.5 min before the organic eluent was increased to 95% in 5 min. After maintaining this high organic mobile phase for 5 min, the condition was brought back to the initial conditions in 0.5 min and kept the composition for 5 min before the next analysis, thus giving a total runtime of 16 min. The determination of nereistoxin residue was performed via multiple reaction monitoring (MRM) experiments with two precursor-daughter ion transitions. The detailed settings of the MRM experiment such as the declustering potential (DP), entrance potential (EP), collision energy (CE), and collision cell exit potentials (CXP) are summarised in Table 1. Examples of blank and nereistoxin standard chromatograms at 10 ng g^{-1} are shown in Figure 2. It can be observed that no significant interference was found within the window period of ± 30 s from the expected retention time for nereistoxin suggesting that selectivity was not a problem in this study.

Table 1. MRM parameters setting in nereistoxin and internal standard detection

Ion Transition	DP (Volt)	EP (Volt)	CE (Volt)	CXP (Volt)	Remark
150→105	20	7	22	5	Quantifying ion
150→61	20	7	31	51	Qualifying ion
156→105	39	9	18	13	Quantifying ion (IS)

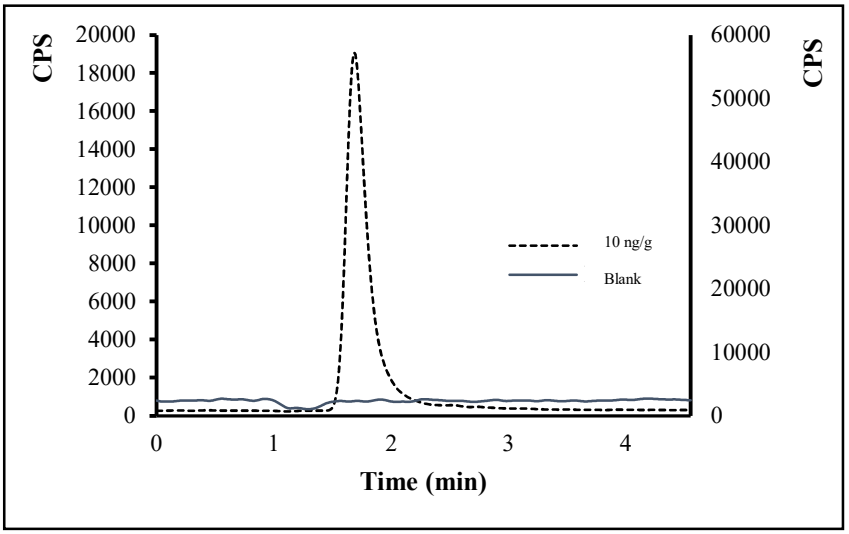

Figure 2. Overlay chromatograms of nereistoxin standard at 10 ng g-1 (dotted line and referring to right vertical axes) and blank extract (solid line and referring to left vertical axes)

Results and Discussion

Matrix effect and linearity

Figure 3 shows the calibration curves prepared using three different techniques: neat solvent, matrix matched solution, and spiked calibration technique. Results revealed that the nereistoxin signal was suffering from ~15% ion suppression due to the matrix effect. Although this was acceptable according to the SANTE guidelines [9], efforts were still made to examine the possibility of utilising other calibration techniques [10,11]. In this study, the spiked calibration technique is selected although preliminary data showed that the matrix-matched calibration technique is viable with sufficiently good linearity and recovery. Furthermore, it can be observed from Figure 3 that the spiked calibration curve is no different (%ME ~7.4%) from the calibration curve prepared in a neat solvent, thus suggesting that the spiked calibration technique is also viable for the quantification of nereistoxin residue in the palm oil matrix. Both % of ME shown by using matrix-matched and spiked calibration techniques were well within the analytical errors (± 20%) as stipulated in the SANTE guidelines [9].

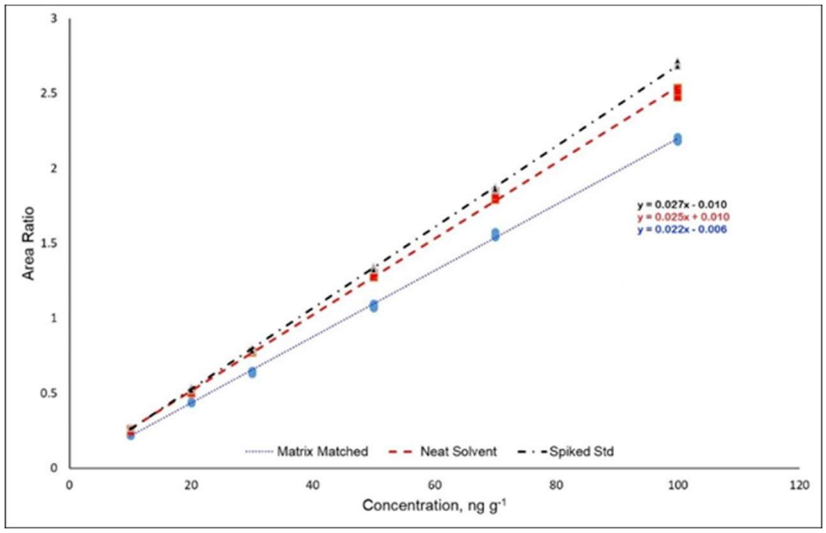

Figure 3. Comparison of calibration curves prepared in neat solvent, blank matrix extract and following spiked standard technique

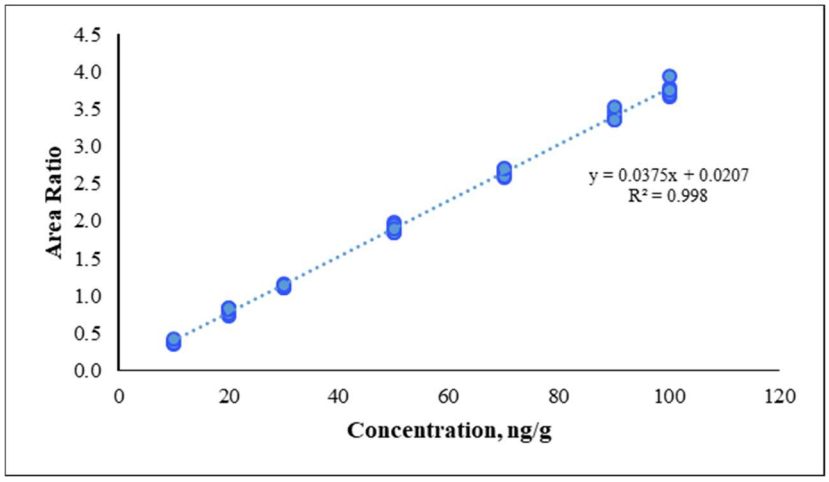

Figure 4. Nereistoxin calibration curve prepared according to the spiked standard technique

Figure 4 shows the representative spiked nereistoxin calibration curve ranging from 10 to 100 ng mL^{-1} (six injections per level) which were used for quantification in this study. It can be observed that nereistoxin responses were linear throughout the calibration range with a coefficient of determination (r^2) of 0.998. Plotting of Y residues against nereistoxin concentrations showed that the distribution of the errors was fairly randomised around the concentration axis except for some degree of increase in the standard deviation of measurements following the increase in the nereistoxin concentrations (Figure 5). This indicates the presence of heteroscedasticity in the linear regression model fitted for the calibration curve [12, 13].

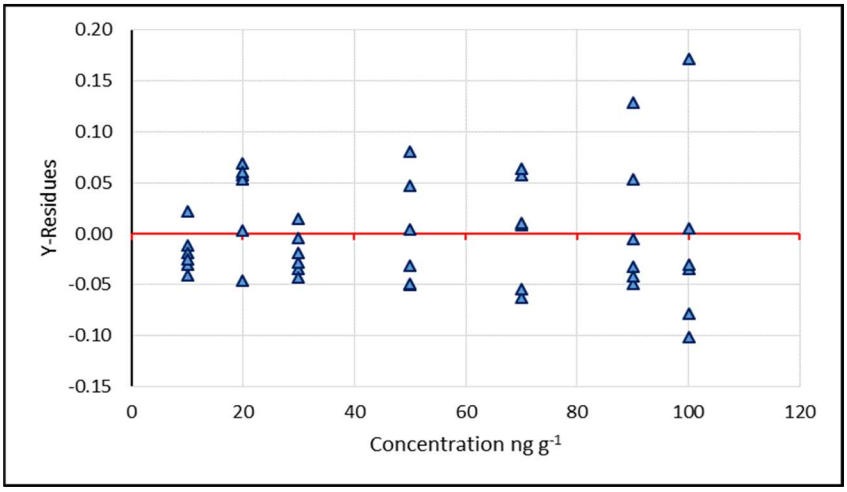

Figure 5. Residual plot for homoscedasticity evaluation

To ascertain the heteroscedasticity in the linear regression model used, the *F*-test was conducted by comparing the variances between the highest (100 ng g^{-1}) and the lowest (10 ng g^{-1}) calibration levels following Equation (2) [12-15].

$$F_{exp} = \frac{S_H^2}{S_L^2} \quad \text{and} \quad F_{tab}(f_1, f_2; 0.99) \qquad (2)$$

where F_{exp} is the experimental F value from the calibration data expressed as a ratio of the variance between the highest concentration level (S_H^2) and the lowest concentration level (S_L^2). The F_{exp} is then compared with the F_{tab} from the F-table at a 99% confidence level for $f_1 = f_2 = (n\text{-}1)$ degrees of freedom. The homoscedasticity test is passed when $F_{tab} > F_{exp}$.

Upon computation, the presence of heteroscedasticity in the calibration curve is confirmed whereby the experimental F-value (F_{exp} = 19.41) was found to be larger than the tabled F-value (F_{tab} = 10.97). Thus, a weighted linear regression model is used in this study for the quantitation of nereistoxin residue. Only a few weighting factors such as 1/X, $1/X^2$, ln X, 1/Y, $1/Y^2$, and ln Y are considered in this study depending on the built-in functions that are available in the data processing software bundled to the LC/MS/MS. The selection of a suitable weighting factor is based on the sum of absolute relative error (∑%RE) computed from each regression model for every weighting factor. A regression model that gives the lowest ∑%RE will be chosen for calibration curve construction.

Table 2 shows the regression parameters of the calibration curve generated for each weighing factor and the respective ∑%RE for the calibration data. The data show that the regression model with $1/Y^2$ as a weighting factor was chosen in this study.

Table 2. Regression parameters of the calibration curve generated for each weighing factor and the respective ∑%Re for the calibration data

Model	Weighting Factor	Slope	y-Intercept	Correlation Coefficient, r	∑%RE
1	None	0.03752	0.02073	0.99898	135.66
2	1/X	0.03763	0.01459	0.99906	131.36
3	$1/X^2$	0.03791	0.00657	0.99814	129.15
4	ln X	0.03749	0.02236	0.99880	136.80
5	1/Y	0.03764	0.01277	0.99909	129.83
6	$1/Y^2$	0.03788	0.00381	0.99830	126.85
7	ln Y	0.03763	0.01148	0.99878	128.80

Limit of detection (LOD) and limit of quantification (LOQ)

LOD and LOQ are crucial parts of method validation. In this study, LOD and LOQ were estimated from the standard deviation of the calibration curve and calculated according to Equations (3) and (4) [16-18]. The LOD and LOQ were estimated to be 5.0 ng g^{-1} and 15.0 ng g^{-1}, respectively at a 95% confidence level. The estimated LOQ was further verified through the conduct of recovery tests at 12.0 ng g^{-1}, a value close to the estimated LOQ. The results suggested that the estimated LOQ is appropriate in describing the performance of the developed method and the final LOQ was altered to 12.0 ng g^{-1} resulting from the acceptable recovery results obtained at this level of spiking.

$$LOD = 3.3 * \frac{\sigma}{s} \quad (3)$$

$$LOQ = 10 * \frac{\sigma}{s} \quad (4)$$

Where σ is the standard deviation and S is the slope of the calibration curve.

Recovery and precision

The performance of the developed method was further evaluated from the recovery study. For precision evaluation, two analysts of different analytical skills were accessed for 3 months, and the method repeatability and intermediate precision were recorded. From Table 3, it can be observed that nereistoxin recoveries throughout the assessment period were all within 80-95% with a relative standard deviation (RSD %) of < 10%. For intermediate precision evaluation, the recovery values of every measurement by both analysts across 3 months period were taken into consideration. The calculated RSD % represents the extent of error among those measurements including the factors of different analysts, different time, different reagent batches, and different spiking concentrations, of which were between 3.6% to 8.3%. Judging from the present data, the precision of the method is well accepted and far below the set value of 20% as stipulated in the SANTE guidelines [9].

Conclusions

This study demonstrates how an appropriate linear regression model (with or without weighting factor) in pesticide residue method development can be chosen based on the statistical analysis and, in brief, how the decision was made by using the incorporation of nereistoxin residue into the existing analytical method for thiosultap disodium residue in the palm oil matrix as an example. From the matrix effect evaluation, it was found that the analysis of nereistoxin residue in the palm oil matrix did not suffer much from the matrix effect and both matrix-matched, and spiked calibration curve techniques were viable and effective in quantifying the nereistoxin residue. With the introduction of the spiked calibration technique, the current method is found to be simple and effective as published in the initial method. Analysis of sodium thiosultap and nereistoxin residues in palm oil matrix can now be performed simultaneously.

Table 3. Recovery of nereistoxin residue (at different spiking levels and times of experiment by different analysts)

Spiking Level (ng g^{-1})	12 (Low)		30 (Medium)		50 (High)	
Analyst	**A**	**B**	**A**	**B**	**A**	**B**

Abstract

A phosphorescent Ir(III) complex was synthesised between 2-(1*H*-1,2,4-triazol-1-yl)pyridine and Ir(III) dimer, $[Ir(2,4\text{-}F_2ppy)_2(\mu\text{-}Cl)]_2$, where ppy denotes 2-phenylpyridine by reflux method. The Ir(III) complex was fully characterised by FTIR, NMR, LC-MS, and UV-Vis absorption spectroscopic methods. The presence of a strong band at 2220 cm^{-1} due to ν(C≡N) was revealed by the IR analysis. Both pyridine and phenyl aromatic rings have C=N stretching band at 1598 cm^{-1} and C=C stretching bands at 1554 and 1400 cm^{-1}, respectively. The ^1H NMR spectrum showed signals in the aromatic range of δ 5.00–9.00 ppm corresponding to phenylpyridine protons. The ^{13}C NMR spectroscopic data were consistent with the Ir(III) complex formula, which revealed 37 carbon signals. The Ir(III) complex displayed the ESI-MS spectrum at m/z = 823. The UV-Vis spectrum displayed a weaker and broader band (374 nm) in the visible region due to the spin-forbidden ^{3}MLCT transitions. The X-ray crystallographic study revealed that the Ir(III) ion was coordinated to the pyridine-formimidamide ancillary ligand and two 2-(2,4-difluorophenyl)pyridine cyclometalating ligands in an octahedral geometry. Steady-state emission spectroscopy determined that

the Ir(III) complex emitted blue-green light in dichloromethane solution at room temperature with the vibronic structure to the peak shape (λ = 462 nm and 487 nm) due to the admixture of ^{3}LC and ^{3}MLCT character excited states.

Abstrak

Kompleks Ir(III) berpendar fosfor disintesis antara 2-(1*H*-1,2,4-triazola-1-yl)piridina dan dimer Ir(III), [Ir(2,4-F_2ppy)$_2$(μ- Cl)]$_2$ di mana ppy mewakili 2-fenilpiridina melalui kaedah refluks. Kompleks Ir(III) dicirikan sepenuhnya melalui kaedah spektroskopi: FTIR, NMR, LC-MS, dan penyerapan UV-Vis. Kehadiran satu jalur kuat pada 2220 cm^{-1} disebabkan oleh ν(C≡N) telah dikenal pasti daripada analisis IR. Kedua-dua gelang aromatik piridina dan fenil, masing-masing mempunyai jalur regangan C=N pada 1598 cm^{-1} dan jalur regangan C=C pada 1554 dan 1400 cm^{-1}. Spektrum ^{1}H NMR menunjukkan isyarat dalam julat aromatik δ 5.00–9.00 ppm sepadan dengan proton fenilpiridina. Data spektroskopi ^{13}C NMR juga konsisten dengan formula kompleks Ir(III), yang menunjukkan 37 isyarat karbon. Kompleks Ir(III) menunjukkan spektrum ESI-MS pada m/z = 823. Spektrum UV-Vis mempamerkan jalur yang lebih lemah dan lebar (374 nm) di rantau yang boleh dilihat disebabkan oleh peralihan ^{3}MLCT spin-terlarang. Kajian kristalografi sinar-X menunjukkan ion Ir(III) dikoordinasi kepada ligan ansilari piridina-formimidamida dan dua ligan siklometalasi 2-(2,4-diflorofenil)piridina dalam geometri oktahedral. Spektroskopi pancaran keadaan-stabil menunjukkan kompleks Ir(III) memancarkan cahaya biru-hijau dalam larutan diklorometana pada suhu bilik dengan struktur vibronik kepada bentuk puncak (λ = 462 nm dan 487 nm) disebabkan oleh bauran ciri keadaan teruja ^{3}LC dan ^{3}MLCT.

Introduction

Phosphorescent transition metal complexes have attracted increased scientific interest because they are widely used in organic light-emitting diodes (OLEDs) for next-generation lighting sources and flat-panel displays [1,2]. The spin-orbit coupling of phosphorescent transition metal complexes has been used to access the triplet excitons that fluorescent emitters previously could not reach [3,4]. Ir(III) complexes are considered to be the most promising triplet harvester because of their high phosphorescence quantum efficiencies, short phosphorescence lifetimes, and colour-tuning flexibility [5–7]. Blue OLEDs are the most severe research issues compared to red- and green-emitting materials [8,10]. In this regard, the design and synthesis of deep-blue-emitting Ir(III) complexes are challenging. Although high quantum efficiencies (QEs) exceeding 30% have been achieved for green and red OLED devices, high QEs for deep-blue OLED devices have rarely been reported because blue phosphors have faster decomposition due to their highly energetic excited states [7].

It has been found that there are numerous ways to change the emission colour of a variety of heteroleptic Ir(III) complexes with cyclometalated phenylpyridine ligands. One of the most promising techniques to produce the emission to blue is to substitute the cyclometalating ligand with an electron-withdrawing group, such as a fluorine atom that will stabilise the highest occupied molecular orbital (HOMO) orbitals that are localised on the phenyl ring and the metal atom [7,9]. Additionally, the inclusion of novel chelating ligands as ancillary ligands can lower the lowest unoccupied molecular orbital (LUMO) level [9], increasing the HOMO-LUMO energy gap. Therefore, to have stable efficiencies of blue emitters for OLEDs, Ir(III) complex must have a sufficiently large energy difference between HOMO and LUMO [7–10]. In this report, we presented the use of novel pyridine-formimidamide as the ancillary ligand for Ir(III) complex and detailed explanation of the synthesis, spectroscopic, and X-ray crystallographic analysis studies.

Materials and Methods

Materials

Unless otherwise specified, all chemicals were obtained from various sources and used exactly as obtained.

Physical measurements

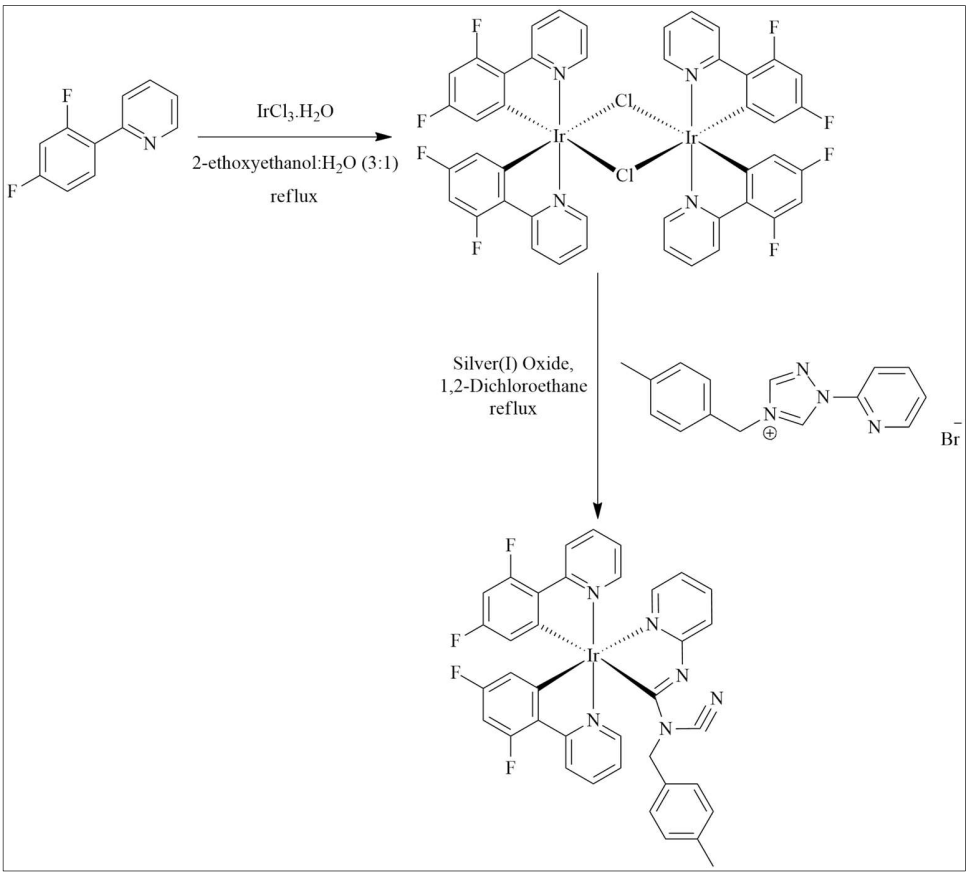
Elemental analysis for carbon (C), hydrogen (H), and nitrogen (N) was performed using a CHNS-O elemental analyser model Flash EA 1112 Series. ^{1}H NMR and ^{13}C

NMR spectra using deuterated dichloromethane (CD_2Cl_2) as solvent were analysed by a nuclear magnetic resonance (NMR) spectrometer (JNM-ECX-500, JEOL). At room temperature, the IR spectrum from a Thermo Nicolet 6700 spectrometer was acquired in the 4000–500 cm^{-1} range. The mass spectrum was analysed by a liquid chromatography-mass spectrometer (LC-MS) model 6490 Triple Quadrupole, Agilent Technologies. The column used was a Phenomenex Gemini NX (C_{18}, 150 × 2.0 mm, ID 5.0 µm). The sample was prepared by dissolving 10 mg in 10 mL of acetonitrile and injected using the gradient ratio of acetonitrile and formic acid as the eluent. A Cary 60 UV-Vis spectrophotometer (Agilent Technologies) was used to analyse the UV-Vis absorption spectra in methylene chloride solution.

A photoluminescence spectrometer model FLS920 (Edinburgh Instrument) was used to obtain the steady-state emission spectrum and time-resolved fluorescence lifetime from an air-equilibrated dichloromethane solution at 298 K. Fluorescence quantum yield was measured by relative method using *tris*(2-phenylpyridine)iridium(III), $Ir(ppy)_3$ in dichloromethane solution ($\Phi = 0.4$) as the standard [11]. The equation $\Phi_s = \Phi_r(I_s/I_r)(A_r/A_s)(\eta_s^2/\eta_r^2)$ was used to calculate the quantum yield, where, Φ_s is the quantum yield of the sample, Φ_r is the quantum yield of the reference, I_s is the area of the emission fluorescence spectrum of the sample, I_r is the area of the emission fluorescence spectrum of the reference, A_s is the absorbance of the sample, A_r is the absorbance of the reference, η_s is the refractive index of the solvent for the sample, and η_r is the refractive index of the solvent for the reference.

Synthesis

Chloro-bridged iridium(III) dimer (0.0605 g, 0.1 mmol equiv.), 2-[4-(4-methyl-benzyl)-[1,2,4]triazol-1-yl]-pyridine ligand (0.0289 g, 0.25 mmol equiv.), and silver(I) oxide (0.0290 g, 0.21 mmol equiv.) in 15 mL of 1,2-dicholoroethane were refluxed in the dark and under an N_2 atmosphere for 24 h. The solution was collected by filtering through celite after it had cooled to room temperature. Then, the solution was dried over anhydrous sodium sulphate and purified with dichloromethane/methanol (90:10 v/v) solvent. The column yielded a yellowish product.



Yield: 69%. ^{1}H NMR (500 MHz, CD_2Cl_2): δ 8.21 (d, J = 8.6 Hz, 2H), 7.73 (t, J = 7.7 Hz, 1H), 7.67 (d, J = 2.3 Hz, 1H), 7.61 (t, J = 7.2 Hz, 1H), 7.49 (t, J = 8.0 Hz, 1H), 7.42 (t, J = 5.7 Hz, 1H), 7.35 (t, J = 4.0 Hz, 1H), 6.94–6.88 (m, 4H), 6.66 (t, J = 6.0 Hz, 1H), 6.46–6.42 (m, 2H), 6.28 (t, J = 11.5 Hz, 1H), 5.67 (d, J = 2.3 Hz, 1H), 5.65 (d, J = 2.3 Hz, 1H), 5.59 (t, J = 6.3 Hz, 1H), 4.88 (d, J = 14.3 Hz, 1H), 2.26 (s, 5H). ^{13}C NMR (126 MHz, CD_2Cl_2): δ 172.0, 165.3, 165.3, 165.0, 164.9, 164.5, 164.4, 162.9, 162.8, 162.5, 162.4, 160.7, 160.6, 154.5, 148.6, 147.7, 139.6, 137.8, 136.6, 133.6, 128.9, 127.7, 127.0, 123.7, 123.6, 123.4, 123.1, 123.0, 122.0, 118.2, 117.9, 112.7, 112.5, 98.4, 96.3, 20.8. FTIR (ATR, ν/cm^{-1}): 3077 (w, ν(C–$H_{aromatic}$)), 2925 (w, ν(C–H_{alkyl})), 2220 (s, ν(C≡$N_{nitrile}$)), 1600–1400 (s, ν(C=$C_{aromatic}$); s, ν(C=N_{py})), 1244 (s, ν(C–N)); 830–720 (s, δ(C–$H_{ortho/para\ out\text{-}of\text{-}plane}$); 1100–984 (s, δ(C–$H_{ortho/para\ in\text{-}plane}$). LC-MS (ESI, m/z): 823 [M+H] (calc. 822). Anal. calcd. for $C_{37}H_{25}N_6F_4Ir$: C, 54.07; H, 3.07; N, 10.23%. Found: C, 53.53; H, 3.46; N, 9.27%.

X-ray crystallographic analysis

Single crystal X-ray crystallographic study was performed using a Bruker D8 QUEST with a PHOTON III charge- integrating pixel array detector area-detector diffractometer (Bruker, AXS Inc., Madison, WI, USA) and graphite-monochromated Mo-Kα radiation (λ = 0.71073 Å). The data collected were reduced using the SAINT [12] programme, and empirical absorption correction was carried out using SADABS [12]. The structure was solved by direct methods and refined via a SHELXTL [13] software package using a full-matrix least-squares approach. The molecular graphics were created using SHELXTL software. All hydrogen atoms were assigned by assuming idealised geometries with d(C–H) = 0.93 and 0.96 Å for aromatic and aliphatic, respectively, with Uiso(H) = 1.2 Ueq(C). All non-hydrogen atoms were refined anisotropically. The PLATON programme was used for molecular structure calculation [14]. The ellipsoids of one Cl of the dichloromethane are relatively elongated, suggesting a disorder; however, any attempt to split the position of the Cl failed. Hence, it is kept as it is (Figure 3).

Results and Discussion

The chloro-bridged iridium(III) dimer, $[Ir(2,4\text{-}F_2ppy)_2(\mu\text{-}Cl)]_2$ (F_2ppy = difluorophenylpyridine), was synthesised by reacting $IrCl_3{\cdot}nH_2O$ with 2-(2,4-difluorophenyl)pyridine in a refluxed 2-ethoxylethanol/water (3:1) under an N_2 atmosphere [15] and was then used in the subsequent reaction without further purification. The previously synthesised ligand, (2-(4-methylbenzyl)-1*H*-1,2,4-triazol-1-yl)pyridine (mbpyta) [16], was refluxed with $[Ir(2,4\text{-}F_2ppy)_2(\mu\text{-}Cl)]_2$ to give $[Ir(2,4\text{-}F_2ppy)_2(mbpyf)]$ (69%). Scheme 1 depicts the schematic process leading to $[Ir(2,4\text{-}F_2ppy)_2(mbpyf)]$, including the silver carbene-complex intermediate. The difficulty and challenge of separating the pure product from the crude mixture during the purification stage prevented the yield of the synthesised Ir(III) complex from reaching 80% and above. The elemental analysis of $[Ir(2,4\text{-}F_2ppy)_2(mbpyf)]$ complex matched the suggested chemical formula. In addition, the electrospray mass spectrometry (ESMS) spectrum of the $[Ir(2,4\text{-}F_2ppy)_2(mbpyf)]$ complex was recorded to determine the molecular species in the solution (Figure S1). The observed pattern of the ESMS spectrum, which displayed a peak at m/z = 823, complemented the calculated one, suggesting that the structure of the species was $[Ir(2,4\text{-}F_2ppy)_2(mbpyf)] + H]$.

Scheme 1. Schematic reaction pathway and chemical structures of chloro-bridged iridium(III) dimer and $[Ir(2,4\text{-}F_2ppy)_2(mbpyf)]$ complex

Figure 1 depicts the IR spectrum of the $[Ir(2,4\text{-}F_2ppy)_2(mbpyf)]$ complex. A strong, significant band that can be observed at 2220 cm^{-1} is due to ν(C≡N), which resembles the predictable pattern for the nitrile group [17]. The C=N stretching band appeared at 1598 cm^{-1} [18] and C=C stretching bands appeared in two absorption bands at 1554 and 1400 cm^{-1} [19], respectively, indicating the presence of aromatic rings of

pyridine and phenyl [18]. Furthermore, a strong band was detected at 1244 cm^{-1}, representing ν(C–N). The typical weak ν(C–H) in aromatic phenyl and pyridine rings was observed at 3077 cm^{-1}, while the stretching bands for (C–H) in alkyl are shown in the spectral region of 2981–2925 cm^{-1}. Additionally, strong bending bands of (C–H) were observed in the range of 830–720 cm^{-1} for ortho/para out-of-plane and in the region of 1100–984 cm^{-1} for ortho/para in-plane substituents on the aromatic ring [17,18].

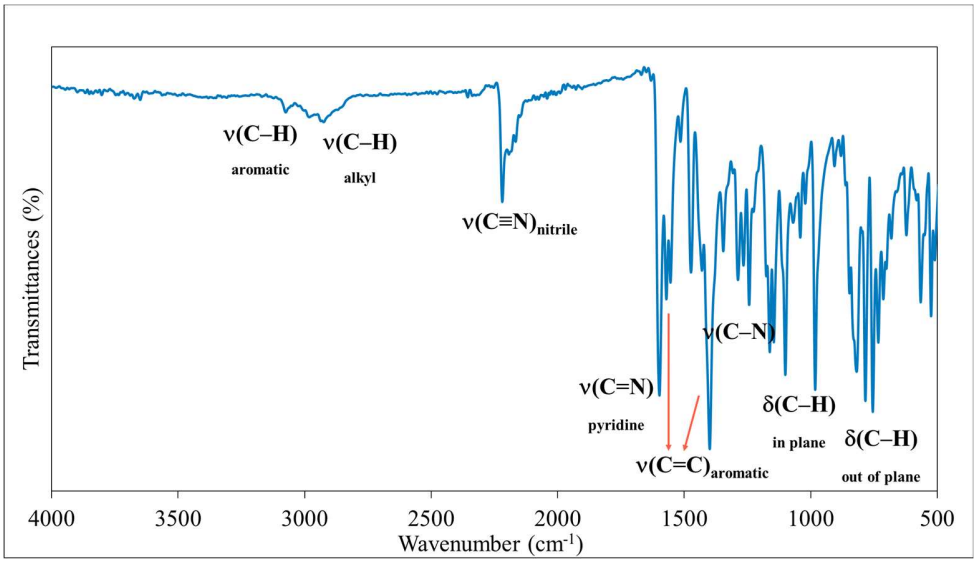


Figure 1. IR spectrum of [Ir(2,4-F_2ppy)$_2$(mbpyf)] complex

The structure of the [Ir(2,4-F_2ppy)$_2$(mbpyf)] complex was further investigated using NMR spectroscopy. The ^{1}H NMR and ^{13}C NMR spectra were recorded in deuterated dichloromethane (CD_2Cl_2) and are presented in Figures 2 and S2, respectively. Based on the HMQC spectrum, the proton resonances of the [Ir(2,4-F_2ppy)$_2$(mbpyf)] complex were assigned and compared to the ^{1}H NMR spectra of its iridium(III) dimer and ligand mbpyta in Figures S3 and S4, respectively. The aromatic signals appeared between 8.30 and 4.90 ppm, correlating to the phenylpyridine protons [6]. In addition, as expected, the signal of two singlet peaks for the mbpyta proton disappeared after deprotonation and coordination of the ancillary ligand. The multiplet signals in the aliphatic region at 2.25 ppm are caused by methylene protons at H13 and H14, together with methyl substitution groups at H19, H20, and H21 [17,18]. Hydrogen and fluorine (spin ½) have extremely strong coupling; thus, the interaction with two fluorine nuclei causes the proton signals of H5 and H5' to divide into a multiplet, while H6 and H6' split into triplets [17,18].

Furthermore, the ^{13}C NMR spectrum assisted in the structural identification of [Ir(2,4-F_2ppy)$_2$(mbpyf)]. Three distinct peaks can be ascribed to –CH_3 (20.8 ppm), –CH_2– (20.9 ppm), and C≡N (128.9 ppm) [17,18], while the other 34 significant carbon signals appeared between 96.3 and 172.0 ppm, corresponding to the number of carbon atoms in aromatic regions, consistent with the low-symmetry structure. According to Barnard and Hogan, aromatic carbon bonded to a nitrogen atom can be seen at approximately over 150 ppm, while aromatic carbon attached to a fluorine atom was found between 90 and 100 ppm [20]. Four –CF peaks appeared at 98.6, 98.4, 96.4, and 96.3 ppm, while six peaks of –C=N aromatic appeared at 162.9, 162.8, 162.5, 162.4, 160.7, and 160.6 ppm. However, a peak at 172.0 ppm ascribed to the –N–C=N bonded to the iridium atom showing a deshielded effect to the lower field of ^{13}C NMR spectrum due to the substantial electron donor effect contributed by the formimidamide ligand [21].

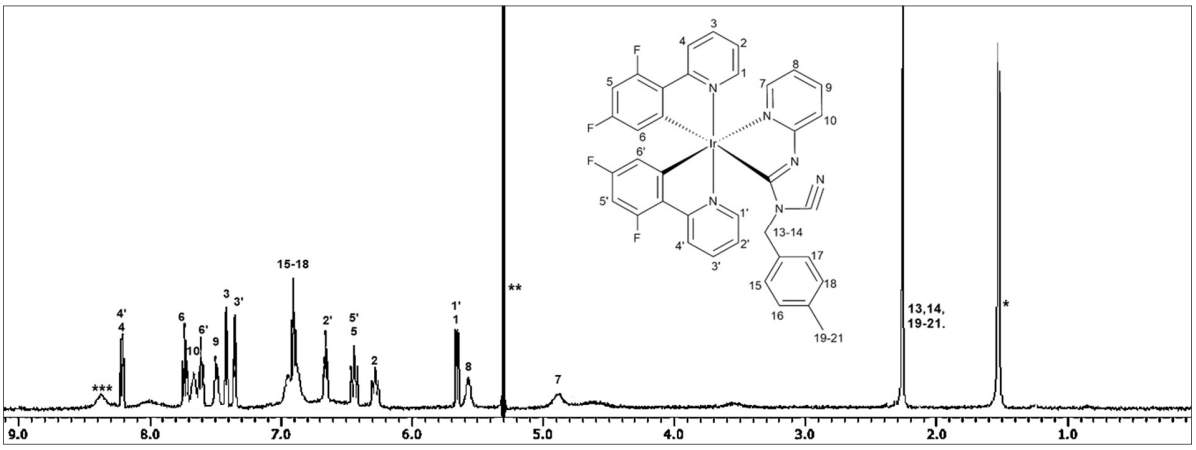

Figure 2. ^{1}H-NMR spectrum for [Ir(2,4-F_2ppy)$_2$(mbpyf)] complex in deuterated CD_2Cl_2 with its labelling scheme, H_2O is marked with *, residual solvent is marked with **, and impurity is marked with ***.

Crystal structure

Slow diffusion of hexane into a dichloromethane solution of [Ir(2,4-F_2ppy)$_2$(mbpyf)] resulted in single crystals of the compound. Despite the challenge of getting high-quality crystals, a single yellow crystal was chosen and put on a glass fibre before data collection. The [Ir(2,4-F_2ppy)$_2$(mbpyf)] complex crystallised in a monoclinic system with space group $P2_1/n$, a = 11.2164(4) Å, b = 15.5922(4) Å, c = 20.8074(7) Å, α = 90.0°, β = 91.098(2)°, γ = 90.0°, Z = 4, and V = 3638.3(2) Å^3. Table 1 presents the crystal system and refinement parameters. The ORTEP diagram of the [Ir(2,4-F_2ppy)$_2$(mbpyf)] complex with the solvated dichloromethane molecule is shown in Figure 3. Atomic coordinates and equivalent isotropic and anisotropic displacement parameters for [Ir(2,4-F_2ppy)$_2$(mbpyf)] are listed in Tables S5 and S6, respectively.

The structure of the [Ir(2,4-F_2ppy)$_2$(mbpyf)] complex is depicted in Figure 3. Two difluorophenylpyridine ligands are coordinated to the central Ir1 atom through their two pyridyl N and two phenylated C atoms, while one (2-(4-methylbenzyl)-pyridine-2-yl)formimidamide ligand is coordinated to the central Ir1 atom through its N and C atoms in a bidentate manner. The geometry of the Ir(III) complex is a distorted octahedron. The C12 and N3 atoms occupy the axial position with C12–Ir1–N3 bond angle of 176.03(12)°. The other trans atoms occupy the equatorial position with N1–Ir1–N2 and C1–Ir1–C26 bond angles of 173.08(13)° and 168.87(14)°, respectively. The steric structure of the ligands plays a significant role in the complex's distorted nature [22]. The *cis* angles about the central Ir atom are between 80.06(17)° and 96.30(13)°. The axial C12–Ir1 and N3–Ir1 are 2.017(4) Å and 2.122(4) Å, respectively. The fact that the axial N3–Ir1 bond length (2.122(4) Å) is a little bit longer than the other *trans*–oriented Ir1–N bonds (Table 2) implies that there is only weak coordination between the ancillary ligand and the central metal [23]. Other relevant bond angles and lengths are shown in Table 2. Both difluorophenylpyridine ligands are coordinated to the central Ir1 atom and give planar planes of Ir1/F1/F2/N1/(C1–C11) and Ir1/F3/F4/N2/(C12–C22) with a maximum deviation of 0.046(4) Å for C1 atom and 0.108(1) Å for Ir1 atom from the least square plane, respectively. The dihedral angle between the two planes is 79.51(7)°. The Ir1/N3/N4/N5/N6/C12/(C23–C29) fragment of the third ligand is also planar with a maximum deviation of 0.106(5) Å for the C12 atom from the least square plane. The plane makes dihedral angles of 88.96(7) ° and 89.85(8)° with the fluoropyridyl Ir1/F1/F2/N1/(C1–C11) and Ir1/F3/F4/N2/(C12–C22) planes, respectively. The cyclometallated carbon atoms C11 and C12, which are *cis* to one another, showed approximately the same distances from Ir1 (2.055(4) Å and 2.017(4) Å), which are similar to many analogous cyclometallated Ir(III) complexes [24]. The C29–N6 bond length of 1.13(9) Å indicates the presence of the nitrile triple bond functionality [6].

Photophysical study

Figure 4 illustrates the UV-Vis absorption spectrum of [Ir(2,4-F_2ppy)$_2$(mbpyf)] complex in a dichloromethane solution at room temperature. Most cyclometallating Ir(III) complexes have a two-part spectra absorbance pattern, with the weak intensity absorbance at the longer wavelength being associated with metal-to-ligand charge-transfer (MLCT) transitions [dπ(M)-π*(L)] near the visible region, while the shorter wavelength is attributed to spin-allowed singlet ligand-centred, ^{1}LC (π-π*) transitions of the ligands within the range of ultraviolet spectra [23–26]. The presence of phenylpyridine ligands was revealed by the intense absorption peak at 262 nm (ε = 30769.23 $M^{-1}cm^{-1}$), which is comparable to other cyclometallated Ir(III) complexes [5–9]. This peak is in the same region of the absorption spectrum as the free mbpyta ligand [16]. In addition, instead of the Gaussian form, the commonly weak, broad, and unstructured peaks due to the strong intersystem crossing by the triplet (T_1) and singlet (S_1) excited states that are driven through the central metal of an iridium atom appeared (315 nm, ε = 11031.90 $M^{-1}cm^{-1}$; 342 nm, ε = 8847.05 $M^{-1}cm^{-1}$; 374 nm, ε = 6102.56 $M^{-1}cm^{-1}$). These absorbances are related to ^{1}MLCT (ε > 10700 $M^{-1}cm^{-1}$), and ^{3}MLCT (ε ≈ 1,000–

6,000 $M^{-1}cm^{-1}$) transitions near the visible region [25–29]. Furthermore, a weak broad absorption peak at 446 nm (ε = 637.57 $M^{-1}cm^{-1}$) as a result of vibronic coupling is ascribed to the d-d transition of octahedral complexes that are forbidden due to symmetry according to the Laporte rules. However, this d-d transition band absorption is less intense than the charge transfer transition. Except for the LC transition, all these peaks are absent from the free mbpyta ligand absorption spectrum [16].

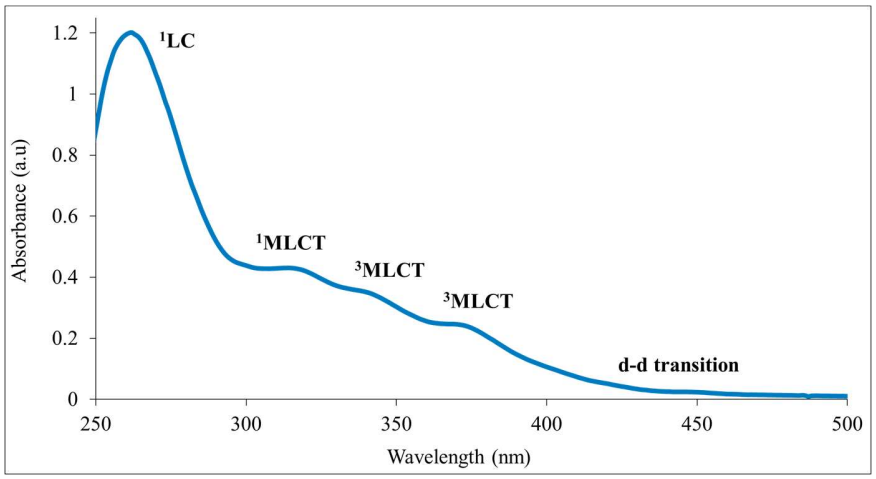

Figure 4. UV-Vis absorption spectrum of [Ir(2,4-F_2ppy)$_2$(mbpyf)] complex in a dichloromethane solution (39 μM) at 298 K labelled with the transition according to their molar absorption coefficient (ε) [30]

In Ir(III) complexes, the HOMO region is primarily metal-based and partially based on the phenyl moieties of the two phenylpyridine ligands. The photoluminescence is triggered by the excitation of an electron from the HOMO to a ligand-based π*antibonding orbital [31]. Upon excitation at λ_{ex} = 374 nm, in an air-equilibrated dichloromethane solution, the [Ir(2,4-F_2ppy)$_2$(mbpyf)] complex emits blue-green light and has a vibronic structure that reaches its peak at 298 K (Figure 5). The most visible peak is at 487 nm, while the peak at 462 nm appears as a less intense shoulder, similar to earlier Ir(III) complexes [8]. Therefore, this emission is ascribed to a transition that contains admixtures of excited states with ^{3}LC and ^{3}MLCT characters [8]. The complex's HOMO energy decreased due to the effect of the electron-withdrawing group, fluorine atoms at the 2 and 4 positions of the phenyl ring, which is *meta* with respect to the orthometallated carbon atom [30]. Furthermore, the pyridine-formimidamide auxiliary ligand is expected to increase LUMO energy, hence increasing the band gap. Thus, the emission energy of this Ir(III) complex increased and emitted blue-green light under UV light. At room temperature, the [Ir(2,4-F_2ppy)$_2$(mbpyf)] complex's emission decay time was calculated to be 29.51 ns, which is a shorter decay time compared to other cyclometallated iridium(III) complexes like FIrpic [28]. The influence of the 5d-electron densities of the iridium centre on the HOMO results in a short triplet lifetime [31]. In dichloromethane solution, the phosphorescence quantum yield (ΦP) is 0.37 compared to *fac*-Ir(ppy)$_3$ (ΦP = 0.40), and the radiative and non-radiative rate constants are 12.5 × 10^5 s^{-1} and 21.4 × 10^5 s^{-1}, respectively.

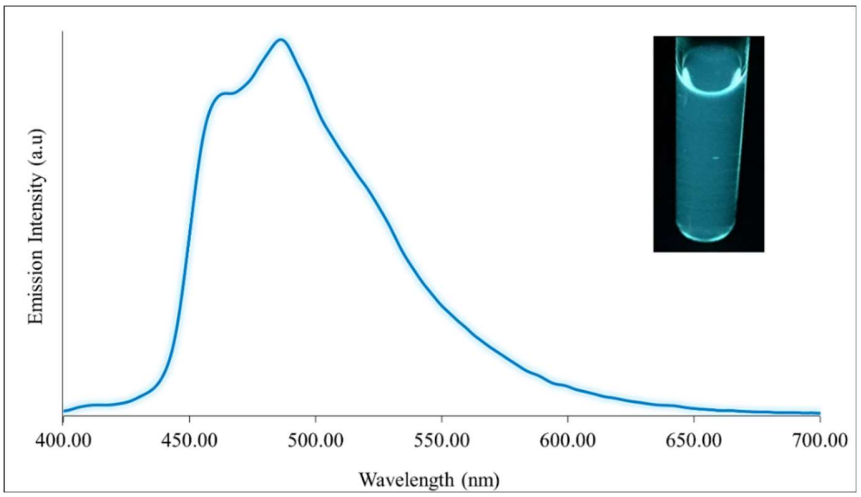

Figure 5. The emission spectrum of [Ir(2,4-F_2ppy)$_2$(mbpyf)] complex in air-equilibrated dichloromethane solution (39 μM) at 298 K. Inset: Luminescence photo of Ir(III) complex in CH_2Cl_2 under UV light

Conclusion

Ir(III) complex bearing pyridine-formimidamide ancillary ligand was successfully synthesised in good yield, characterised by spectroscopic methods, exhibited almost blue emission (λ_{em} = 464 nm) at room temperature, with phosphorescence quantum yield (Φ_p) of 0.37. The crystal structure of the Ir(III) complex was identified, and in the solid state, the Ir(III) complex approved a distorted octahedral coordination environment. This study demonstrated that substituting a pyridine-formimidamide-based ligand as an ancillary ligand could alter the electronic properties of the Ir(III) complex, paving the way for a new method for creating an innovative blue emitter of the phosphorescent complex. Therefore, time-dependent density-functional theory calculations will be conducted to investigate the relationship between triplet states and emission spectra of the synthesised Ir(III) complex.

Abstract

Microalgae are regarded as suitable feedstock for biofuel due to the~~ir~~ high growth rate and substantial lipid content Furthermore, the physiological functions of microalgal lipids contribute to their effectiveness as bioactive compounds with economic value particularly in pharmaceutical and health supplement industries. Extracting the stored lipid from microalgae is a major challenge for industrial applications as their tough cell wall is difficult to break down. Therefore, extraction solvents and cell disruption techniques are key procedures for high lipid extraction and recovery. Traditional methods used for cell disruption and extraction are effective but time consuming and could be detrimental to the environment. Hence, different innovative cell disruption techniques such as microwave-assisted extraction are developed to overcome these issues. This paper is a review of traditional and microwave-assisted extraction methods that are used for lipid extraction from microalgae biomass. The advantages, challenges and future trends of microwave-assisted extraction are also discussed.

Keywords: lipid extraction, microwave-assisted extraction, microalgae, traditional lipid extraction

Abstrak

Lipid yang dihasilkan oleh mikroalga dianggap sebagai bahan mentah yang sesuai untuk biofuel kerana kadar pertumbuhan dan kandungan lipid yang tinggi. Selain itu, fungsi fisiologi lipid mikroalga juga menjadikannya sebagai sebatian bioaktif yang tinggi dalam industri farmaseutikal dan suplemen kesihatan. Mengekstrakkan lipid daripada mikroalga merupakan cabaran utama untuk aplikasi perindustrian kerana dinding selnya yang kukuh dan sukar dipecahkan. Oleh hal demikian, pelarut pengekstrakan dan teknik gangguan sel adalah prosedur penting untuk pengekstrakan lipid tinggi. Kaedah tradisional yang digunakan untuk gangguan sel dan pengekstrakan adalah berkesan tetapi tidak mesra alam dan mengambil masa. Oleh hal demikian, pelbagai teknik gangguan sel inovatif seperti pengekstrakan bantuan gelombang mikro telah dibangunkan. Kertas kerja ini ialah sebuah ulasan terhadap kaedah tradisional dan pengekstrakan bantuan gelombang mikro yang telah digunakan untuk pengekstrakan lipid daripada biojisim mikroalga. Kelebihan, cabaran dan trend masa depan pengekstrakan bantuan gelombang mikro juga dibincangkan.

Kata kunci: pengekstrakan lipid, pengekstrakan bantuan gelombang mikro, mikroalga, kaedah pengekstrakan lipid tradisional

Introduction

Escalated population and economic development have led to the increase in global energy demands annually. Meanwhile, reducing consumption of fossil fuels should be mandatory considering the negative environmental impact, depleting resources and steep increase in

petroleum prices. Renewable energy is an alternative choice to fulfil energy demands with minimal environmental impact. Among the different types of existing renewable energy, liquid biofuel such as biodiesel has gained considerable attention as a future energy supply due to fact that it is biodegradable, renewable, carbon-neutral and is less flammable [1]. Biodiesel can be extracted from oil-producing, terrestrial plants, however, public conflicts relating to food security, freshwater demand and deforestation issues have been raised [2]. Hence, microalgae are currently regarded as an attractive option for biodiesel production. Compared to oil-producing terrestrial plants, microalgae have better carbon dioxide sequestration and faster growth rate [3]. Moreover, microalgae can grow in non-arable land and utilize wastewater as nutrient sources [4]. Microalgae with 30% lipid in dry biomass is estimated to produce up to 58700 litres of lipids per hectare in one year, which is considerably better than oil-producing terrestrial plants [5]. Besides that, the biodiesel that is trans-esterified from microalgal lipids has been demonstrated to meet European and United State biodiesel specifications (EN 14214 and ASTM D6751). The studies showed that microalgal biodiesel with proper blends can be used in diesel engines with low pollutant emission [6-7]. Apart from the application in biodiesel production, the physiological functions of microalgal lipid such as eicosapentaenoic acid (EPA), docosapentaenoic acid (DPA) and docosahexaenoic acid (DHA) make them high bioactive compounds with huge potential in pharmaceutical and health supplement industries [8-9].

Lipid production from microalgae involves several key processes which are cultivation, harvesting and lipid extraction. Transesterification may be included as part of the process for biodiesel production. Among these processes, lipid extraction has been found to be challenging particularly as it can affect the overall quality of the biodiesel [10-11]. During the conventional process of lipid extraction, organic solvents such as chloroform and hexane are employed, but these solvent may not be suitable enough for the complete extraction of lipids due to the hindrance of the rough cell wall contained in microalgae [12]. Some of the lipids might embedded in or cannot pass through the cell wall, and therefore cannot be extracted by the solvent [13]. Hence, it is crucial to ensure that the microalgal cell structure has been completely damaged to improve the extraction efficiency. However, selecting an ideal cell disruption technique is quite a challenging task. In lieu of considering the efficiency of the extraction process, finding a greener and more economical lipid extraction method is necessary to ensure that it will be environmentally friendly, energy efficient and suitable for upscale lipid production. Various methods are applied for extracting lipids from microalgae [14-15], out of which microwave-assisted extraction (MAE) is one of the more attractive green methods because it offers several benefits including efficient cell disruption, fast extraction and requires less consumption of solvents [16].

In this review, some basic information on microwaves and traditional methods of lipid extraction from microalgae biomass are discussed and compared. In additional, an overview of the factors, challenges and future trends of MAE are presented.

Traditional lipid extraction

Soxhlet extraction is a traditional technique used for extracting lipids from microalgae [17-18]. In the conventional Soxhlet extraction (Figure 1), the sample is placed in a porous thimble and once the distillation flask is heated, the extraction solvent evaporates and flows into the condenser where it is cooled down and condenses into liquid. This liquid then drips back into the thimble and extracts the lipids from the sample. When the thimble is almost full, a siphon aspirates the solvent from the chamber and returns it into the distillation flask. This process is repeated for several cycles until the extraction of lipids is completed. After extraction, no filtration or centrifugation is required to separate the samples and extraction solvent. Furthermore, the process is automated and no manual operation is required to rinse the sample with solvent [19]. However, several studies revealed that the lipid yield using Soxhlet extraction was very low compared to both the Folch Method and Bligh & Dyer method [20-22]. This is probably because hexane, which was commonly used in Soxhlet extraction, is nonpolar therefore is unable to effectively extract neutral lipids from microalgae [21-22]. Therefore, it was suggested that hexane be replaced by a mixture of nonpolar and polar solvents such as hexane: ethanol to extract the microalgal lipids. The studies showed that the lipid and fatty acid yield improved significantly using this combination of solvents compared to just using hexane [23-24]. Still, the time required to complete Soxhlet extraction usually lasts for several to twenty-four hours, which is extremely time-consuming compared to other lipid extraction methods, resulting in more a laborious and ineffective method for extracting high numbers of samples [23]. In the analysis of fatty acid profiles by previous research, the extraction yield of unsaturated lipids was very low compared to other extraction

methods [21, 25]. This was probably caused by the instability of unsaturated lipids due to the long-time exposure at elevated temperatures which caused the degradation of these lipids during reflux [26].

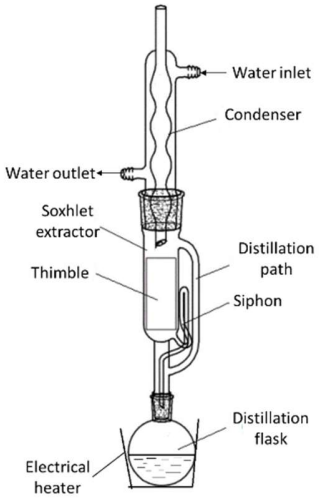

Figure 1. Soxhlet extraction

Folch Method [27] and Bligh & Dyer method [28] are common lipid extraction procedures that are frequently used for lipid extraction. In the Folch method, a mixture of organic solvents, usually chloroform and methanol at a ratio of 2:1 (v/v), is added to the microalgae biomass then vortexed for 30 seconds to several minutes. Water is then added to induce phase separation. Centrifugation is subsequently carried out in some studies to generate a clear phase separation [21, 29]. The organic phase on the top is collected and the lipids can be recovered after rotary evaporation or vacuum evaporation. The process in the Bligh and Dyer method are similar to the Folch Method whereby a mixture of chloroform, methanol and water at the ratio of 2:2:1.8 (v/v) is used as the extraction solvent [28]. The process of these two methods is easy to perform and do not require high pressure or high temperature during the extraction.

Although both the Folch and the Bligh & Dyer methods are well established for lipid extraction from solid animal tissue, the lipid extraction from microalgae could be lower [49]. In order to achieve better extraction results, the modifications of the Bligh and Dyer method has been investigated by several studies. One of the proposed modifications is the addition of sodium chloride solution instead of water [29-30] to restrict the binding of acidic lipids to denatured lipids [31]. In another study, the parameters in the Bligh and Dyer method were modified using response surface methodology [32]. The optimal extraction of 1 g dry biomass was obtained by using a solvent mixture of chloroform: methanol: water with ratio of 5.7:3:1 (v/v) under 25°C and 2-hours extraction [32].

Another reason for low extraction yield of microalgae lipids using Folch and Bligh & Dyer method is the difference between microalgal cell structure and animal tissue. Microalgae are usually covered with cell walls that isolate the intracellular compounds from the outer environment. In some cases, these cell walls are recalcitrant, complex and thick thereby hindering solvent penetration, resulting in low recovery of lipids [13, 33]. Cell disruption has been suggested to disintegrate the microalgal cell wall followed by the lipid extraction process. Many studies have shown that the yield of average lipids after cell disruption are much higher compared to lipid extraction without any cell disruption [33-37].

Microwave-assisted extraction

Microwave is an electromagnetic wave that is positioned between the X-ray and infrared rays in the electromagnetic spectrum with frequencies ranging from 300 MHz to 300 GHz. The electric and magnetic fields of the microwave are responsible for the heating effects under through the microwave dielectric heating and magnetic loss heating effects respectively. In the microwave dielectric heating, dipolar polarization and ionic conduction are two main energy transfer mechanisms that render localized and superheating of the reaction material within a very short time [38]. According to Balasubramanian et al. [25], microwaves can reach up to 80-°C or 95-°C within 100 seconds or less whereas conventional heating requires more than 1000 seconds to reach the target temperature. The slow heating rate in conventional heating is due to the heat transfer through thermal conduction and convection in which heat is transferred to the wall of the target object before reaching the internal object [38]. In this process, the energy is utilized inefficiently as it might be lost to the environment. In contrast, the molecules in the reaction material that have dipole moment absorb the microwave energy and convert it to heat through dipolar polarization and ionic conduction. In the case of MAE on microalgae, inner molecules in the microalgae cells are heated up and lead to a tremendous increase in pressure within the cells. The cell wall is then disrupted when the internal pressure exceeds the endurance limit [39]. The comparison between microwave heating and conventional thermal cell disruption is summarized in Table 1.

Table 1. Comparison between microwave heating and other conventional thermal cell disruption on microalgae.

Aspects	Microwave heating	Conventional thermal cell disruption
Heating mechanism	Dipolar polarization & ionic conduction	Conduction/convection
Time	Very fast, usually less than 1 hour	Slow, can up to several hours
Heating direction	Heat transfer from inner molecule or solvent to wall of object	Heat transfers from wall of object to the cells
Selectivity	Only polar solvent can convert microwave energy to heat	Non-selectivity
Cellular image	Microalgal cell wall is severely disrupted	Microalgal cell wall is remained intact

The cellular images under microscopy from several studies have illustrated that the microalgal cell wall was severely disrupted after microwave treatment whereas the cell wall of these microalgae remained intact after conventional heating [40-42]. Thus, target molecules such as lipid can easily spill out from the ruptured cell wall. Besides that, the volumetric heating generated by the microwave, induce the sudden rising of temperature within the cells thereby creating pressure effects on the cell wall. This phenomenon causes the diffusion of intracellular components to the exterior of the cells, eventually leading to the destruction of the cell structure and subsequent shrinking of the cell wall [42].

Different conditions of MAE can generate various lipid extraction yields and fatty acid profiles from microalgae. The parameters and lipid yields from various studies are summarized in Table 2. The effects of parameters such as solvents, extraction time, microwave power and mass of microalgae used in the lipid extraction must be studied carefully in order to achieve high extraction yield. Among these parameters, the solvent plays a determining factor on extraction yield of lipids. In some studies, the solvent in MAE acted as "pretreatment solvent" to break down the cell wall of microalgae by absorbing the microwave irradiation and increasing the temperature in the cells. The lipid was then extracted using other extraction solvents [37, 43-44]. Whereas, in other studies, the solvents not only have the function thereof, but also act as an extraction solvent to extract the lipid [41, 45-46]. To break down the cell wall effectively, polar solvents such as water, ethanol and methanol are usually chosen because of their high dielectric loss constant which is able to absorb the microwaves and convert them into heat [39-40]. On the other hand, the nonpolar solvents such as hexane and chloroform are excellent to dissolve lipids, however, they are microwave-transparent and are thereby unable to transform microwave energy into heat [46]. Lin and Lin [45] showed that the lipid extracted from *Isochrysis galbana* using nonpolar hexane was significantly lower than when polar isopropanol was used. Mansour et al. [41] also showed that the polar solvents such as methanol and ethanol, can extract higher amounts of lipid compared to nonpolar solvents. This is probably due to the strong association of lipids with proteins via hydrogen bonds which are difficult to be disrupted by nonpolar solvents. However, this association can easily be destroyed by polar solvents through the formation of hydrogen bonds [47]. Moreover, the presence of polar lipids such as phospholipid and glycolipids, are more soluble in polar solvents thereby enhance the lipid yield. Nevertheless, high amount of phospholipids might not beneficial for biodiesel production during transesterification because free fatty acids are enclosed by phospholipids which makes it difficult to be trans esterified into fatty acid methyl ester [48]. Moreover, some of the polar lipids and polar compounds that are non-saponifiable, when extracted by polar solvents may destroy the catalyst during transesterification, thereby reducing the conversion of lipids into fatty acid methyl esters [49]. In another study conducted by Dai et al. [46], however, contrasting results were obtained where nonpolar n-heptane produced better lipid extraction yields from dry microalgae powder. This contradictory result could probably be attributed to the different types of lipids present in different microalgae species.

In order to optimize lipid yield, most studies use a mixture of polar and nonpolar solvents. Several studies demonstrated that solvent mixtures can produce higher extraction yields compared to using a single solvent [15, 47, 50]. In this context, polar solvents have the capacity to absorb the microwaves and quickly induce heat production. The breakdown of cell walls and lipid-

protein linkages result in the rapid mass transfer of lipids from the interior to the exterior of the cells. The neutral lipids are then dissolved in the nonpolar solvents [50]. Besides of types of solvents, the ratio of solvents in mixture are also an important factor for extracting lipids that are suitable for biodiesel production. Iqbal et al. [49] showed that lipid extraction yields using methyl soyate with 60% ethanol was 50% higher than when methyl soyate was used with 80% ethanol. Similar results were also obtained by Saifuddin et al. [51] and Dai et al. [46] who showed that a lower proportion of polar solvents could generate higher lipid extraction.

Temperature is another crucial factor that greatly influences the extraction yield of MAE [40]. It can be controlled directly by altering the microwave setting or indirectly by adjusting the microwave power or irradiation time. Moderate power (180 – 800W) or high temperatures with long irradiation time (2- 40min) usually can generate a good lipid yield [52-55]. High temperatures with short irradiation time also can generate a good lipid yield. In the optimization study conducted by Menéndez et al. [53], the lipid and fatty acid yield extracted using MAE at 60 °C for 20 minutes was similar to the result at 90 °C for 10 minutes. Conversely, high temperature or high power with long irradiation time reduces the lipid yield and their fatty acid profiles [56-58]. At high temperatures, the amount of saturated fatty acid extracted increases while the amount of unsaturated fatty acids decreases [40, 58]. This phenomenon can be elucidated by the production of hydroxyl free radicals during MAE which have strong oxidation capacity that can cleave the double bonds of unsaturated fatty acids [44]. The reduction of unsaturated fatty acids, however, is not favorable for pharmaceutical or food production since microalgae polyunsaturated fatty acids such as DHA and EPA are bioresources with high value [8]. However, low amounts of polyunsaturated fatty acids have a positive effect on biodiesel production as high level of polyunsaturated fatty acid causes poor ignition quality and low oxidative stability [59]. Hence, temperature, power and irradiation time should be monitored carefully based on the requirement of product quality and its use.

The amount of biomass used for MAE has a considerable effect on the recovery of lipids. High amounts of biomass with either low microwave power or short irradiation time [21, 55] can result in low extraction yield. Longer irradiation time or high microwave power are required to break down the cell and improve the yield. Whereas, the lipid yield extracted from low amounts of biomass with high microwave power and long irradiation time are also suboptimal [52]. Therefore, it is essential to carefully select the optimal amount of biomass for MAE in order to maximize the lipid yield.

Advantages of MAE

Numerous studies have reported the comparison of MAE with other extraction techniques for lipid. Owing to its unique heating effect, MAE has been found to extract high amounts of lipid very quicky, usually within 40 minutes. Whereas, conventional extraction techniques such as Soxhlet extraction and water bath heating have been shown to require up to ten hours to extract similar amounts of lipids [25, 50-51]. Moreover, MAE of lipids can be operated in lower temperature environments [14]. Short reaction time and low temperature not only can reduce the change of oxidization of unsaturated lipids but also avoid degradation of proteins and bioactive compounds which can be used in bio-refinery process.

In addition, water, which is non-toxic and safe, can serve as an excellent solvent to disrupt and extract lipids using MAE [43-44]. Before extraction, dewatering and drying is usually required prior to extraction to remove water from microalgae biomass. In MAE, several studies reveal that removal of water is not necessary [60-63]. The water content in microalgae biomass or cultivation medium can be used as solvent to absorb microwaves and break down the cells [55]. Pôjo et al. [69] showed that the drying process required 89% of energy input and 70-75% total processing costs. Consequently, utilization of wet microalgae biomass can reduce the cost and energy consumption. In terms of energy consumption in different extraction techniques, MAE was observed to require lower amounts of energy (70 - 270 MJ/kg) whereas sonication, high-pressure homogenization and bead milling require more extensive energy usage (132, 529 and 504 MJ/kg respectively) [58]. In terms of cost analysis, the cost required to extract 1 kg lipid from microalgae using MAE is more than 50% lower than using Soxhlet extraction [21].

Table 2. Lipids extracted from microalgae by MAE

Microalgae Species	Dry/Wet	Solvent	Sample Weight; Solvent Volume	Microwave Setting	Lipid Extraction Yield*	Reference
Chlorella vulgaris	Wet	Chloroform-methanol (add after microwave)	1:2	100°C, 5 min	17.5%	[35]
Scenedesmus obliquus	Wet	Water	1:1	95°C, 30 min	31%	[25]
Nannochloropsis occulata	Wet	Dichloromethane	NA	140°C, 15 min	11.3%	[58]
Chlorogloeopsis fritschii				120°C, 15 min	1.4%	
Pseudochoricystis ellipsoidea				140°C, 15 min	37.5%	
Chlorella pyrenoidosa	Wet	Chloroform: methanol (1:1)	1g; 8 mL	500W, 40 s	19%	[61]
Nannochloropsis sp.	Wet	Methyl soyate: ethanol (3:2)	3.3 g; 20 mL	120 °C, 20 min	56.6%	[49]
		Chloroform: ethanol (1:2)	3.3 g; 20 mL		53.1%	
Dunaliella tertiolecta	Dry	Chloroform: methanol (2:1)	0.2g; 20 mL	490 W; 2.67 min	57.02%	[52]
Nannochloropsis sp.	Wet	Methanol: Hexane (1:2)	-	65 °C, 5 min	38.31%	[39]
Nannochloropsis sp.	Wet	Isopropanol: hexane (2:3)	15 mL; 50 mL	65 °C, 500 W; 5 min	8.19%	[62]
Tetraselmis sp.	Wet	Chloroform: methanol (2:1)	15 mL; 75 mL	65 °C, 500 W; 5 min	8.47%	
Tetraselmis sp.	Wet	NA	NA	80 - 90 °C, 5 min	20.26%	[63]
Microalgae^{+}	Wet	Chloroform: methanol (2:1)	0.5 g: 75 mL	530 W, 75s	11.6%	[60]
Nannochloropsis gaditana	Dry	Methanol	5g; 50 mL	90 °C, 10 min	40%	[53]
Scenedesmus dimorphus	Dry	Chloroform: methanol (2:1) (add after microwave)	NA	557 W, 3 min	17%	[64]
Selenastrum minutum					23%	
Chlorella					17%	

protothecoides						
Isochrysis galbana	Dry	hexane/isopropanol (2:1)	NA	NA	22.13%	[45]
Chlorococcum sp.	Dry	Distilled water	0.2 g; 100 mL	100 °C, 2 min	24.12%	[37]
Botryococcus sp. MCC31				100 °C, 6 min	48.33%	
Chlorella sorokiniana				100 °C, 6 min	24.43%	
Chlorella vulgaris	Dry	Chloroform: methanol (2:1)	1:10	100 °C, 15 min	22.68%	[65]
Nannochloropsis oculata	Wet	Ethanol (add after microwave)	1:5	443 W, 5 min	0.149 g/g	[56]
Nannochloropsis sp.	Wet	Biodiesel: ethanol (2:3)	8 g; 50mL	180 W, 15 min	0.654 g/g	[51]
Chlorella sorokiniana *Nannochloropsis salina* *Galdieria sulphuraria*	Dry	[BMIM][HSO_4] (Add After microwave)	1 g; 5g	800W, 120 °C, 60 min	0.23 g/g 0.10 g/g 0.19 g/g	[66]
Spirulina platensis	Dry	Water	1g; 10 mL	620 W, 20s	0.385 g/g	[43]
Chaetoceros calcitrans	Dry	Water	0.3 g; 20 mL	1400W, 40s	24.2%	[44]
Scenedesmus obliquus	Dry	chloroform/methanol (2:1)	NA	400W, 130°C, 30 min,	0.234 g/g	[42]
Scenesdemus quadricauda	Wet	Methanol: sulphuric acid (50:1)	500 mL; 500 Ml	473W, 8 min	41.94%	[54]
Nannochloropsis gaditana	Dry	Distilled water	NA	800W, 80 °C, 60 min	11.22%	[67]
Chlorella vulgaris	Dry	Chloroform: methanol (1:2) (Add after microwave)	NA	700W, 3 min	0.183 g/g	[68]
Chlorella pyrenoidosa	Wet	NA	NA	700W, 5 min	16.73%	[55]

* in percent dry weight

+ The name of microalgae species is not stated in original article.

Several studies also revealed the potential of microwave for direct transesterification of lipids into fatty acids, where lipid extraction and transesterification are carried out in the same process. Higher amount of fatty acid methyl ester could be attained in less time compared to transesterification after microwave-assisted extraction of lipids [61, 70-72]. Moreover, less impurities such as chlorophyll are detected in fatty acid methyl ester using microwave-assisted direct transesterification. Such processes minimize the requirement to remove impurities while simultaneously enhances the production of other high-valuable bioactive compounds [70].

Challenges and future trends

Although microwaves have been successful utilized to

disrupt the microalgae cells and extract lipids, there are several limitations in using MAE. In many studies, organic solvents especially chloroform and methanol are usually used to extract lipids during or after microwave treatment due to their excellent ability to absorb microwaves and their high solubility for different types of lipids. However, chloroform is toxic and therefore poses a health risk to the operator and may, in addition, cause environmental pollution [71]. There is a study which used ionic liquids to extract the lipids and the results showed that it could extract higher lipid yields compared to chloroform and methanol [72]. In addition to considering the extraction efficiency, safety, and being environmentally friendly, the cost of the solvent used in the MAE should not be too expensive to the point that it would hinder the development towards up-scale production. Some of the green solvents also known as deep eutectic solvents have been explored using MAE technology to recover natural products from plant material [73-75] but the application for lipid extraction from microalgae is less extensively studied.

Another challenge of MAE is identifying critical parameters from a pool of different factors for achieving high lipid extraction efficiency. There are multiple parameters in MAE that could simultaneously influence the extraction efficiency, hence, it would be better to study and optimize these parameters at the same time. In this extent, a multi-factorial approach would be superior than a one-factor-at-a-time approach because the levels of all the factors of interest can be changed simultaneously [76]. By utilizing advanced software, researchers can systematically estimate the interactions between multiple factors and decide the number of experiments required for optimizing these factors simultaneously.

In most MAE studies, once the microalgal cells have been disrupted and the lipids extracted by adding solvents, an additional separation process is needed to remove microalgae residues. Centrifugation is usually carried to achieve this. However, centrifugation consumes high energy thereby increasing production costs [77]. Herein an innovative idea is required to separate lipids from microalgae residues effectively but with low energy consumption.

Conclusion

As microalgae can accumulate high lipid content within a short period of time, it has been explored as suitable feedstock for biofuel, pharmaceutical and health supplement industries. Traditional lipid extraction such as Soxhlet extraction, Folch extraction and Bligh & Dyer extraction have been used to extract lipid from microalgae. However, the lipid extraction yield using these methods are less efficient due to the presence of microalgal cell wall. Therefore, MAE has been proposed to break down the cell wall and enhance the extraction efficiency of lipids from microalgae. It is evident that MAE has resulted in the increase in extraction efficiency and rate. These superior results can be attributed to the distinct heating mechanism of the microwave which is different from conventional heating. To optimize the extraction yield, the selected solvent should utilize the microwave to break down the cell wall prior to extracting the lipids. Most studies select a mixture of polar and nonpolar solvents as they are able to generate higher extraction yield. Other parameters including temperature, microwave power, irradiation time and amount of biomass should also be studied and optimized to achieve a higher extraction yield of lipids. Apart from high extraction efficiency and short extraction time, wet biomass can be directly used for extraction in MAE. Lipid extraction and transesterification also can be carried out in single step using microwave treatment thereby reducing the process time and necessity to remove impurities. Thus, MAE has the potential to extract microalgal lipids at the industrial level in the future. Nevertheless, it is undeniable that most of the results collected so far are from studies that still use a mixture of toxic chloroform and methanol, and centrifugation is needed to remove microalgae residues. Certainly, comprehensive research is required to explore the possibility of a greener solvent and to reduce the energy consumption in separation after extraction.

Abstract

Heterogeneous photocatalysis is a viable treatment approach for removing organic dye compounds from textile wastewater, and ZnO-based photocatalysts is an appealing system to investigate. In this work, Mg-doped ZnO had been synthesized using modified sol-gel technique to evaluate the effect of different Mg molar concentrations towards the photocatalytic degradation performance of methylene blue (MB) dye. It had been characterized by X-ray diffraction (XRD), scanning electron microscope (SEM) and energy dispersive X-ray (EDS) analysis. According to XRD analysis, all samples showed a hexagonal wurtzite structure with average crystallite approximate sizes ranging between 74.82–81.64 nm. The SEM-EDS results demonstrated that the particle-like Mg-doped ZnO samples consist of elements Zn, O and Mg. The photocatalytic activity of the pure ZnO and Mg-doped ZnO was investigated through photodegradation of MB under ultraviolet radiation. The results showed that 1 mol% Mg-doped ZnO exhibited enhanced photocatalytic activity with a percentage of degradation of 89.54% and photodegradation rate constant, k of 0.0432 min^{-1}. Extended visible absorption, inhibition of photoexcited electron and hole recombination, and higher absorptivity of MB dye on the surface of Mg-doped ZnO photocatalyst might have contributed to the increased photocatalytic activity.

Keywords: magnesium, methylene blue, photocatalyst, photocatalytic, ZnO

Abstrak

Fotokatalisis heterogen adalah pendekatan rawatan yang terbaik untuk menghilangkan sebatian pewarna organik dari sisa buangan daripada industri tekstil, dan pemangkin berasaskan ZnO adalah sistem yang menarik untuk dikaji. Dalam penyelidikan ini, ZnO

yang didopkan dengan Mg telah disintesis menggunakan teknik sol-gel yang diubahsuai untuk menilai kesan kepekatan molar Mg yang berbeza terhadap prestasi penguraian pewarna metilena biru (MB) dan dicirikan dengan difraktogram (XRD), mikroskop elektron (SEM) dan sinar-X penyebaran tenaga (EDS). Dapatan dari analisis XRD, semua sampel menunjukkan struktur wurtzit heksagon dengan ukuran kristal kira-kira dalam julat 74.82-81.64 nm. Hasil SEM-EDS menunjukkan bahawa sampel ZnO yang didopkan dengan Mg terdiri daripada unsur Zn, O dan Mg. Aktiviti foto-penguraian ZnO dan Mg-doped ZnO dikaji dengan menjalankan pemerhatian penguraian larutan akues MB di bawah sinaran ultraviolet. Hasil kajian menunjukkan bahawa sampel 1 mol% ZnO yang didopkan dengan Mg menunjukkan peningkatan kecekapan fotomangkin dengan peratusan penguraian 89.54% dan kadar penguraian tetap, k 0.0432 min^{-1}. Penyerapan yang lebih meluas di kawasan cahaya nampak, penghambatan pengumpulan semula elektron dan lubang yang terangsang dengan foto, dan foto penguraian larutan akues metilena biru yang lebih tinggi pada permukaan fotokatalis ZnO yang didopkan dengan Mg mungkin menyumbang kepada peningkatan aktiviti fotokatalitik.

Kata kunci: magnesium, metilena biru, pemangkin, fotokatalitik, ZnO

Introduction

Environmental contamination has recently been recognized as one of the most serious challenges confronting modern society, with contamination of natural water supplies being the most serious, owing primarily to unmeasured population growth and increased industrial activity. The textile sector is one of the industrial processes that produces enormous amounts of wastewater. The dye effluent and colored discharge disposed into the water causes a significant impact on aquatic life and the environment due to their high stability under ambient conditions. As a result, researchers have focused on removing azo dyes from wastewater to comply with severe environmental requirements. Up to now, various treatment methods such as physical methods and chemical methods have been investigated to remove azo dyes [1]. Generally, the wastewater treatment process should be cost-effective and feasible for large-scale applications [2]. Overall, wastewater treatment might save a lot of water, and the treated water could be recycled or reused in industries like textiles and agriculture.

Recently, the utilization of oxide semiconductor nanomaterials as effective photocatalysts in wastewater treatment has become a subject of major concern [3]. Among the oxide semiconductors, zinc oxide (ZnO) is chosen as the semiconducting photocatalyst for pollution treatment in water because of its advantages such as easy to prepare, abundance, low cost, photostability, and large exciton binding energy of 60 MeV [4,5]. It also has a direct band gap energy at 3.37 eV at room temperature, making it a suitable candidate in absorbing UV-light as an excitation source [6]. Several researchers reported that ZnO has good photocatalytic activity and shows the appropriate activity in the range of solar radiation [7–9]. Unfortunately, the industrial application of ZnO in the photocatalytic field has been impeded by two significant limitations which are (i) ZnO has a high recombination ratio of photo-induced electron-hole pairs, which limits its photocatalytic effectiveness; and (ii) ZnO largely absorbs ultraviolet light (380 nm) and can only be activated by visible light, restricting its photocatalytic activity in the visible light region [10,11]. Proposing effective techniques to improve visible light absorption and reduce recombination of photo-generated electron-hole pairs to achieve high-efficiency photocatalysts is therefore critical. One of the most common methods for achieving these goals is via metal doping [12,13]. Recently, efforts have been made to improve the photocatalytic activities of ZnO nanostructures by doping various chemical elements such Al [14,15], Ni [16,17], Fe [18–20] and Ag [21,22]. Other than that, there is also a possibility that Mg-doping can also improve the photocatalytic activity of ZnO nanostructures by creating oxygen or zinc vacancies, due to the similar ionic radii of Zn^{2+} (0.060 nm) and Mg^{2+}(0.057 nm) [23–25].

In this work, Mg-doped ZnO at various concentration (1 – 10 mol%) were prepared through sol-gel method. The structural and morphological properties were characterized by XRD, and SEM equipped with EDS. Furthermore, the photocatalytic activities of pure ZnO and Mg-doped ZnO were also studied by degrading methylene blue (MB) in water.

Materials and Methods

Synthesis of photocatalyst

Commercial zinc oxide powder (denoted as pure ZnO) and magnesium nitrate ($Mg(NO_3)_2$) were purchased from Sigma-Aldrich with 99 % purity while hexamethylenetetramine (HMTA) was purchased from R&M chemicals with 99.5 % purity. For photocatalytic study {[7-(dimethylamino) phenothiazin-3-ylidene]-dimethylazanium;chloride} ($C_{16}H_{18}ClN_{13}S$) commonly known as methylene blue dye was used. The aqueous solutions were prepared with deionized water throughout the experimental process.

Mg-doped ZnO photocatalysts were synthesized using a modified sol-gel method as our previous work [26]. A mixture solution was prepared by dissolving the commercial ZnO powder and HMTA at constant molar concentration of 0.1 M in 100 ml of deionized water. For the synthesis of Mg-doped ZnO samples, magnesium nitrate ($Mg(NO_3)_2$) as a dopant source was added into the mixture solution at different mol % concentration of 1, 3, 5, 7 and 10 with respect to Zn, respectively. The mixed solution was magnetically stirred at 95 °C for 2 h to gain a homogenous mixture under vigorous stirring. The solution was aged for 24 h until a homogenous gel was formed. Next, the resulting gel was then collected and rinsed thoroughly using deionized water, followed by a drying process at 300 °C for 2 h. The pure ZnO and prepared Mg-doped ZnO photocatalysts at different doping concentration were characterized using several techniques. The crystal structures and phases of prepared nanoparticles were examined through X-ray diffraction (XRD) (PANanalytical) X'pert Pro powder diffraction equipment using Cu-Kα radiation (k = 1.54056 Å). The estimated crystallite size of pure ZnO and Mg-doped ZnO at various mol % concentration were obtained and calculated by using Scherer's as in equation (1) below [26]:

$$d = k\lambda\, \beta cos\theta \qquad (1)$$

Where k is the constant dependent on crystallite shape (0.94 nm), λ is the X-ray wavelength (1.54 Å), β is referring to the full width at the half max (FWHM) of the sample and θ is the Bragg's diffraction angle. The morphology of chosen samples was characterized by using field emission scanning electron microscopy (FE-SEM) (JEOL JSM-7600F). Subsequently, the samples were then used for photocatalytic degradation measurement.

Photodegradation evaluation

The photocatalytic activities of the pure ZnO and Mg-doped ZnO photocatalyst were evaluated by determining the degradation of methylene blue (MB) in aqueous solution on each interval at constant room temperature. The amount of catalyst used was 10 mg of pure ZnO and Mg-doped ZnO in a beaker containing 100 ml of MB solution with 5mg/L as the initial concentration. The UV-light with 365 nm wavelength with the definite power of 12 W, 230 Volts and 50 Hz frequency was used as a light source. Before switching on the lamp, the mixture was stirred in the dark for 30 min to reach adsorption-desorption equilibrium between the photocatalyst and MB. 5 ml of aliquots were extracted out at every 10 min interval and was monitored for 1 h. The schematic expression of experimental setup of photocatalytic measurement is shown in Figure 1. The photocatalytic analysis was performed using UV–Vis spectrophotometer under absorbance, (A), mode. The residual concentration of MB was measured at 664 nm using UV-vis spectrophotometer (Shidmadzu UV-1800UV). The percentage of degradation (%) was measured regarding the maximum photodegradation collected at each interval using the equation below:

$$\text{Degradation percentage (\%)} = (C_0 - C)/ C_0 \times 100 \qquad (2)$$

in which C_0 is the initial dye concentration and C being the dye concentration at time t, respectively. Photodegradation rate constant, k, was also calculated for all the samples.

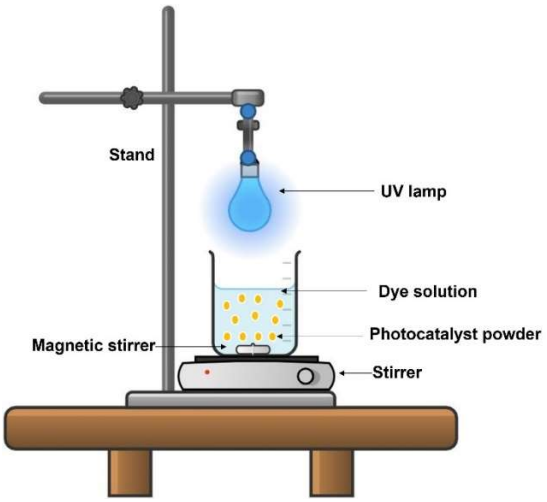

Figure 1. Schematic photodegradation measurement setup for degradation of methylene blue (MB)

Results and Discussion

Morphology of pure ZnO and Mg-doped ZnO

The morphology of pure ZnO and selected Mg-doped ZnO photocatalysts were recorded using FESEM and displayed in Figure 2. The images of pure ZnO (Figure 2(a) and (b)) were recorded at different magnification portrayed irregular rod-cubic like structures with approximately of 100- 500 nm dimensions. Image (c-d) and (e-f) represents 1 mol % Mg-doped ZnO and 10 mol % Mg-doped ZnO morphology and it was clearly seen that, similar rod-cubic like structures was formed for Mg-doped ZnO which were evenly distributed and well dispersed with the size similar to pure ZnO. Moreover, from the highly magnified image, the doping of Mg to the ZnO was not clearly shown. Besides, there are no significant changes on their size and morphology when Mg is doped to ZnO, and this might be due to the little amount of dopant that has been used during the synthesis method.

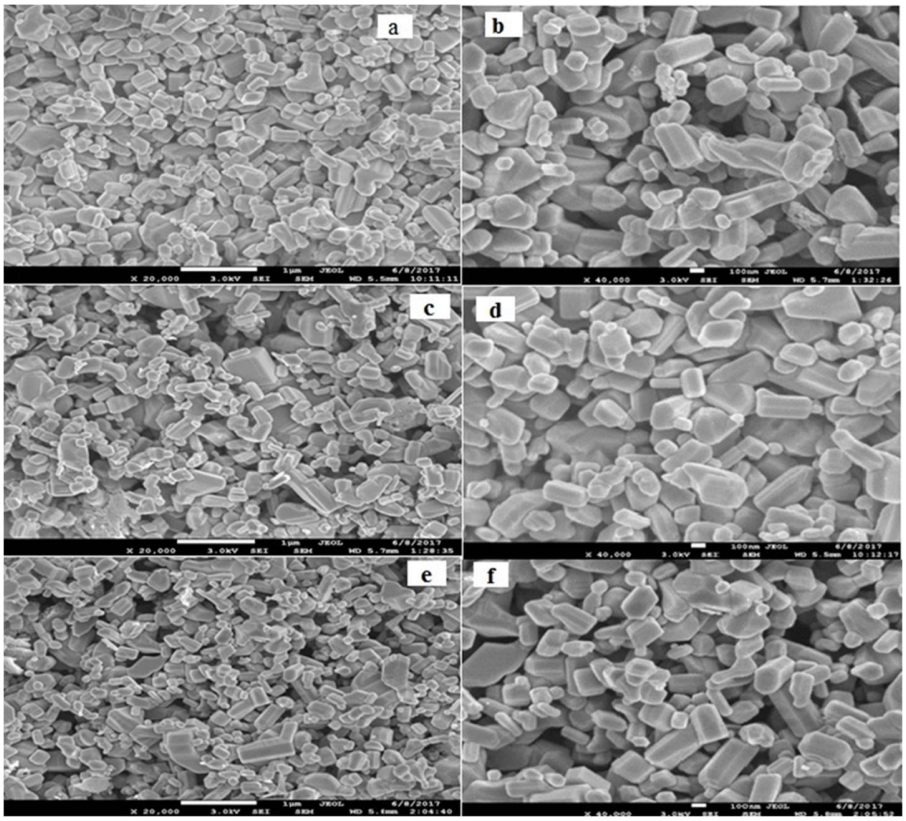

Figure 2. FESEM images of (a-b) pure ZnO, (c-d) 1 mol % Mg-doped ZnO and (d-e) 10 mol % Mg-doped ZnO at magnification 20, 000x and 40,000x

X-ray diffraction analysis

The structural properties of pure ZnO and Mg-doped ZnO photocatalysts were studied using XRD. Figure 3 represents the XRD spectra of pure ZnO and Mg-doped ZnO at different mol % of 1, 3, 5, 7 and 10, respectively. According to the XRD patterns, all the samples were highly crystalline with five major peaks that revealed the presence of hexagonal wurtzite structure of ZnO and the samples were excellent crystalline in nature. The diffraction peaks were identified at 2θ = 31.75°, 34.48°, 36.20°, 47.69°, 56.72°, 62.85°, 66.53°, 67.88° and 69.09° indexed to (100), (002), (101), (102), (110), (103), (200), (112) and (201) being in good agreement with those of JCPDS card no. (No. 05-0664) [24, 27]. Besides, there were no corresponding peak related to Mg or MgO phase due to low amount of dopant that had been used during the synthesis method, which suggested that the presence of Mg was in the form of impurity atom [28, 29]. Similar phenomenon was also reported by Moulahi et al. [30] who prepared the Mg-doped ZnO nanostructures at different concentrations via a polyol process. They observed the pure phase formation of ZnO for all the composition of Mg-doped ZnO nanostructures. Furthermore, they also found a small shift towards a higher angle with Mg concentration, suggesting the decrease of the crystallites size and which similar findings had been observed in this work.

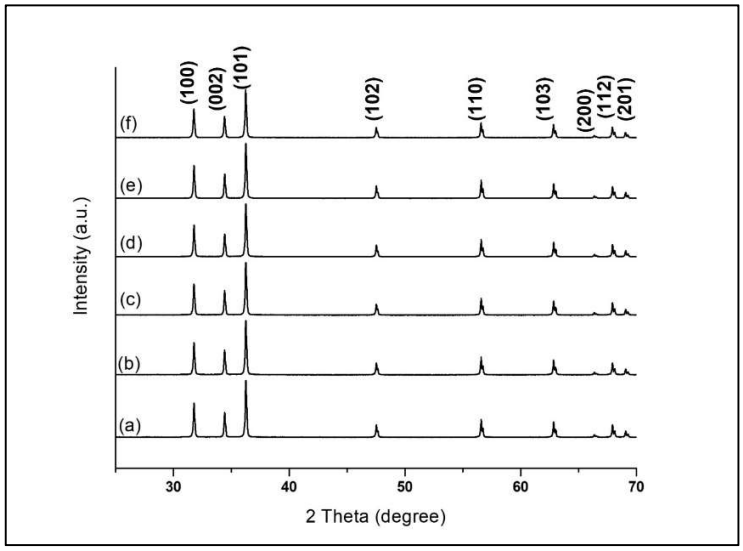

Figure 3. XRD spectra of (a) pure ZnO and Mg-doped ZnO at (b) 1, (c) 3, (d) 5, (e) 7 and (f) 10 mol % in the range of 25 – 70° prepared using modified sol-gel method

The estimated crystallite size was calculated using Scherer equation and was found to be 81.64, 80.50, 80.12, 76.65, 76.17 and 74.82 nm for pure ZnO and Mg-doped ZnO with different concentration (1, 3, 5, 7 and 10 mol %) respectively. Table 1 shows the attributed peak, FWHM and calculated value of estimated crystallite size of pure ZnO and Mg-doped ZnO at different concentration. It can be observed that the FHWM value increased as higher concentration was incorporated into the ZnO from the pure ZnO up to 10 mol % Mg-doped ZnO and the estimated crystallite sizes of the samples were found to decrease as the concentration of Mg dopant was increased. Based on Alam et al. [31] the diffraction peak shifted and wider FWHM with consistent increased in Mg doping is an indication of doping, suggesting a higher defect concentration and decreased quality of crystal with increased in Mg doping concentration. Moreover, because the ionic radii of Zn and Mg ions are similar (0.060 nm and 0.057 nm), Mg ions are expected to be replaced with Zn ions [32].

Table 1. Estimated crystallite size of pure ZnO and Mg-doped ZnO at different concentration obtained from (101) peak

Sample	Highest Peak (2θ degrees)	FWHM, β (degrees)	Estimated Crystallite Size, D (nm)
Pure ZnO	36.25	0.10693	81.64
1 mol% Mg-doped ZnO	36.25	0.10845	80.50
3 mol% Mg-doped ZnO	36.25	0.10896	80.12
5 mol% Mg-doped ZnO	36.25	0.11390	76.65
7 mol% Mg-doped ZnO	36.25	0.11461	76.17
10 mol% Mg-doped ZnO	36.23	0.11668	74.82

Photocatalytic activities analysis

Photocatalytic degradation measurements were carried out for all photocatalyst. The degradation of MB dye was measured by using pure ZnO and Mg-doped ZnO photocatalyst at different concentrations i.e., 1, 3, 5, 7 and 10 mol%, respectively under UV light irradiation for 60 minutes. Figure 4(a) shows the percentage degradation of MB under the UV light tested with the pure ZnO and Mg-doped ZnO at different concentrations. From Figure 4(a), it can be observed that the percentage of degradation of 1 mol% shows the highest percentage degradation with value of 89.54% compared to pure ZnO and other Mg-doped ZnO samples. Once 3 and 5 mol% was incorporated to the Mg-doped ZnO, the percentage of degradation showed a decrease pattern with the value of 82.99% and 84.78% and started to increase when doped with 7 (88.05%) and decreased back to 86.88% when 10 mol% Mg was applied indicating that optimization of concentration of dopant is significant to the performance of photocatalyst.

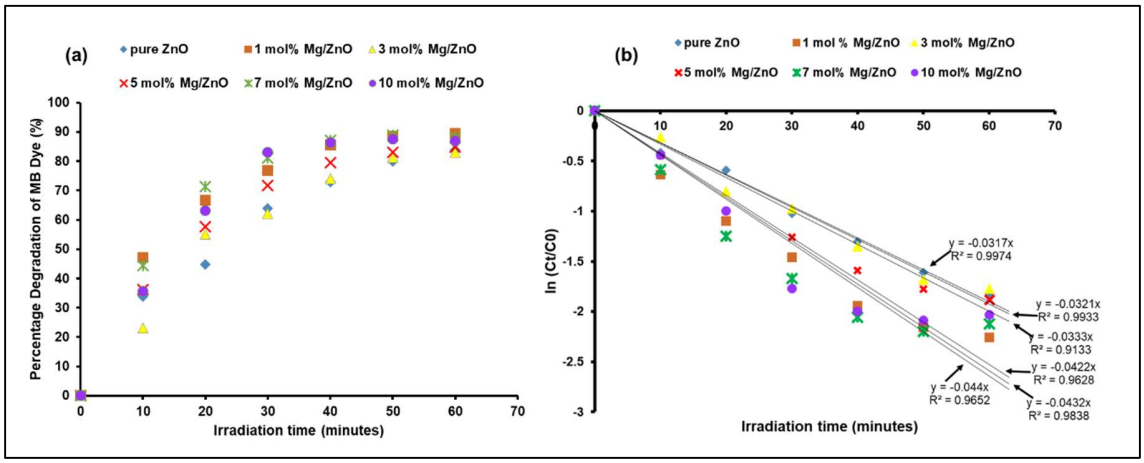

Figure 4. Plot of (a) Percentage of degradation of pure ZnO and Mg-doped ZnO and (b) ln (C/C0) vs. irradiation time for the degradation of MB using pure ZnO and Mg-doped ZnO

Vargas et al. synthesized ZnO doped with MgO in different concentrations (1, 2 and 4 mol%) using Pechini polymer precursor method and reported on the effect of MgO doped on the pollutant removal [33]. They observed that the degradation of MO dye solution was effective using MgO doped ZnO compared to ZnO samples and 2% Mg showed the most efficient in removing MO with a degradation percentage of 73% in 3 h irradiation time. Another study done by Okeke et al. worked on pure and Mg-doped ZnO prepared by one step simple process. They determined that the photodegradation performance of Mg-doped ZnO

against MB dye solution have a greater degradation percentage; more than 50% after 100 min of exposure light [32]. It is worth noting that the doped sample significantly enhanced the photocatalytic activities which is associated to the higher surface defects and smaller particle size, which consequently aid in the separation of photo-generated electron-holes pairs and slowing of their recombination rate.

The photodegradation rate constant, k of pure ZnO and Mg-doped ZnO has been assessed using the kinetic model suggested by Langmuir-Hinshelwood, which is pseudo-first kinetics model of photocatalysis [34] as stated in the Equation 3, as follows:

$$\ln(Ct/Co) = -kt \quad (3)$$

Where Ct/Co is the ratio of dye concentration at adsorption-desorption equilibrium of those at different time intervals (t) and k is the photodegradation rate constant. The results are shown in Figure 4(b) and the photodegradation rate constant value, k was obtained from the linear fitting of the plotted graph. The observed k values are listed in Table 2 together with percentage degradation of MB dye. It can be seen that, 1 mol% Mg-doped ZnO exhibited the highest photodegradation rate constant, k with value of 0.0432 min^{-1} compared to pure ZnO and other samples. Enhancement of the photocatalytic activity of 1 mol % Mg-doped ZnO compared to pure ZnO might be attributed to the increasing of surface area considering that the photocatalytic reaction occurred on the catalyst surface [35]. Moreover, as reported by Wang et al., doping of Mg^{2+} into ZnO increased the width of the band gap and therefore enhanced the photocatalytic performance as it could effectively delay the electron-hole recombination from valence band to conduction band [25]. Moreover, it can be observed that Mg-doped ZnO prepared by higher than 1 mol% Mg shows a decreasing performance which this might be due to an excessive Mg content which resulting in agglomeration of particles hence the photodegradation rate will be saturate. Samanta et al. reported that the photocatalytic performance was reduced when more Mg is loaded and concluded that there exists an optimum amount of Mg for enhancing the catalytic degradation process that influenced by band gap energy and crystallite size of the photocatalyst [36].

Table 2. Photocatalytic performance of pure ZnO and Mg-doped ZnO at different concentration

Sample	Percentage Degradation, (%) after 60 minutes	Photodegradation Rate Constant (k, min^{-1})	R^2 Value
Pure ZnO	83.86	0.0317	0.9974
1 mol% Mg-doped ZnO	89.54	0.0432	0.9838
3 mol% Mg-doped ZnO	82.99	0.0321	0.9933
5 mol% Mg-doped ZnO	84.74	0.0333	0.9133
7 mol% Mg-doped ZnO	88.05	0.4290	0.9601
10 mol% Mg-doped ZnO	86.88	0.0422	0.9628

Conclusion

Mg-doped ZnO at various concentrations were successfully prepared using sol-gel method and characterized by FESEM and XRD analysis. XRD results revealed that Mg is substituted in ZnO without altering its hexagonal wurtzite structure. FESEM analysis revealed that surface features of ZnO shows an irregular rod-cubic like structures with approximately of 100- 500 nm dimensions for all samples. For photodegradation analysis, after comparison with pure ZnO and other doped Mg-doped ZnO samples, 1 mol % Mg-doped ZnO exhibited better photocatalytic activity with degradation percentage of 89.54 % and photodegradation rate constant, k value of 0.0432 min^{-1}, respectively. These results suggest that doping play a crucial role in the efficiency of ZnO photocatalytic activities and the improved performance of Mg-doped ZnO suggests that it could be used as an alternate

photocatalyst for environmental problem.

Abstract

PVA-alginate hydrogel is formed by mixing PVA and alginate with a simple method and then dropping it into a cross-linking agent that leads to rapid gelation. The PVA-alginate hydrogel can be synthesised in water due to the high solubility of starting material. Both compounds have hydroxyl group (-OH) in their structure that helps in terms of solubility and is consequently classified as an inexpensive, safe, and environmentally friendly synthesis method. Although its starting material is soluble in water, the PVA-alginate hydrogel is lessened. This is because the formation of hydrogen bonding of -OH in the PVA-alginate structure reduces its ability. Meanwhile, the presence of carboxyl ion ($-COO^-$) in the PVA-alginate hydrogel structure acts as an active site for the metal ion to bind. Some researchers modified the PVA-alginate hydrogel to improve the binding effect to metal by increasing the active sites of metal. The PVA-alginate hydrogel can act as a metal ion binder to remove heavy metals such example from transition metal elements in wastewater that are considered harmful to the ecosystem. This review provides an overview of PVA-alginate hydrogel design and its modification to improve the binding properties, and cross-linking. Finally, the limitation of PVA-alginate and its modification were revealed with suggestions for future research in the catalytic study.

Keywords: PVA-alginate, metal binder, metal

Abstrak

Hidrogel PVA-alginat dihasilkan melalui percampuran PVA dan alginat dengan mengunakan kaedah yang mudah dan kemudian dititiskan ke dalam agen penghubung silang untuk mempercepatkan gelatin. Hidrogel PVA-alginat boleh disintesis dalam air kerana keterlarutan bahan permulaan yang tinggi. Kedua-dua sebatian mempunyai kumpulan hidroksil (-OH) dalam strukturnya yang membantu dari segi keterlarutan dan seterusnya dikelaskan sebagai kaedah sintesis yang murah, selamat dan mesra alam. Walaupun bahan permulaannya mempunyai sifat larut dalam air, PVA-algina berkurangan disebabkan pembentukan ikatan hidrogen -OH

dalam struktur hydrogel PVA-alginat mengurangkan keupayaannya. Sementara itu, kehadiran ion karboksil (-COO^-) dalam struktur PVA-alginat bertindak sebagai tapak aktif untuk pengikat ion logam. Sesetengah penyelidik mengubah suai hydrogel PVA-alginat untuk meningkatkan kesan pengikatan kepada logam dengan meningkatkan tapak aktif logam. Hidrogel PVA-alginat boleh bertindak sebagai pengikat ion logam untuk membuang logam berat contohnya daripada unsur logam peralihan dalam air sisa yang dianggap berbahaya kepada ekosistem. Kajian ini memberikan gambaran keseluruhan reka bentuk hidrogel PVA-alginat dan pengubahsuaiannya untuk meningkatkan sifat mengikat dan pautan silang. Akhirnya, batasan hidrogel PVA-alginat dan pengubahsuaiannya telah didedahkan dengan cadangan untuk penyelidikan dalam kajian pemangkin pada masa depan.

Kata kunci: PVA-alginat, pengikat logam, logam

Introduction

Heavy metals are emitted from mining, metallurgy, and manufacturing from the consumption of natural resources through the development of industry and agricultural activities. Low or trace-level concentrations of heavy metals in water are harmful to ecosystems. Industrial wastewater such as Ni, Pb, Hg, Cd, Cr, and As can interfere with the functioning of living creatures by binding with their vital cellular components. The clean-up of the contaminated water is very challenging because toxic metals are non-biodegradable [1,2]. Therefore, methods for the removal of heavy metal ions from wastewater are of great significance.

Chemical precipitation, coagulation, solvent extraction, membrane processes, electrochemical, ion exchange, and adsorption are methods for the removal of heavy metals [3]. Adsorption is the process of adsorbent as a binder that content active functional that bounded to the metal ions. Binding is a simple process, with high efficiency, and a low-cost method. Moreover, binding is an environmentally, and efficient binder used to bind heavy metals. Examples of biopolymers binder (alginate, chitosan, and cellulose hydrogels) are widely used for the removing heavy metals [4].

Alginate is widely used in research because it can be obtained in natural resources (the cell wall of brown algae) [5]. It is non-toxic and biodegradable of linear biopolymers. It has a rich carboxyl and hydroxyl functional group [4]. The presence of the carboxyl functional group has excellent form to bind with heavy metals in wastewater. The composition of alginate and cross-linking ions determines the binding strength and properties of alginate beads [5]. However, the mechanical strength, stability, and heat resistance of alginate beads are relatively low; hence their applicability is limited [1].

In research the polymer blend method is used to improve physicochemical properties of alginate. Poly(vinyl alcohol) (PVA) polymer is used to blend with alginate, it is a non-toxic, synthetic, high-strength polymer and environmentally friendly [6,7]. PVA contains a hydroxyl (-OH) group that can form hydrogen bond with -OH of alginate to form PVA-alginate (Figure 1) [8]. The produced PVA-alginate is physically stronger and more durable than alginate alone, in spite of the fact that both polymers are soluble in water [9]. Also, the chemical and physical properties of PVA-alginate can be improved by the addition of cross-link agent in the structure, such as calcium chloride ($CaCl_2$) [10-14] or the combination of $CaCl_2$ and boric acid [15-17].

PVA-alginate needs modification to improve its binding properties [18]. The aim of this review is to study the synthesis and modification of PVA-alginate to improve the binding properties. Modification of PVA-alginate is by using Polyaniline (PANI), Fe_2O_3 nanoparticles, γ-Fe_2O_3 nanoparticles, γ- Fe_2O_3-TiO_2, zeolite, zeolite-polyethylene oxide and carbon corncob- Zoogloea sp. MFQ7. The review also concentrates on suitable cross-links used to synthesis and modified PVA-alginate such as $CaCl_2$, $CaCl_2$-$B(OH)_3$ and glutaraldehyde.

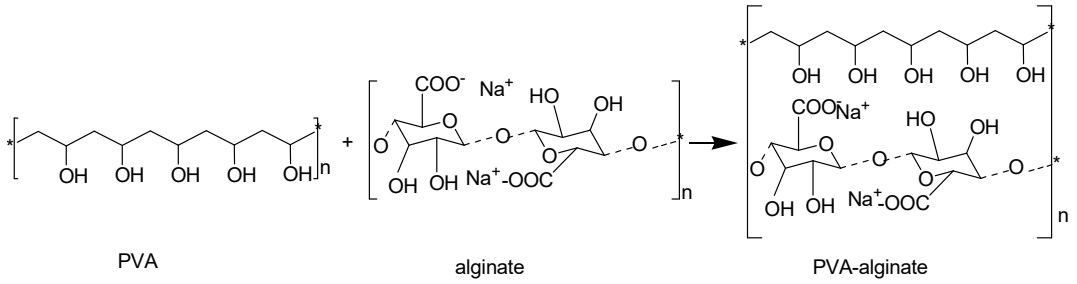

Figure 1. Chemical structure of PVA, alginate and PVA-alginate blended

Synthesis and Modification

In this paper, the PVA-alginate was synthesized by reaction between PVA and alginate. The discussion was continued with modification of PVA-alginate mixed either organic or inorganic or both compounds to take advantage of improving the binding properties. Then, capability of PVA-alginate as a binder with the transition metal was also scrutinized.

PVA has a lot of hydroxyl groups, which form hydrogen bonds with the water molecules and make it very soluble in water. The molecular weight and degree of PVA hydrolysis determine its solubility. The molecular weight is proportional to degree of hydrolysis. Meanwhile, the degree of hydrolysis is inversely correlated with its solubility. Due to the formation of intra- and inter- molecular hydrogen bonds between the hydroxyl groups amongst PVA (Figure 2), higher degree of hydrolysis was present and blunt its solubility in water. In contrast, inter- and intra- molecular hydrogen bonds are reduced due to the lower degrees of hydrolysis of steric hindrance brought on by a high concentration of hydrophobic acetate groups. Therefore, the solubility of PVA molecules in water molecules increased because the interaction of PVA and water increased [19,20].

Alginate is also soluble in water due to the presence of -COO^- and -OH functional group in the structure that can form a hydrogen bond with water. The molecular weight determines the solubility of alginate and its directly proportional to viscosity and degree of hydrolysis. The alginate has high viscosity because of the formation of a hydrogen bond due to the protonation of carboxylate groups in the backbone of alginate (Figure 3) [21]. To break the hydrogen bond between PVA and alginate during preparation by using water as a solvent is through heating [22], stirring [5], microwave [23] and distillation [22] process to form a homogenous PVA-alginate as shown in Table 1. Glycerin [7] and ferrofluids [23] are also used as solvent together with water. Preparation of PVA-alginate involves a single step (Number 10-13) or a few steps (Number 1-9). Form of PVA-alginate produced are beads [3,15], and fiber [22]. The temperature usually used is from 25 °C to 100 °C and duration to prepare PVA-alginate is 1 hours-24 hours.

Lee Te Chuan et al. [15] prepared PVA-alginate as binder of Cr^{6+}. PVA was dissolved in water and then heated with microwave for 1 minute, while alginate was also dissolved in water and stirred until dissolved. The PVA and alginate was blended until homogenous. PVA-alginate is a good binder of Cr^{6+}, where by 100% Cr^{6+} was bound to PVA-alginate. Li et al. [30] modified PVA-alginate in their study by using Polyaniline (PANI). Polyaniline (PANI) synthesized from phenylamine (PAN) was dissolved in acidified water and added with ammonium persulfate (APS). PANI obtained was added to PVA-alginate (Figure 4) because PANI contain many amine and imine functional groups, which is a good binder to metal. Amine and imine in PANI cause PANI to have three oxidation states, which are leucoemeraldine, emeraldine, and pernigraniline. During transition of PANI, electron donations occur from leucoemeraldine or emeraldine state to pernigraniline state. PVA-alginate-PANI was bound to Cr^{6+} at 95.25%.

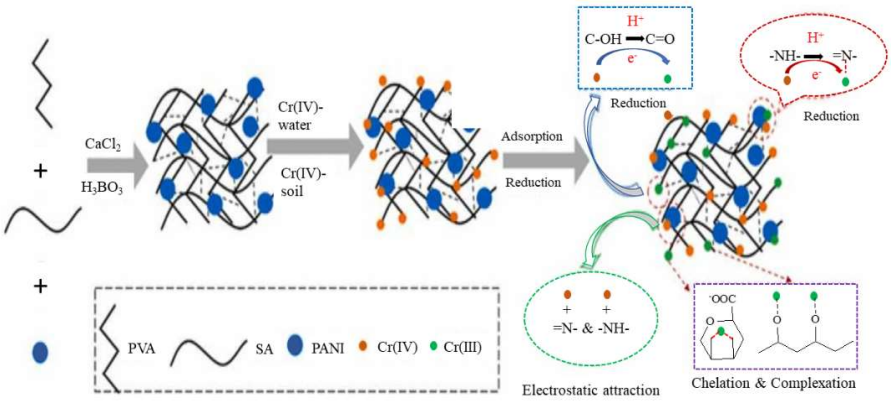

Figure 4. PVA-alginate-PANI as binder of Cr (VI) and Cr (III) [30]

Nie et al. [31] modified PVA-alginate by adding Fe_2O_3 which has surface that functionalize easily to bind with metals. Moreover, Fe_2O_3 have magnetic properties and superparamagnetic which leads to very high utilization in many fields. However, Fe_2O_3 nanoparticles are toxic causing limited usage. To reduce toxicity, they are blended with other polymers, proteins, silica or surfactant [32]. Nie synthesized Fe_2O_3 with green tea waste to reduce toxicity. Green tea was chosen because it is easy to find and many utilizations produce a lot of wastes. In addition, green tea waste contains a lot of hydroxyl groups and benzene rings known as polyphenols. Polyphenols are good as metal binders and have powerful reducibility. Fe_2O_3 was synthesized using

reflux $FeCl_2 \cdot 4H_2O$ and $FeCl_3$ dissolved in water and then added with ammonium hydroxide and heated. The Fe_2O_3 produced was added to green tea waste to obtain Fe_2O_3 nanoparticles. Fe_2O_3 was dissolve in water then added with PVA and alginate produce PVA-alginate- Fe_2O_3 nanoparticles. PVA-alginate-Fe_2O_3 nanoparticles (Figure 5) that were bound with Cr^{6+} and Cu^{2+} were 52.12 % and 59.78%, respectively. Result from three studies showed that the Cr^{6+} was excellently bound to PVA-alginate without modification.

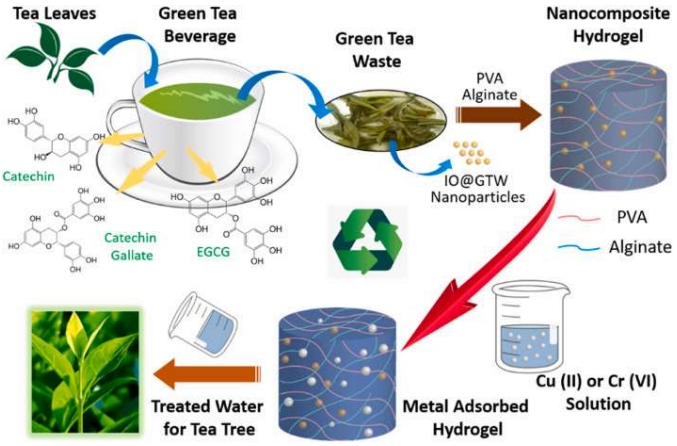

Figure 5. Synthesis of iron oxide nanoparticles by using green tea waste. Iron oxide nanoparticles were blended into PVA-alginate hydrogel to form PVA-alginate-Fe_2O_3 nanoparticles as a binder of Cu^{2+} and Cr^{6+} in an aqueous solution. The treated water was re-used for tea cultivation [31]

Zohreh Majidnia and Fulazzaky [3] also synthesized γ-Fe_2O_3 nanoparticles, magnetite (Fe_3O_4) precipitate which were acidified by using nitric acid form iron (III) nitrate nanoparticles. Then they were oxidized at 90 ºC. Then, γ-Fe_2O_3 nanoparticles were coated with trisodium citrate to remove all charges. The γ-Fe_2O_3 nanoparticles were blended with PVA-alginate to bind with Cs (I). PVA-alginate- γ-Fe_2O_3 nanoparticles that was successfully bound to Cs (I) was 91.8 %. In the study PVA-alginate also blended with titania (TiO_2) nanoparticles.

TiO_2 nanoparticles is non-toxic, have good stability, chemical and biological inert, with a larger surface area with relates to high binding properties (metal and non-metal) [33]. Zohreh Majidnia and Fulazzaky [3] prepared TiO_2 from titanium isopropoxide combined with acetyl acetone with presence of ethanol as solvent. The prepared solution was added with urea solution to deionized water via continuous stirring. The solution obtained was heated by using a furnace until yellowish white TiO_2 nanoparticles were obtained. The study found that PVA-alginate blended with TiO_2 able to bind to 90.1% Cs (I). They also prepared PVA-alginate blend with γ-Fe_2O_3 nanoparticles and TiO_2 nanoparticles. PVA-alginate- γ- Fe_2O_3-TiO_2 was successfully bound with 93.1% Cs (1). Therefore, PVA-alginate modified with Fe_2O_3 was suitable to bind more with Cs(I) that larger sized compared to Cr^{6+} small sized metal.

Ebrahimi et al. [22] synthesized PVA-alginate by reflux through distillation and stirring while alginate was heated and stirred. Then, PVA and alginate was blended until homogenous. PVA-alginate was used to bind with Cd^{2+} and it was found that 47.5% of Cd^{2+} could bind with PVA-alginate. Isawi [9] used the heating and stirring method to blend PVA and alginate. Then, zeolite was added to PVA-alginate due to its high binding properties because it is commonly used in the industry as a binder in ion-exchange separation and gas purification, molecular sieve, and soil modifier. Zeolites have a larger surface area with a small pore size. Moreover, it owes a

cage-like configuration which cause only medium size of metal ions to bind with zeolite. The larger surface area of zeolite is due to its structural form which is a three-dimensional tetrahedral framework in which each oxygen atom is shared by two tetrahedra, known as hydrated micro-porous alumino-silicate constituents [9].

Zeolite has a neutral charge caused by only Si in the structure. Substitution of Al in zeolite to replace Si causes its charge to be negative and need other metal ions (positive charge) to balance the charge, showing that it is very suitable to be a binder. Isawi [9] found PVA-alginate-zeolite (Figure 6) could bind to Pb^{2+}, Cd^{2+}, Sr^{2+}, Cu^{2+}, Zn^{2+}, Ni^{2+}, Mn^{2+}, and Li^{2+} at 99.5%, 99.2%, 98.8%, 97.2%, 95.6%, 93.1%, 92.4%, and 74.5% respectively, under pH 6. Meanwhile binding with Fe^{3+} and Al^{3+} that occurred at pH 5 were 96.5 % and 94.9 %, respectively although the binding process just allocated PVA-alginate-zeolite in solution that contained metal with shaking. Tabatabaeefar et al. [34] also used PVA-alginate-zeolite to bind with Ni^{2+} and Co^{2+} under pH 5.5 and reported that the percentages of Ni^{2+} and Co^{2+} bound were 83.7 and 84 %, respectively. A study done by Ebrahimi, et al. [22], Isawi [9] and Tabatabaeefar et al.[34] showed that larger size metals (Pb^{2+}, Cd^{2+}, Sr^{2+}, Cu^{2+}, Zn^{2+}, Ni^{2+}, Mn^{2+}, Fe^{3+} and Al^{3+}) bound excellently with PVA-alginate-zeolite. Meanwhile small size metals (Ni^{2+} and Co^{2+}) were less efficiently bound to PVA-alginate zeolite.

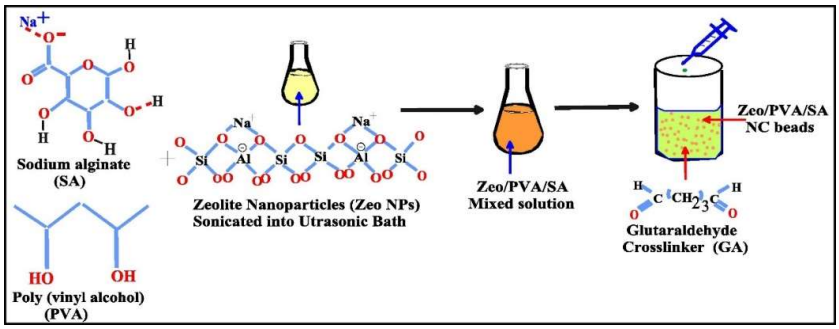

Figure 6. PVA-alginate-zeolite [9]

Although PVA-alginate-zeolite is suitable for metal binding, the large pore size on the surface of PVA-alginate-zeolite causes a barrier to the larger sized metals. Adding polyethylene oxide makes PVA-alginate-zeolite bind to the bigger sized of metals, especially metals located at the bottom of the periodic table that have a larger size. Polyethylene oxide can form cavities when added to PVA-alginate-zeolite, and thus form PVA-alginate-zeolite-polyethylene oxide (Figure 7). Fazel Zahakifar et al. [35] produced PVA-alginate-zeolite-polyethylene oxide to bind with U^{6+}. PVA and polyethylene oxide (PEO) were dissolved in a water in separate container and then heated until homogenous. Then, alginate was dissolved in water and heated until homogenous and added with zeolite. The alginate-zeolite was added to PVA-PEO. PVA-alginate-zeolite-polyethylene oxide produced was successfully bound either 81.4% of U^{6+}. Zahakifar et al. [36] also used PVA-alginate-zeolite-polyethylene oxide in their study and found 65.2 % of thorium (Th) (IV) was successfully bound with PVA-alginate-zeolite-polyethylene oxide.

Bacteria are also good in combining with PVA-alginate to bind with metal. Wang et al. [28] utilized corncob from agricultural waste. Corncob was heated by using a furnace to form carbon corncob. Carbon corncob is used for Zoogloea sp. MFQ7 bacterium to do microbial activity in anaerobic form and convert Mn^{3+} to Mn^{2+} (Figure 8). PVA and alginate were dissolved in water and heated. The cooling PVA-alginate was added with carbon corncob- Zoogloea sp. MFQ7. PVA-alginate-carbon corncob- Zoogloea sp. MFQ7 synthesized was used to bind Mn^{2+}, whereby 72.74% Mn^{2+} was successful bound.

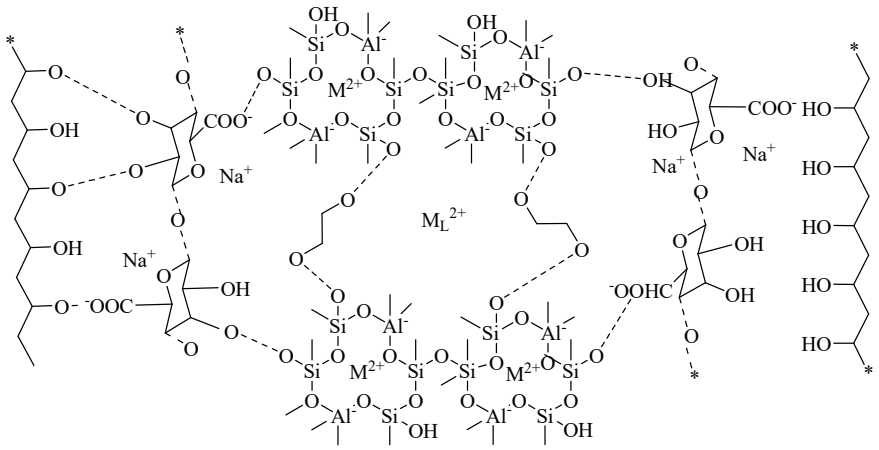

Figure 7. PVA-alginate-zeolite-polyethylene oxide (Note: M^{2+}= metal ion and M_L^{2+}= large metal ion)

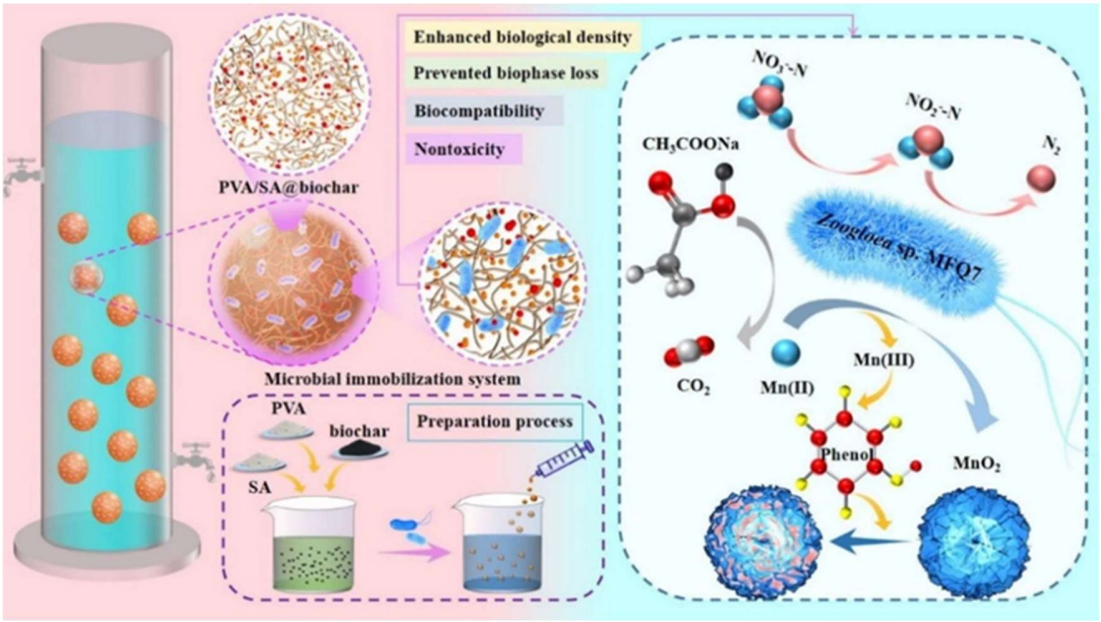

Figure 8. PVA-alginate-carbon corncob- Zoogloea sp. MFQ7 [28]

Table 2 lists modifiers to modify PVA-alginate as a binder of metals. Each modifier has criteria and is very selective to help PVA-alginate as a metal binder. PVA-alginate alone is a suitable binder for metal atoms. The surface area of PVA-alginate increases upon modification with the modifier to increase the selectivity and percentage of binding metals. The combination of PVA-alginate with modifier also increases the character of PVA-alginate as a binder towards bigger metal atoms. Usually, the best pH value condition used by researchers during the binding process is between pH 4-8 which, influence the percentage of binding PVA-alginate and modifier to metals ions.

Table 2. List of modifiers to modified PVA-alginate as a binder of metals

Modification	Metal Bind	Percentages of Binding (%)	Cross-Link	References

Cross-link

The combination structure of PVA and alginate are physically robust, in spite of the fact that both polymers are soluble in water [9]. To reduce the solubility and increases the physical and chemical properties of PVA-alginate by the addition of a cross-link agent in the structure. Chen et al. [37] reported that, chemical cross-linking was widely used to alter the physical properties of polymeric materials. Linking of polymer chains through chemical linkages gives a more rigid material structure and potentially a better-defined shape. The chemical cross-linking of polymers was not only limited to bulk materials, but also led to the creation of micro- or nano-sized organic particles which occurred as a covalent or ionic cross-link. List of chemical cross-links of PVA-alginate are calcium chloride ($CaCl_2$) [10-14] or the combination of $CaCl_2$ and boric acid [15-17] and glutaraldehyde [9,34]. Physical cross-link PVA-alginate is a freeze-thawing process [22,34,35].

Calcium chloride ($CaCl_2$) is the commonly used cross-linker to solidify PVA-alginate. Solidification occurs based on adsorbent via ion exchange, and chelation provides the resulting PVA-alginate gel with a significant structural strength. The ion exchange occurs when calcium ions take the place of sodium in the alginate of PVA-alginate. A polyvalent ion binding reaches the cross-linking with two carboxylic functional groups on adjacent polymer chains. Besides, this reaction can be accompanied by the chelation of calcium ions at the hydroxyl and carboxyl functional groups of sodium alginate chain [38]. Wang [39] found that the best per cent of $CaCl_2$ cross-linker used was 2 % because the function of Ca^{2+} enlarged the material suction space.

The formation eggbox model (each calcium atom is coordinated to the carboxylates and hydroxyl groups of four G monomers from two adjacent chains of alginate) was extensity studied (Figure 9) [40].

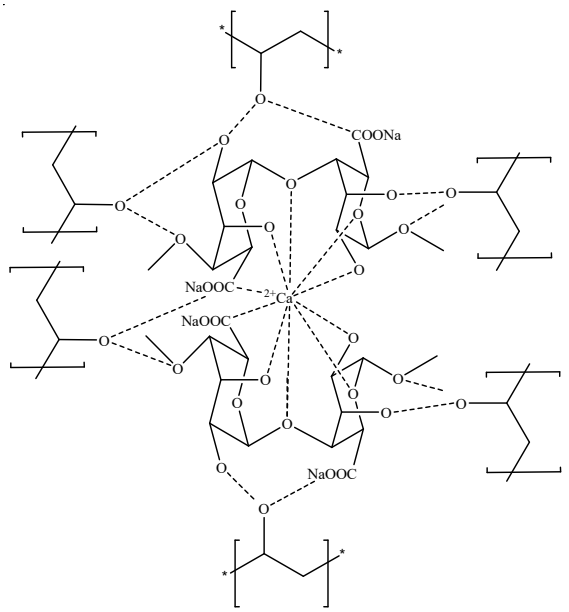

Figure 9. The reaction mechanism of $CaCl_2$ cross-linker with PVA-alginate

Mixed calcium chloride ($CaCl_2$) and boric acid ($B(OH)_3$) which were utilized as cross-linker to obtain spherical beads, prevented agglomeration during the PVA-alginate cross-linking process and improved surface properties (Figure 10). Boric acid was used to assist the cross-link between PVA polymer with tetrahydroxyborate ions ($B(OH)^{4-}$) cross-linked with the hydroxyl group (OH) on adjacent chains. The cross-link between two hydroxyls (PVA) and one borate ion is known as “di-diol” complexation. Boric acid is an electron acceptor (Lewis acid); it has an empty p orbital attracted to lone pair of the hydroxyl group of PVA. At the same time, calcium replaces the position of sodium in alginate, whereby two carboxyl’s in alginate bond to calcium. Since the crosslink process between PVA-alginate by boric is slow, it is not used as a stand-alone cross-linker as a consequence of agglomeration problem that trigged the polymer rigid to break up [41].

Glutaraldehyde is an organic compound with formula $(CH_2)_3(CHO)_2$. It consists of a five-carbon chain doubly terminated with formyl (CHO) groups. It is most widely used as a cross-link because it is inexpensive and easily available [43]. Moreover, it has good mechanical performance and stable chemical properties [44]. Glutaraldehyde has highly reactive bifunctional agent of aldehyde groups located at both ends, while able to bond to hydroxyl, imidazole group, amine, thiols and phenols [45]. The cross-linking occurs between aldehyde groups of glutaraldehyde and hydroxyl groups of alginates [9, 34] and PVA polymers [44] (Figure 11).

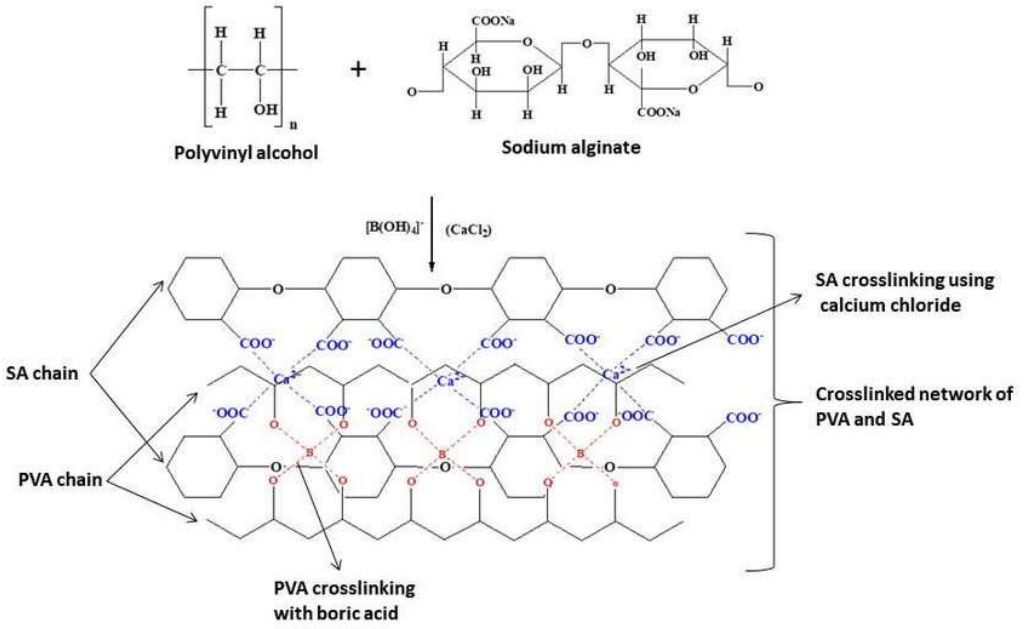

Figure 10. The reaction mechanism of $CaCl_2$ and $B(OH)_3$ cross-linker with PVA-alginate [42]

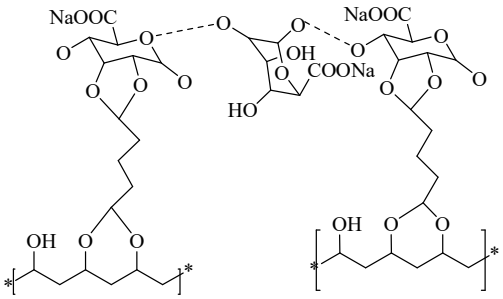

Figure 11. The reaction mechanism of Glutaraldehyde cross-linker with PVA-alginate

Freeze-thawing is a physical cross-link PVA-alginate which is widely used for pharmaceutical and biomedical applications. It is non-toxic, chemical free and biocompatibility [46]. In the freeze-thaw method, the concentration of polymer is increased due to bulk solvents or low molecule solutes freezing (crystallization). The network structure formed because chain space in the polymer was minimized and enabled the chains to align and connect to each other during the freezing process [47]. During thawing process, the polymer assembles and cross-link between the polymer due to defrosting solvent [48, 49] (Figure 12). Gel of PVA-alginate by freeze-thawing has high water uptake and is rubbery [46]. Therefore, chemical cross-link especially $CaCl_2$ as a cross-linker is preferable because it is easy to solidify and the structure strength of PVA-alginate is used as a metal binder.

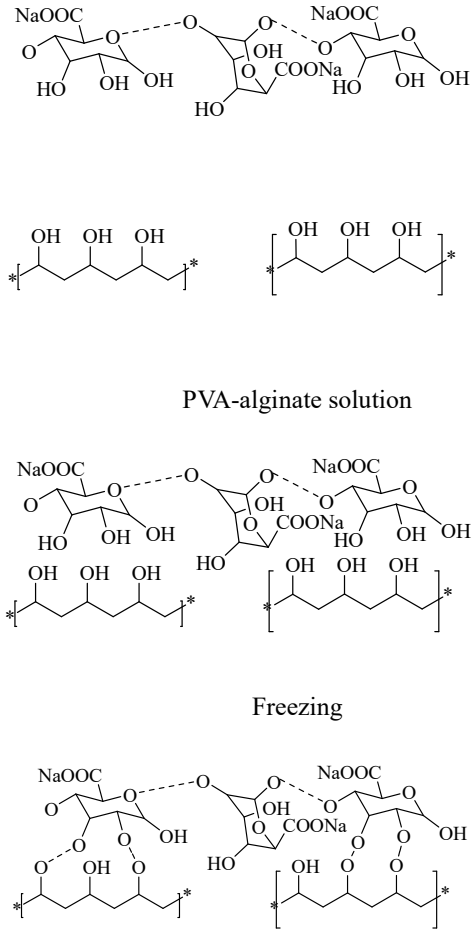

Figure 12. The reaction mechanism of freeze-thawing cross-linker with PVA-alginate

Conclusion

In this study, the synthesis and modification PVA-alginate binder were summarized. These binders have shown excellent binding performance towards metal ions. Highlights in this finding are: (i) PVA-alginate are good binder to small metal with low cost and an environmentally friendly binder, (ii) zeolites are good modifiers of PVA-alginate but only with a large sized of metal ion, (iii) PVA-alginate- zeolite- polyethylene suitable binder of larger sized of metal ion, (iv) $CaCl_2$ cross-linking agent are good to solidify PVA-alginate. Suggestions for future study are that PVA-alginate polymer is a good metal catalyst support for catalytic study of the carbon-carbon coupling reaction because it is a good metal binder and have good structural strength.

Abstract

A rapid and simple extraction method was developed for the analysis of caffeine in tea and coffee using high performance liquid chromatography (HPLC). Independent factors such as extraction method, temperature and residing time were optimized using response surface methodology (RSM) followed by Box-Behnken Design (BBD). All samples were analyzed using HPLC and separated on C_{18} (150 mm × 4.6 mm, 5µm particle) column. The mobile phases were: (A) water and (B) acetonitrile at the flow rate of 1 mL min^{-1} under ultraviolet (UV) detection at 273 nm. Good linearity was obtained in the range of 1–60 mg L^{-1} (regression coefficient (R^2) > 0.995). The limit of quantification (LOQ) and limit of detection (LOD) were 1.0 and 0.4 mg L^{-1}, respectively. Relative standard deviation (RSD) at the range between 3.11 and 11.37 is deemed as highly precise and it is 92% to 98% accurate. Based on the RSM-BDD analysis, extraction of caffeine from tea was directly proportional to temperature, time and method extraction, which exhibited all independent factors of this study were significant. The most optimal condition of caffeine extraction was heat treatment at 100 °C in 16 min and free from any chemical treatment. The highest concentration of caffeine was 366 mg L^{-1} in Mahmood's green tea, while it was 334 mg L^{-1} in Mahmood's coffee. The proposed method exhibited good results and easier quantification of caffeine in different samples using HPLC, and free from possible interferents.

Keywords: caffeine, tea, coffee, Box-Behnken design, high performance liquid chromatography

Abstrak

Kaedah pengekstrakan cepat dan mudah telah dibangunkan untuk penganalisaan kafein dalam sampel teh dan kopi dengan menggunakan kromatografi cecair berprestasi tinggi (HPLC). Faktor bebas yang penting seperti kaedah pengekstrakan, suhu dan masa tinggal telah dioptimumkan menggunakan kaedah gerak balas permukaan (RSM) diikuti oleh reka bentuk Kotak-Behnken (BBD). Semua sampel telah dianalisis menggunakan HPLC dan diasingkan pada turus C_{18} (150 mm × 4.6 mm, 5µm). Fasa gerak alih yamg digunakan ialah (A) air dan (B) asetonitril pada kadar aliran 1 mL min^{-1} di bawah pengesanan ultra ungu (UV) pada 273 nm. Kelinearan yang baik diperoleh dalam julat 1–60 mg L^{-1} (pekali regresi (R^2) > 0.995). Had kuantifikasi (LOQ) dan had pengesanan (LOD) masing-masing ialah pada 1.0 dan 0.4 mg L^{-1}. Kejituan sisihan piawai relatif (RSD) pada julat antara 3.11 dan 11.37 didapati hampir tepat dan mempunyai ketepatan antara 92% hingga 98%. Berdasarkan analisis RSM-BDD, pengekstrakan kafein daripada teh adalah berkadar terus dengan suhu, masa dan kaedah pengekstrakan yang menunjukkan bahawa semua faktor bebas tersebut adalah signifikan. Keadaan pengekstrakan kafein paling optimum ialah pada suhu 100 °C selama 16 minit dan bebas daripada sebarang rawatan kimia. Kepekatan kafein tertinggi sebanyak 366 mg L^{-1} diperoleh dalam teh hijau Mahmood manakala 334 mg L^{-1} dalam kopi Mahmood. Kaedah yang dicadangkan mempamerkan keputusan yang baik dan mudah untuk mengukur kafein dalam sampel yang berbeza menggunakan HPLC.

Kata kunci: kafein, teh, kopi, reka bentuk Kotak-Behnken, kromatografi cecair berprestasi tinggi

Introduction

Caffeine is an alkaloid, which is a naturally occurring compound with a wide range of pharmacological properties [1]. Caffeine is used as stimulant drug to reduce headache and other treatment purposes. It is commonly found in popular beverages worldwide consumed during breakfast, tea and dinner. It was reported that caffeine as an antioxidant plays an important role to reduce risk of coronary heart disease [2,3].

Caffeine belongs to methylxanthine group, which is a derivative of xanthine that occurs naturally in plants with no obvious odor and slightly bitter. The empirical formula of caffeine is $C_8H_{10}N_4O_2$ and its molecular structure is shown in Figure 1. Caffeine is not easily biodegradable nor absorbed into the human system as they can be continuously present in the aquatic environment through human excretion and its bioaccumulation into the wastewater, domestic wastewater and hospital effluents [15,16,17]. Furthermore, it can further affect the marine ecosystem.

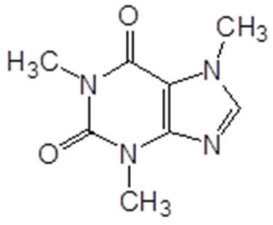

Figure 1. Structural formula of caffeine

In order to collect more information regarding the direct consumption of caffeine in consumer's daily diet, a comprehensive study of analysis of caffeine in tea and coffee samples was performed. The application of response surface methodology is vital in this study to determine the amount of consumed caffeine per cup, as there is no previous data regarding this study in Iraq. Caffeine has been analyzed in different samples such as biological fluids, foods, plants and water samples using different analytical instruments such as high-performance liquid chromatography (HPLC) [4], gas chromatography–mass spectrometry-flame ionization detection (GC–MS-FID) [5], Fourier transform-infrared spectrophotometry (FT-IR) [6], near-infrared spectroscopy (NIR) [7], Ultraviolet–Visible spectroscopy (UV-Vis) [8], FT-Raman spectrometry [9], and capillary electrophoresis (CE) [10]. Among the listed analytical techniques, HPLC offers advantages, such as simplicity and selectivity coupled with ultraviolet-visible (UV–Vis) detector, was the most preferred analysis system for the analysis of caffeine [8,11,12].

The issue of extracting caffeine from tea without using chemical reagents has led to the development of various extraction techniques. Conventional liquid–liquid extraction (LLE) and solid-phase extraction (SPE) have been used for pre-concentration and clean-up before analysis. Liquid-liquid extraction is time-consuming and hazardous to health due to the high volume of toxic solvents used [13]. Solid-phase extraction requires less

solvent, but is still time consuming, and often requires a concentration stage that presents disadvantages such as losses in the evaporation step [14]. To resolve time consumption of the proposed extraction techniques, response surface methodology has been utilized to determine the significant factors of this study.

The aims of this study are: (i) to optimize different extraction method, temperature and residing time using response surface methodology; (ii) to identify and confirm presence of caffeine in tea using LC-TOF/MS as a very accurate instrument based on mass-to-charge ratio; (iii) to determine the concentration of caffeine in real samples using HPLC-UV.

Materials and Methods

Reagents and chemicals

Caffeine (purity 99%) was purchased from Sigma-Aldrich (USA). Acetonitrile (ACN), methanol (MeOH) and ethyl acetate were HPLC-grade and provided by Sigma-Aldrich (USA). Other reagents such as hydrochloric acid and sodium carbonate were purchased from Sigma-Aldrich (USA). Double distilled water was prepared using the distillation apparatus (Manufacturer, Country of Manufacturer) in the laboratory setting.

Sample Collection

Samples are Mahmood green tea, Mahmood red tea, Al Ghazaleen red tea, Brazilian coffee and Mahmood coffee samples were collected from the local market in Babylon City, Iraq as presented in Table 1. All samples were stored at 4 ℃ refrigerator throughout the analysis to avoid further enzymatic or denaturation effect on the samples. Laboratory glassware and glass apparatuses were properly cleaned with tap water and rinsed with double distilled water.

Sample preparation

Each sample was treated with three different extraction methods (extraction method 1, extraction method 2 and extraction method 3), three different temperatures (40, 70 and 100 °C) and three different residing times (4, 10 and 16 min). Each independent factor was optimized using RSM to select the significant output.

Experimental design

Response surface methodology has been used to investigate each variable on the effectiveness of caffeine extraction through: extraction method (A), temperature (B), and residing time (C). For each of the three studied variables, high and low set points were selected to construct an orthogonal design (Table 2). Box-Behnken Design (BBD) was used to optimize the values of these three factors and reach the best response. Design included 30 treatments in three levels for three factors and consisted of six center points. The experimental design matrix and data analysis were carried out using the software package Minitab 19 statistical software. The peak area and/or concentration of caffeine was used as the HPLC response to evaluate the extraction efficiency.

Table 1. Description of tea and coffee samples

Brand Name	Origin	Expiry Date
Mahmood red tea	Produced and packed in Sri Lanka	06/2022
Mahmoud green tea	Produced and packed in Sri Lanka	02/2023
Al Ghazaleen Tea	Produced in Sri Lanka- Ceylon	04/2022
Brazilian coffee	Produced in India	09/2022
Mahmood coffee	Produced in Poland	11/2021

Table 2. The experimental range and levels of the variables in the BBD

Factor	Symbol	Range and Levels		
		Low	Centre	High
Extraction Method	A	1	2	3
Temperature (°C)	B	40	70	100
Residing time (min)	C	4	10	16

The regression equation in uncoded units was presented below:

$$CONC. = -217.7 + 55.8\,\mathbf{A} + 4.199\,\mathbf{B} + 1.89\,\mathbf{C} - 32.27\,\mathbf{A^2} - 0.04961\,\mathbf{B^2} - 1.049\,\mathbf{C^2} + 1.217\,\mathbf{AB} + 4.854\,\mathbf{AC} + 0.2958\,\mathbf{BC}$$

Three different extraction methods used in this research were:

Extraction Method 1

One gram of each tea leaves and coffee beans were soaked in 100 mL of boiled water (100 °C) separately and continuously, for 10 minutes. After cooling each extract, 5 mL aliquot was mixed with 0.1 M hydrochloric acid (2.5 mL) and saturated basic acetate solution (2 mL). The solution was centrifuged at 8000 rpm for 15 minutes. $NaHCO_3$ solution (0.1 g $NaHCO_3$ to 10 mL of water) was added to the supernatant then shaking using stir device. The solution was centrifuged again at 10000 rpm for 15 minutes, after that the extract was diluted with water into a 50 mL volumetric flask. 20 µL of final extract was filtered through a 0.45 mm membrane (Millipore) then injected into the HPLC column.

Extraction Method 2

One gram of tea and/or coffee sample has been soaked in 100 mL of hot water (100 °C) and stirring for 10 minutes. The aqueous phase was extracted with ethyl acetate using separation funnel, which is categorized as liquid-liquid extraction. Each extract was injected into the HPLC instrument.

Extraction Method 3

One gram of tea and/or coffee sample was soaked in 100 mL of hot water, separately for 10 minutes. This method does not require any treatment with reagents and/or chemicals, which is categorized as normal extraction method. After that each extract was cooled and filtered by a sterile filter (0.45 µm). Before injection into HPLC instrument, each extract was diluted in 10% double distilled water then 20 µL of extract was injected directly into the HPLC.

Preparation of stock and working solution

Caffeine stock solution of 1000 mg L^{-1} was prepared by accurately weighing 0.01 gram of standard caffeine, then dissolved in 10 mL methanol. Working standard caffeine solutions of 1, 10, 30 and 60 mg L^{-1} were prepared by serial dilution of the stock solution with double distilled water. The calibration curve of peak areas versus concentration of the standards was plotted. The caffeine content (mg L^{-1}) of the various samples was calculated by interpolation within the regression equation of the best line of fit.

Chromatographic separation

All selected samples in the present study were analyzed using high performance liquid chromatography (HPLC, Knaur Germany system) to identify and quantify caffeine compound. A binary high pressure pump and diode array detector were involved in the instrument. The separation was provided on C_{18} column (150 mm × 4.6 mm I.D., 5 µm particle size; Knuar, Germany). The mobile phase is consisted of water (A) and acetonitrile (B). The initial gradient composition (5% B) was maintained for 4 min and then linearly increased to 95% B over 9 min and maintained for 2.5 min before being decreased to 2% B over 0.1 min. Then, equilibration was performed for 2.9 min. The injection volume was 20 µL

and the flow rate was set to 0.3 mL min^{-1}. The column temperature was fixed at 35℃. All samples were subjected to 73 nm wavelength.

Mass spectrometry analysis (MS) was carried out using a time-of-flight (ToF) instrument (Bruker/Germany) equipped with a Z-spray electrospray interface. The results were obtained with the following settings: MS capillary voltages, 4000 (PI); collision energy for diclofenac, 10 eV; drying gas flow rate, 8.0 L min^{-1}; drying gas temperature, 190 °C; set capillary, 4000 V; set end plate offset, −500 V; set collision cell RF, 250 Vpp; and nebulizer pressure, 4.0 bar. The ToF results were collected between *m/z* 50 and 600. All analytes were acquired using an independent reference spray via the LockSpray interference to ensure accuracy and reproducibility; a mixture of sodium hydroxide and FA was used as the lock mass at *m/*z 90.9766–974.8132. The accurate mass was calculated using Daltonic Analysis software incorporated into the instrument.

Method validation

Analytical method was validated for linearity, limit of detection (LOD), limit of quantification (LOQ), intra day precision and accuracy. Calibration curve was performed in the range of 1 to 60 mg L^{-1}. The linearity was assessed by correlation coeficient (R^2). The LOQ and LOD values are calculated with the following equation (1):

$$\frac{S}{N} = \frac{2H}{h} \quad (1)$$

Where “S” is the signal of target peak. “N” is the noise adjacent to target peak. “H” is the height of target analyte peak so it refers to the signal “S”. “h” is the height of noise.

For repeatability measurement, samples were analyzed with three replicates in the same run. The results are represented as the percentage coefficient of variation values of the concentration of the analyte. All results were treated statistically using Microsoft Excel. Accuracy, however, was calculated after adding known amount of caffeine 1 mL of 10, 30 and 60 mg L^{-1} into 9 mL of tea sample then subtracting the peak area from the origin sample to find recovery% according to equation (2).

$$\text{Accuracy } \% = \frac{A_{spike} - A_{unspike}}{A_{standard}} \times 100\% \quad (2)$$

Where A_{spike} is adding known amount of caffeine to tea sample. $A_{unspike}$ is only tea sample. $A_{standard}$ is the standard concentration of caffeine.

Evaluation of selectivity

Selectivity was evaluated by comparing the chromatograms of three different samples: real sample, spiked real sample, and double distilled water. The results revealed that no interfering peaks visible at the same retention time of caffeine.

Results and Discussion

Method validation

The linearity of analytical method of caffeine was assessed through five concentrations of caffeine: 1, 10, 30 and 60 mg L^{-1}. All working solutions were eluted out of the column at the same retention time (10.6 min) as presented in Figure 2.

Calibration curve was obtained by plotting the peak area of caffeine against the working standard concentration. Calibration curve was fitted to the least-square linear regression. The results showed good linearity for caffeine, in which (R^2) was 0.995. It was observed that limit of quantification (LOQ) was calculated according to the injection of samples reaching up to low concentrations then calculated using equation (1), which is equivalent to 1.0 mg L^{-1}. It was observed that at 0.2 and 0.5 mg L^{-1} of caffeine, the signal was very small compared to noise signal, hence, both concentrations have signal-to-noise ratio less than 10. However, 1 mg L^{-1} of caffeine was analyzed, and it could be confirmed that the concentration has signal-to-noise ratio 10.4 means it represent LOQ.

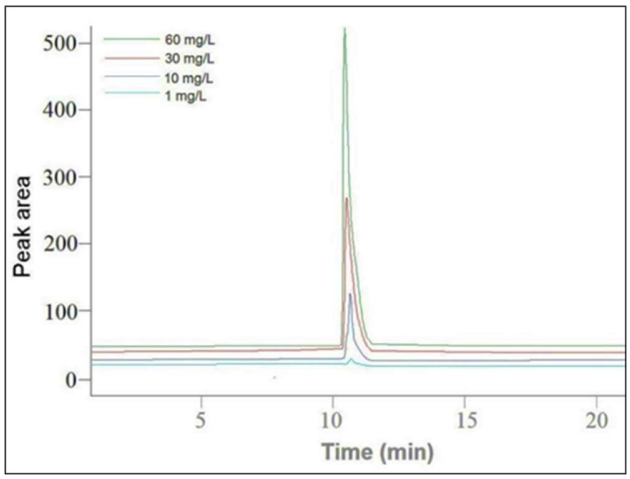

Figure 2. Chromatograms of caffeine at different concentrations (1, 10, 30 and 60 mg L^{-1})

The precision of liquid chromatography method was evaluated through analysis of three samples replicates performed within the same day (refer to Table 3). The precision was determined by analyzing three different concentrations of caffeine (10, 30, and 60 mg L^{-1}). The results were presented as RSD%, ranging from 3.11 to 11.37%, which is considered as small and precise. Accuracy was determined by adding known amounts of caffeine to the sample (10, 30 and 60 mg L^{-1}). The results are in good agreement with the acceptable values for the validation of an analytical procedure, with the accuracy ranging from 92% to 98% as presented in Table 3.

Table 3. Precision data for the analysis of caffeine

Compound	Concentration (mg L^{-1})	Accuracy %	Precision (RSD%)	LOQ (mg L^{-1})	LOD (mg L^{-1})	Regression Linear Equation
Caffeine	10	92	11.37	1.0	0.4	y = 63.96x + 83.54
	30	96	8.31			
	60	98	3.11			

Selectivity of method has been evaluated based on the comparison of standard caffeine, spiked caffeine in tea and blank sample. It was observed that no peaks interfered at the retention times of caffeine at 10.6 minute.

Box-Behnken design-based optimization

It is well known that extraction process is important to make caffeine ready for analysis, when it is present in complex samples like plants and beverages. Tea and coffee were extracted by three different methods as described previously. In comparison to second and third extraction methods, the first extraction method has produced the lowest peak area. This may be caused by the frequent sample transfers that resulted with some caffeine loss. Caffeine was dispersed between two layers in the second extraction method, which uses two immiscible solvents, but the peak area was still moderate in comparison to the third extraction method. However, the third extraction method without chemical reagents provides the most optimal caffeine recovery and less lost of caffeine compared to other extraction methods. Table 4 represents the ANOVA and regression analysis to assess the significance of independent factors, which are extraction method (A), temperature (B) and residing time (C). The model presented a high coefficient of determination (R^2 = 0.9928). This value indicated a good accordance with the experimental data and a good fitting ability for the model. Thus, the procedure demonstrated the ability of the model to work as a

predictive tool. The value of the adjusted determination coefficient (adjusted R^2 = 0.9895) is also sufficiently high to support a high significance for the model.

Box-Behnken design of response surface methodology was used for the analysis of the effect of temperature, residing time and extraction method on the extraction of caffeine and optimization of the independent variables. The linearity and quadratic effect of the independent parameters, their interaction and coefficients on the response variables were obtained by analysis of variance (ANOVA) (Table 4). The significance of the lack-of-fit, regression model and coefficient of determination (R^2) were used to judge the validity of the Box-Behnken design model. The analysis of the P-values of temperature, residing time, and extraction method, as well as the double interaction between these factors, show that those independent factors had a statistically significant effect on caffeine extraction from tea samples, with a p-value less than 0.05, which is 0.001.

Table 4. Analysis of Variance

Figure 3a represents normal distribution of the data towards the straight line (red color) in normal probability plot, means good significance of the results and no evidence of any deviation. Accumulating the datasets represented by blue dots along the straight line refers to a perfectly fitting model with no possibility of deviation. Figure 3b represents the Pareto chart, which is an indication of the individual interaction effect between the independent variables. Student's t-test was used to confirm that some factors are higher than zero point, which are significant. The vertical line (2.09) in Pareto chart refers to all factors that are statistically significant (confidence level > 95%) either individually or overlapped as they lied on the right-hand dashed line. Therefore, extraction of caffeine from tea was directly proportional to temperature, time and method of extraction. Consequently, increasing of time and temperature or development in extraction method, yield high amount of caffeine in the same sample of tea. Figure 3c shows the normal probability plot of the standardized effects with $p \leq 0.05$, to evaluate the significance of each independent factor and its interactions on extraction of caffeine from tea. Normal probability plot could be separated into two regions, right and left. Right region includes positive coefficients (from B to AC), while left region includes negative coefficients (AA to BB). It can be concluded through normal distribution of the data in normal probability plot

and perfect fitting model; Pareto chart with confidence level >95% and $p \leq 0.05$ of the combined factors such as Extraction Method with Temperature (AB), Extraction Method with Time (AC), Temperature with Time (BC), all independent factors are highly significant.

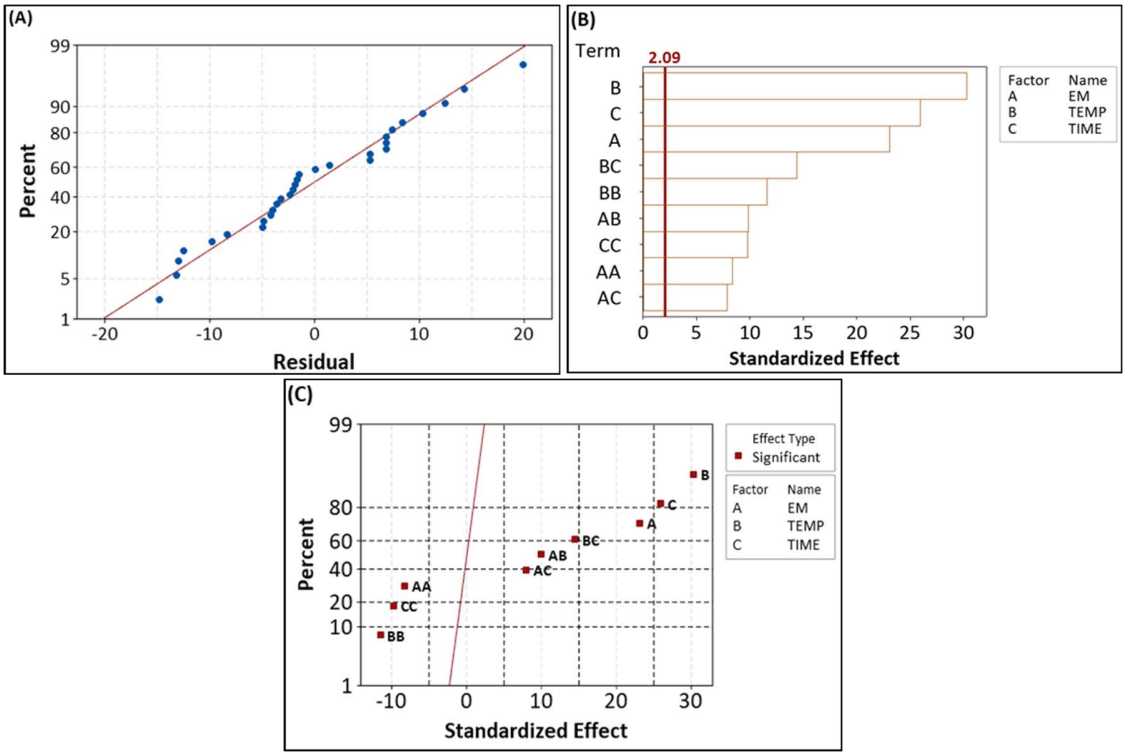

Figure 3. (a) The predicted response vs the actual response, (b) Pareto chart of standardized effects on the extraction efficiency of caffeine at $p = 0.05$, and (c) Normal probability plot of the standardized effects on the extraction efficiency of caffeine at $p = 0.05$.

The result is highly correlating that caffeine content increases considerably with heating time and specific method of extraction 3. In other words, following normal extraction without adding any chemicals is preferred. Furthermore, increasing of time reflect high positive impact on enhancement of caffeine extraction from tea leaves. These results are supported by the contour plot given in Figure 4a as can be seen, whereby tea boiled in 16 min at 100 °C resulted to caffeine concentration reaching up to 400 mg L^{-1}. Figure 4b showed the efficiency of caffeine extraction is improved with increasing time and temperature. However, it could be observed that the extraction of caffeine decreases at short time and low temperature when extraction method 3 was applied. It could be attributed to the role of heating, which accelerates the extraction of caffeine even at a shorter time as supported by the contour plot. The contour plot presented in Figure 4c, exhibited the major role of temperature regardless the type of extraction. It could be observed that all extraction methods performed in this study resulted to reasonable caffeine content. Caffeine concentration is in the range between 300-400 mg L^{-1} at 16 min and 100 °C by using extraction method 3. Similarly, extraction method 2 exhibited caffeine concentration in the range between 200 and 300 at mg L^{-1} in the same time and temperature as extraction method 3.

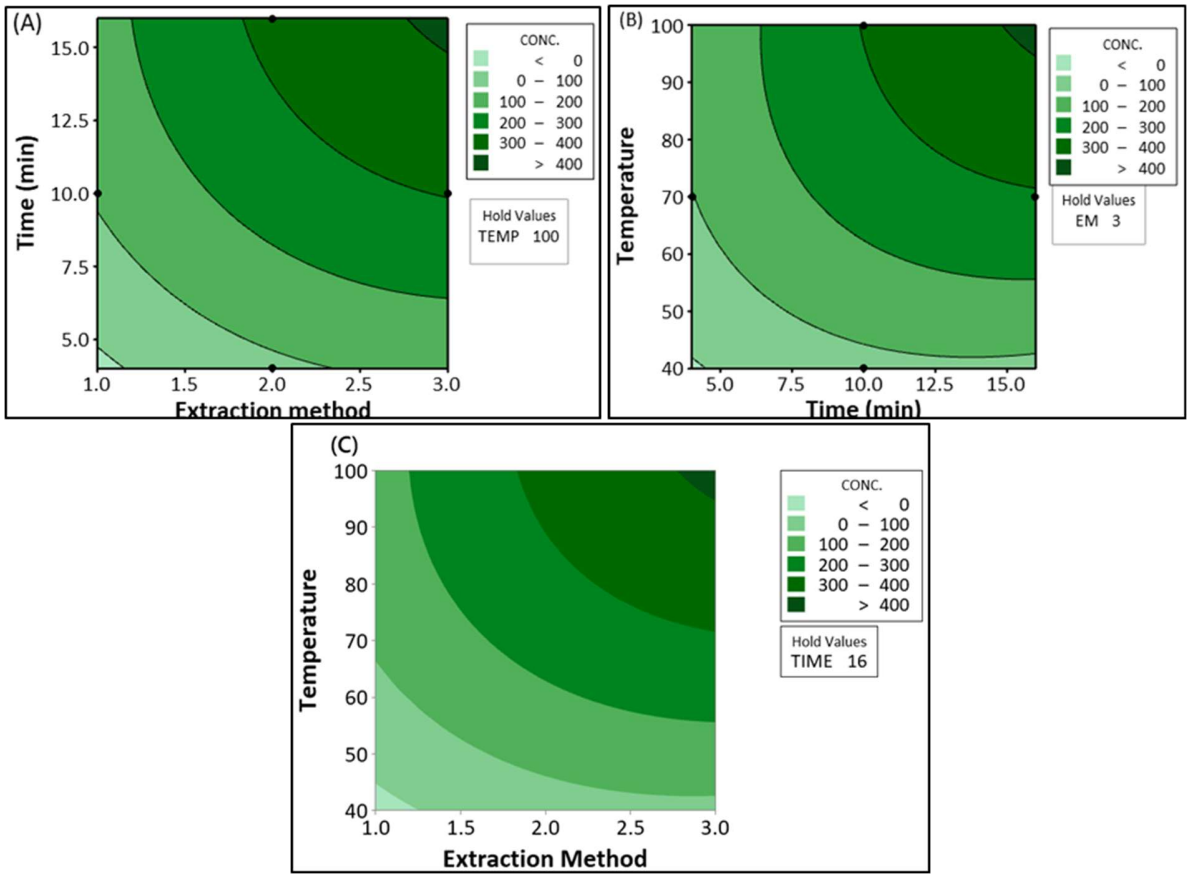

Figure 4. Response using the Box-Behnken Design obtained by contour plotting: (a) time vs. extraction method at 100°C, (b) temperature vs. time using extraction method 3, (c) temperature vs. extraction method in 16 minutes.

Analysis of caffeine in tea, and coffee

Caffeine was identified based on the mass value (*m/z*) in regards to mass spectrometry and retention times in regards to HPLC. Confirmation of presence of caffeine was carried out in the ToF/MS mode by extracting the narrow window extracted ion chromatogram (nwXIC) of the protonated molecular ion $[M+H]^+$. The nwXIC was typically extracted using a 20 mDa window. Positive identification for caffeine was based on (a) an accurate mass measurement of the base ion with an error of $\leq \pm 0.5$ ppm; and (b) LC retention time of the analyte compared with that of a standard [18]. The base peak at *m/z* 195.0884 for caffeine represented protonated molecular ion $[M+H]^+$ as shown in Figure 5. A small daughter peak at *m/z* 138.0655 appeared after the fragmentation of caffeine. This small, intense peak refers to the loss of C_2H_3NO from caffeine to form $C_6H_7N_3O$. The results agreed with previous study reported by Choi et al. [19] on the formation of metabolite of *m/z* 138.12 from caffeine after losing C_2H_3NO moiety.

For analysis of caffeine in tea and coffee samples, 100 mL of double distilled water was boiled in a glass beaker. After that heating was stopped and 1.0 gram of tea leaves or coffee beans was soaked in the boiled water. During this stage, the beaker was covered with a watch glass and stirring continued at a constant speed. Each sample was withdrawn at 1.0 mL after 10 min and filtered with 0.45 µm syringe filter. Caffeine was quantified by the developed reversed phase high pressure liquid chromatography method. All six samples

of tea leaves and coffee beans were analyzed and quantified using HPLC as shown in Table 5 and Figure 6. It was observed that caffeine has same retention time (10.6 min) in all selected samples.

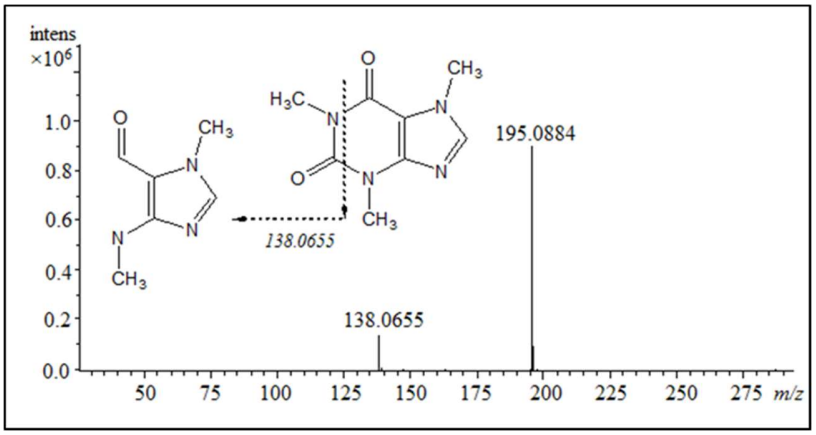

Figure 5. Mass spectrum of caffeine

Table 5. Result of caffeine content in coffee and tea samples using HPLC by extraction method without chemicals after 10% dilution

Sample Name	**Caffeine concentration (mg L^{-1}), M±SD**
Mahmood red tea	311±6.9
Mahmoud green tea	366±10.3
Al Ghazaleen Tea	290±8.1
Brazilian coffee	278±10.9
Mahmood coffee	334±5.7

Surprisingly, the highest concentration of caffeine was present in Mahmood green tea, with the concentration reaching 366 mg L^{-1} compared to Mahmood red tea, which is slightly lower at 311 mg L^{-1} . Hence, it signifies both green tea and red tea cannot be categorized as caffeine-free. Meanwhile, in coffee, the caffeine concentration was 278 and 334 mg L^{-1} in Brazilian coffee and Mahmood coffee, respectively; which is almost identical to Al Ghazaleen tea and Mahmood red tea. In comparison to other tea samples and coffee, the concentration of caffeine is high in the present study compared with that caffeine detected in BOH tea (138.3±4.5 mg/L), Milo (30.4±2.5 mg/L) and white coffee (82.7±2.9 mg/L) as presented in our previous study [18]. Similar study conducted using liquid chromatography has successfully proven that most Malaysian produced coffee and tea products are less in caffeine compared to the imported coffee and tea, which are proven to be highly concentrated with caffeine. The mean caffeine content of tea, green tea, per se, is higher than that of coffee. The fate of caffeine will remain in the body of the consumer throughout the digestion that may cause increased anxiety, increased heart rate and blood pressure, disorientation, hallucinations, acid reflux and sleep disturbance, and being excreted to the environment causing further pollution and bioaccumulation into the wastewater, aquatic and marine environment, and animals [20, 21].

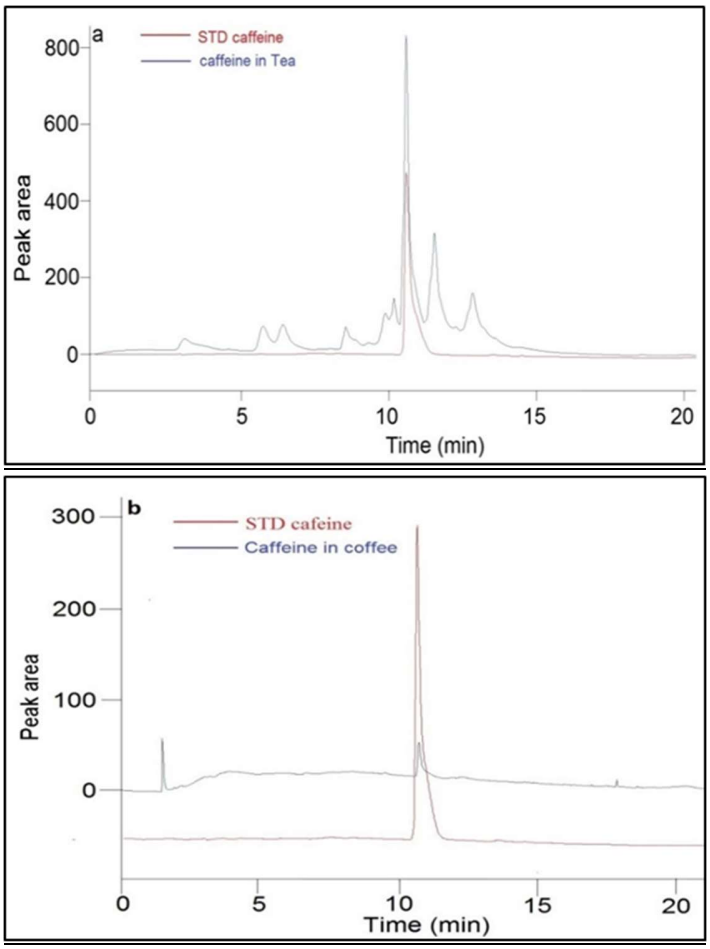

Figure 6. Chromatograms of caffeine in real samples: (a) tea leaves and (b) coffee sample

Conclusion

HPLC is a good technique and instrument to be used in identifying and quantifying caffeine in all selected samples namely tea and coffee. It was observed that HPLC reduces the labor work procedure in which requires less extensive usage of chemicals as proven by extraction method 3 with zero chemical used, but at boiling point and less than 20 minutes extraction time. Good linearity (R^2 = 0.995), a specific and sensitive detection system, low quantification limit 1 mg L^{-1} and fast analysis method are the main advantages of the proposed method. Furthermore, no interferents can be detected through this complex matrix and zero chemical compound. Highest concentration of caffeine was detected in tea sample 366 mg L^{-1} while the lowest concentration was 278 mg L^{-1} as detected in Brazilian coffee sample. This study has significantly exhibited that tea has more caffeine than coffee, which would deter the myth that tea is lighter than coffee, however, tea releases caffeine in a smaller amount but yet more long-lasting than coffee and leaves smaller carbon footprint.

Abstract

Untreatable bacterial infectious diseases have become a leading cause of mortality due to the emergence of drug-resistant bacteria. The search for a new effective pharmaceutical drug can be time-consuming and expensive. Therefore, structural chemical modification of natural product-based compounds with known biological properties for potential drug candidates has gained a great interest among researchers. Microwave-assisted synthesis is quickly becoming the method of choice in modern organic synthesis for drug discovery due to benefits such as higher yield and shorter reaction time. In this study, a series of coumarin derivatives have been synthesized by incorporating halogenated azo moieties in the molecular network *via* diazo-coupling, Knoevenagel condensation, and hydrolysis reactions. Microwave-assisted organic synthesis reaction has produced overall higher yields of products (74-94 %) in 6-17 mins compared to the conventional reflux method (56-85 %) in 6-18 h. The structural activity relationship of all compounds was initially evaluated *via in silico* (molecular docking) for potential antimicrobial properties against *Escherichia coli* and *Staphylococcus aureus*. The synthesized compound gave a higher binding affinity (-6.3 to -8.9 kcal/mol) compared to ampicillin (-6.7 to -7.3 kcal/mol) and coumarin (-6.0 to -6.2 kcal/mol). *In vitro* evaluation (agar well diffusion), nevertheless, gave weak to no bacterial inhibition activity. This study is significant in searching for potential drug precursors to benefit mankind.

Abstrak

Penyakit berjangkit bakteria yang tidak dirawat disebabkan oleh kemunculan bakteria kerintangan ubat telah menjadi punca utama kematian. Proses pencarian ubat farmaseutikal baharu yang efektif boleh mengambil masa yang lama dan memerlukan kos yang tinggi. Oleh itu, pengubahsuaian struktur kimia sebatian yang berasaskan produk semula jadi dengan sifat biologi yang diketahui sebagai calon ubat yang berpotensi telah menarik minat dikalangan para penyelidik. Kaedah sintesis berbantukan gelombang mikro dengan cepatnya telah menjadi kaedah pilihan dalam sintesis organik moden untuk pencarian ubat berpotensi kerana kelebihannya seperti mampu menghasilkan produk yang lebih tinggi dan mengurangkan masa tindak balas. Dalam kajian ini, siri derivatif kumarin telah disintesis dengan menggabungkan moieti azo halogen dalam rangkaian molekul melalui tindak balas gandingan

diazo, pemeluwapan Knoevenagel, dan hidrolisis. Tindak balas sintesis organik berbantukan gelombang mikro telah berjaya menghasilkan produk keseluruhan yang lebih tinggi (74-94 %) dalam masa 6-17 minit berbanding kaedah refluks konvensional (56-85 %) yang memerlukan 6-18 jam. Penilaian hubungan aktiviti struktur semua sebatian untuk potensi aktiviti antimikrob terhadap Escherichia coli dan Staphylococcus aureus dinilai melalui kaedah *in silico* (dok molekul). Sebatian yang disintesis memberikan afiniti pengikatan yang tinggi (-6.3 hingga -8.9 kcal/mol) berbanding ampicillin (-6.7 hingga -7.3 kcal/mol) dan kumarin (-6.0 hingga -6.2 kcal/mol). Walaubagaimanapun, penilaian *in vitro* (penyebaran perigi agar) menunjukkan tiada aktiviti perencatan tumbuhan bakteria. Kajian ini penting dalam mencari prekursor ubat yang berpotensi untuk memberi manfaat kepada manusia.

Introduction

Untreatable infectious bacterial disease is a leading cause of mortality due to the rapid emergence of drug-resistant bacteria [1]. Antibiotics are crucial to combat many advent diseases and treat immune-compromised patients [2]. However, current antibiotics are becoming less effective against drug-resistant bacteria due to daily antibiotic consumption [3] and bacterial mutation [4]. There is an urgent need to develop new antimicrobial agents with high efficacy and effectiveness. The search for an effective pharmaceutical drug can be time-consuming and costly. Natural product-based compounds with known biological potentials have become a great source of inspiration in drug design [5]. Chemical modification of natural product-based compounds for potential drug candidates has gained significant interest among researchers [6-7]. Microwave-assisted synthesis has gained much interest in modern drug development programs due to its efficiency, shorter reaction times, and higher yields [8]. Furthermore, it is more cost-effective and environmentally friendly than the conventional approach via heating [9].

Coumarin is an example of a natural product-based compound that is naturally found in many plants [10]. Naturally occurring coumarin derivatives has many biological activities in plants especially in controlling plant growth, respiration, photosynthesis, and defense against various infections [11-12]. Coumarins' excellent biological properties have led to the development of synthetic coumarin derivatives with medical properties namely anti-bacterial, anti-cancer, anti-inflammation, anti-viral, and many others [11-14]. The biological properties of coumarin are due to its basic molecular structure, which noncovalently interact with many receptors in living organisms and resulting in a diverse range of physical activities [12&15]. Numerous ways are reported to synthesize coumarins namely Perkin reaction [16], Knoevenagel condensation [17], Pechmann condensation [18], and more [19].

In recent years, drugs which comprise two or more pharmacophore groups binding together covalently in one molecular framework have received great interest. The multi-targeted strategy has led to the development of a number of bioactive hybrid molecules with desired pharmacokinetic profiles and less tendency to drug-resistant bacteria [20]. Molecular hybridization of several pharmacophore groups acts by inhibiting two or more conventional targets at once. Structural hybridization of coumarin with other biologically active moieties is envisaged to increase their biological properties as new potential drugs [20-21]. Similar to coumarin, azo dyes are another biologically active moiety found in many natural products [22] with a wide spectrum of biological properties [23]. Azo dyes participate in various biological processes, including DNA inhibition, RNA and protein synthesis, carcinogenesis, and nitrogen fixation [24]. The incorporation of electronegative halogen substituents, on the other hand, improves the penetration of lipid membranes and increases the biological properties of molecules by making the structure more lipophilic [25-26].

This paper reports on the synthesis of coumarin incorporated with halogenated azo moiety, which is further evaluated for antibacterial properties against *E. coli* ATCC 25922 and *S. aureus* S48/81. The reaction involved a diazo-coupling reaction of halogenated azo-benzaldehyde intermediate **1a-d** followed by

Knoevenagel condensation reaction and hydrolysis (MW–assisted and conventional method) to achieve halogenated azo-coumarin derivatives **2a-d** and **3a-d**, respectively. The structure-activity relationship of the compounds for potential bacterial growth inhibition was preliminarily studied *via in silico* (molecular docking) followed by agar well diffusion (*in vitro*).

Materials and Methods

Materials and instrumentation

All purchased reactants and solvents of analytical grade were used without further purification. Microwave-assisted synthesis (MW) (was conducted using Anton Paar Monowave 300 (Austria). ^{1}H NMR and ^{13}C NMR spectra were recorded with DMSO-d6 as a solvent on a JEOL JNM-ECZ500R (Japan). Chemical shifts are given in parts per million (δ). FTIR spectra were obtained using Thermo SCIENTIFIC NICOLET iS10 (United States).

Synthesis of intermediate azo-benzaldehyde derivatives (1a-d)

A mixture of aniline derivatives (10 mmol) was dissolved in 10 mL of 25 % hydrochloric acid, HCl solution and cooled in an ice bath. Sodium nitrite, $NaNO_2$ solution (1.5 eq. mol) was added and reacted under constant stirring for 15 min. 2-Hydroxybenzaldehyde (10 mmol) dissolved in 20 mL of 1M sodium hydroxide, NaOH solution was then added to the mixture and reacted for a few minutes. The pH of the reaction was adjusted to 8-9. The reaction continued to react for 1-2 h. The reaction mixture was acidified using an HCl solution to precipitate out the crude product. The crude product was vacuum filtered, rinsed with distilled water, dried overnight, and purified *via* fast recrystallization from hot ethanol. The data analysis of **1a-d** can be obtained from supplementary file S1.

Synthesis of 3-ethylcarboxylatecoumarin-azo derivatives (2a-d)

The azo intermediate **1a-d** and diethyl malonate with a 1:1 ratio was dissolved into 20 ml of ethanol in a round bottom flask. Piperidine (0.25 eq mol) and a few drops of acetic acid were added to the reaction mixture, refluxed for 8-18 h, and confirmed *via* TLC analysis. Warm 50% ethanol (20 ml) was added to the reaction mixture and allowed to rest in ice water for 1 h. The solid product was filtered and rinsed with ethanol solution. The solid was recrystallized from ethanol to obtain a pure product. The conventional reflux heating method (I) was replaced with microwave irradiation (II) to reduce reaction time and increase product yield. The data analysis of **2a-d** can be obtained from supplementary file S2.

Synthesis of 3-ethylcarboxylatecoumarin-azo derivatives (3a-d)

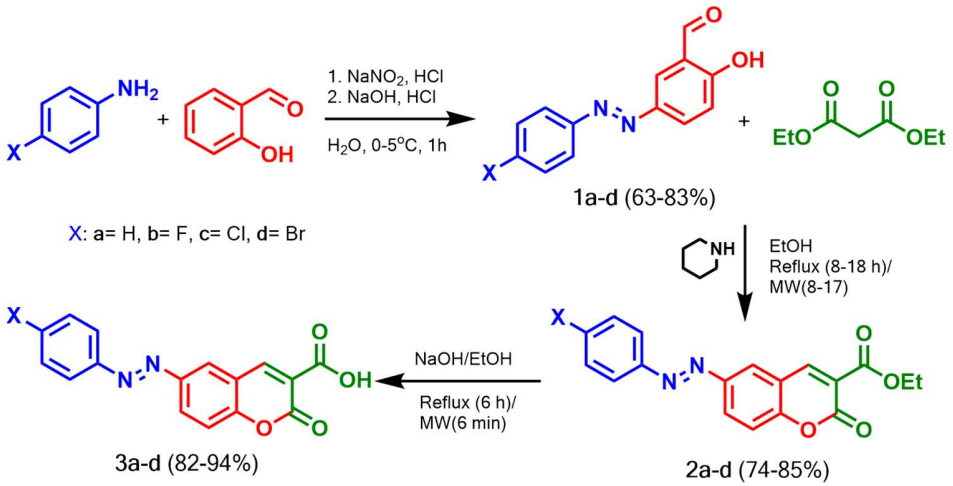
Coumarin-azo **2a-d** dissolved in ethanol (15 ml) in a reaction flask followed by the addition of 1 M NaOH (15 ml). The reaction mixture was reacted for 3 h and confirmed *via* TLC analysis. The reaction mixture was then acidified with concentrated HCl and allowed to react for 15-30 min at room temperature. The solid precipitate was filtered and rinsed with hot distilled water and purified *via* hot filtration from ethanol. The conventional reflux heating method (I) was replaced with microwave irradiation (II) to reduce reaction time and increase product yield. The data analysis of **3a-d** can be obtained from supplementary file S3.

In silico study via molecular docking

Docking studies were performed using Autodock Tools and Vina. The X-ray structure of *E. coli* GyrB24 with inhibitor (PDB entry: 6yd9) and *S. aureus* GyrB ATPase domain in complex with a small molecule inhibitor (PDB entry: 3u2k) was retrieved from Protein Data Bank. The cubic grid box of 40 Å size (x, y, and z) with a spacing of 0.5 Å was centered on the active sites of the protein.

In-vitro study via agar well diffusion

In vitro screening of **1a–d**, **2a–d**, and **3a–d** was performed against *E. coli* (ATCC 25922) and *S. aureus* (ATCC 29213) *via* the agar well diffusion method. *E. coli* and *S. aureus* were cultured in Mueller-Hinton Broth (MHB) as inoculum and incubated at 37.5 ℃ with continuous shaking overnight at 180 rpm. The bacteria were spread on Mueller-Hinton Agar (MHA) plates using a bacteria suspension made with a sterilized cotton-tipped swab. A hole with a diameter of 6 to 8 mm is punched aseptically with a sterile tip and a volume of 10 µL of the synthesized compound in DMSO. The



plates were incubated at 37.5 °C for 24 h. The zone of inhibition was measured in millimeters to evaluate the effectiveness of the synthesized compounds.

Results and Discussion

Chemistry

Prior to the synthesis of halogenated azo-coumarin **2a-d** and **3a-d,** an intermediate halogenated azo-benzaldehyde **1a-d** with a high yield (63-83%) was synthesized *via* diazotization of halogenated aniline in the presence of hydrochloric acid and sodium nitrite followed by coupling with 2-hydroxybenzaldehyde in basic condition. The formation of halogenated azo ethyl coumarin-3-carboxylate **2a-d** was achieved *via* Knoevenagel condensation of **1a-d** with diethyl malonate in piperidine and acetic acid as catalyst. Due to the long refluxing hour in conventional protocol employing hazardous solvent, microwave irradiation has become a great interest to introduce green and facile synthesis of one pot Knoevenagel condensation with higher yield [8]. The synthesis was comparatively performed using conventional heating and microwave irradiated (MW) synthesis. The microwave-assisted Knoevenagel condensation in MW was completed in shorter times of 8-17 min (74-85%) compared to the conventional reflux in 8-18 h (56-79%). The subsequence microwave irradiated hydrolysis of **2a-d** afforded halogenated azo coumarin-3-carboxylic **3a-d** with a higher yield and a shorter time (82-94% in 6 min) compared to the conventional procedure (76-85% and 6 h). The synthetic reactions of **1a-b**, **2a-d**, and **3a-d** are shown in Scheme 1. The yields and reaction times of conventional and microwave-assisted synthesis of **2a-d**, and **3a-d** is depicted in Table 1.

The molecular structure of all the synthesized compounds was characterized and confirmed using FTIR and NMR spectroscopy. Based on Figure 1, the formation of the N=N group of **1a-d** *via* diazo-coupling was confirmed by the strong absorption peak corresponding to the *v*(N=N) bend at 1483–1475 cm^{-1} [6&26]. The formation of **2a-d** *via* Knoevenagel reaction was indicated by the presence of *v*(C-H) stretch at 3051-3031 cm^{-1}. In addition, a strong signal at 1741–1732 cm^{-1} contributed by the *v*(C=O) lactone confirmed the formation of the coumarin lactone ring [27]. IR spectra of **3a-d** showed the presence of a strong signal in the range of 1745-1727 cm^{-1} contributed by *v*(C=O) lactone stretch and the disappearance of *v*(C-H) stretch at 3051-3031 cm^{-1} which confirmed successful hydrolysis of the ethyl group [27].

Scheme 1. Synthesis of **1a-d**, **2a-d**, and **3a-d**

Table 1. Comparison of conventional heating and MW irradiated synthesis of **2a-d** and **3a-d**

Product	Temperature (°C)		Time (min)		Yield (%)	
	Reflux	[MW]	Reflux	[MW]	Reflux	[MW]
2a	80	[140]	480	[8]	79	[85]
2b	80	[140]	600	[9]	74	[80]
2c	80	[140]	720	[11]	68	[83]
2d	80	[140]	1080	[17]	56	[74]
3a	80	[140]	360	[6]	80	[94]

3c	80	[140]	360	[6]	77	[83]
3d	80	[140]	360	[6]	76	[82]

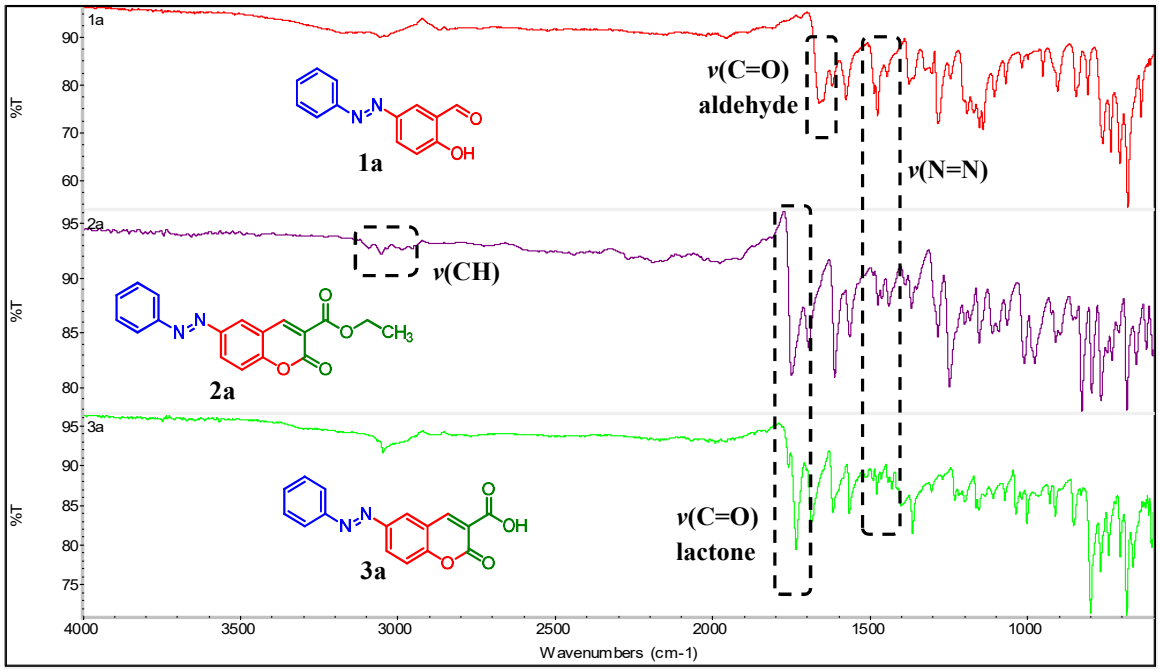

Figure 1. IR spectra of **1a**, **2a**, and **3a**

The ^{1}H NMR spectra of **1a-d**, **2a-d**, and **3a-d** showed the resonances attributed to aromatic protons at 8.93–7.20 ppm integrated with the corresponding number of aromatic protons. Figure 2 illustrated the ^{1}H spectra of **1a**, **2a**, and **3a**. The successful synthesis of -N=N- azo of **1a-d** *via* diazo coupling was confirmed by the duplet (H_a) and duplet-duplet (H_b) peaks at 8.17-8.19 ppm and 8.08-8.10 ppm, respectively. In addition, ^{1}H NMR spectra of **1a-d** showed the presence of proton for aldehyde as a singlet (H_c) at 10.37–10.36 ppm. The ^{1}H NMR spectra of **2a-d** indicated the formation of the coumarin *via* Knoevenagel condensation by the disappearance of the **1a-d** singlet aldehyde proton (H_c) peaks and the appearance of a new singlet (H_d) at 8.93 ppm. The appearance of the ethyl protons as a quartet (H_e) and triplet (H_f) at 4.34-4.55 and 1.34-1.33 ppm, respectively was also depicted by **2a-d**. The disappearance of peaks corresponded to -CH2CH3- at 4.34-1.33 ppm in the ^{1}H NMR spectra has clearly confirmed the formation of **3a-d** *via* hydrolysis.

The ^{13}C NMR spectra of **1a-d**, **2a-d,** and **3a-d** showed the resonances corresponding to aromatic carbons at 163.8–116.2 ppm. Compounds **1a-d** showed the

resonances attributed to *ν*(C=O) aldehyde at 190.6-190.4 ppm. The ^{13}C NMR spectra of **2a-d** showed the peak attributed to $–C_2H_5$ at 61.7–14.0 ppm. The resonance corresponding to *ν*(C=O) of **2a-d** and **3a-d** was observed at 163.8–156.0 ppm.

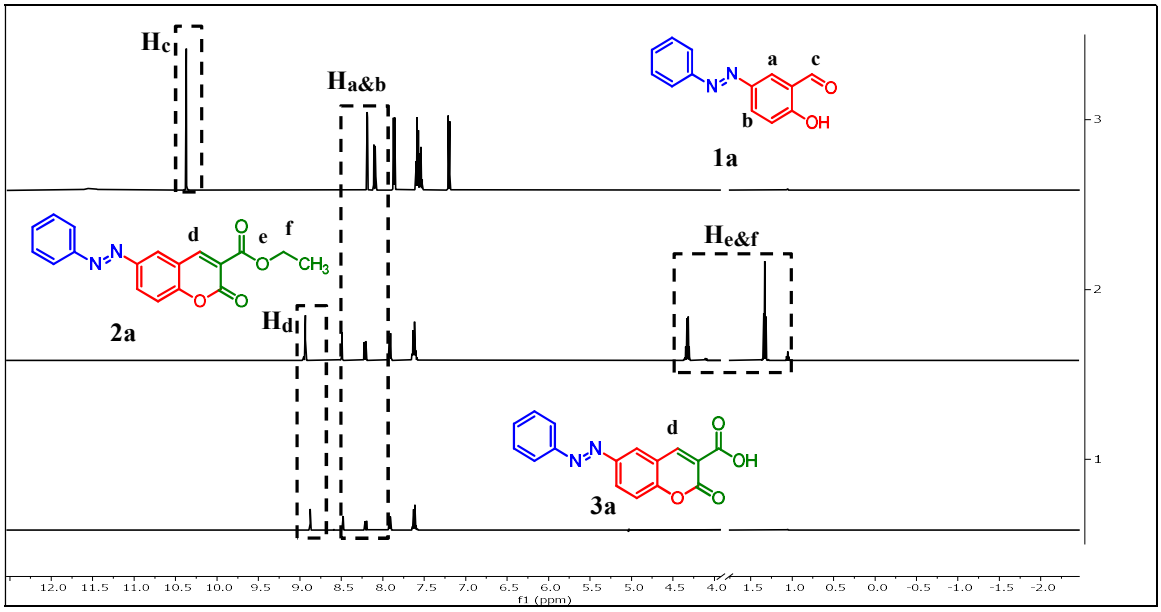

Figure 2. ^{1}H NMR spectra of **1a**, **2a**, and **3a**

Molecular docking study (*In silico*)

A preliminary study on the structural-activity relationship analysis of **1a-d**, **2a-d**, and **3a-d** as ligands was conducted to evaluate the possible binding interactions of the potential antibacterial agent. The binding affinity and interaction visualization between the ligands with DNA gyrase protein of *E. coli* GyrB24 (PDB entry: 6yd9) and *S. aureus* GyrB ATPase (PDB: 3u3k) were performed *via* Autodock Vina [28-29]. The binding affinity of **1a-d**, **2a-d**, and **3a-d** against DNA gyrase protein of *E. coli* and *S. aureus* is depicted in Table 2, where ampicillin was set as the standard drug. The drug candidates are usually chosen from the ligands that able to bind strongly to the target protein [30]. Higher binding affinity of the ligand indicates the ligand's ability to form strong binding interactions and influence the physiological function of target proteins [30].

The binding energies of **2a-d** and **3a-d** were -7.6 to -8.7 kcal/mol and -7.5 to -8.9 kcal/com, respectively for *E. coli* and *S. aureus*. The depicted binding energies of all the ligands were higher compared to the binding energy of the ampicillin (-6.7 to -7.3 kcal/mol) and coumarin (-6.0 to -6.2 kcal/mol). This indicates that coumarin azo derivatives have potential and ability to form stronger interaction, thus inhibit the bacterial enzyme activity. The intermediate **1a-d** scored the lowest (-6.3 to -6.6 kcal/mol). Among all, **3b** gave the highest binding energy -7.9 kcal/mol (*E. coli*) and -8.9 kcal/mol (*S. aureus*). Figure 3(a) depicted the interaction of **3b** to the active site of the enzyme for *E. coli*. The highly lipophilic characteristic of the compound formed hydrophobic interaction at the active site *via* π-alkyl and π-sigma bonding with the π-orbital of the alkyl group of various amino acid residues such as ILE78, PRO79, ARG76, and VAL120. An electrostatic interaction *via* the π-anion bond was also shown between the coumarin nucleus of **3b** with GLU50 residues.

The interaction of **3b** towards the active site of the *S. aureus* DNA gyrase enzyme is shown in Figure 3(b). Hydrophobic interaction *via* π-alkyl and π-sigma was observed between the benzene ring of **3b** with ILE86 and VAL131 residues. Hydrogen bond interaction was observed between the COOH of **3b** and GLU58 residue.

The presence of fluorine enables the ligand to form halogen bond interaction with GLU50 residues. In addition, van der Waals interaction between **3b** and various amino acid residues in the active site of the enzyme has also contributed to the strong ligand enzyme interaction.

Table 2. Binding affinity of **1a-d**, **2a-d**, and **3a-d** against DNA gyrase protein of *E. coli* and *S. aureus*

Compound	Binding Affinity (kcal/mol)	
	E. coli	***S. aureus***
1a	-6.5	-6.6
1b	-6.5	-6.6
1c	-6.4	-6.3
1d	-6.3	-6.3
2a	-7.8	-8.4
2b	-7.6	-8.7
2c	-7.6	-8.6
2d	-7.6	-8.6
3a	-7.9	-8.5
3b	-7.9	-8.9
3c	-7.9	-7.7
3d	-7.5	-8.7
Coumarin	-6.2	-6.0
Ampicillin	-7.3	-6.7

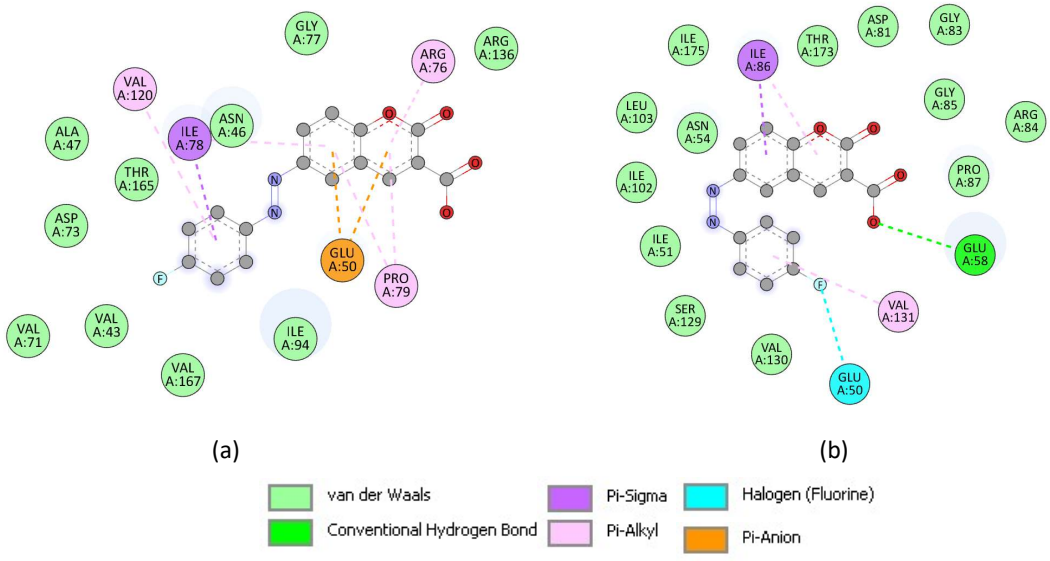

Figure 3: Interaction between **3b** and (a) *E. coli* and (b) *S. aureus*

The majority of DNA enzyme active binding sites has at least one hydrophobic pocket, and the lipophilic property makes it possible for lipophilic ligands to bind to hydrophobic protein binding sites [31].

Agar well diffusion study *(In vitro)*

Based on *in silico* strong interaction of the ligands against the DNA gyrase protein of *E. coli* and S. aureus, *in vitro* evaluations were conducted to evaluate the bacterial inhibition activity of the synthesized compounds against *E. coli* and *S. aureus via* agar well diffusion [32]. Ampicillin was used as the positive control and DMSO as the negative control. The results are depicted in Figure 4.

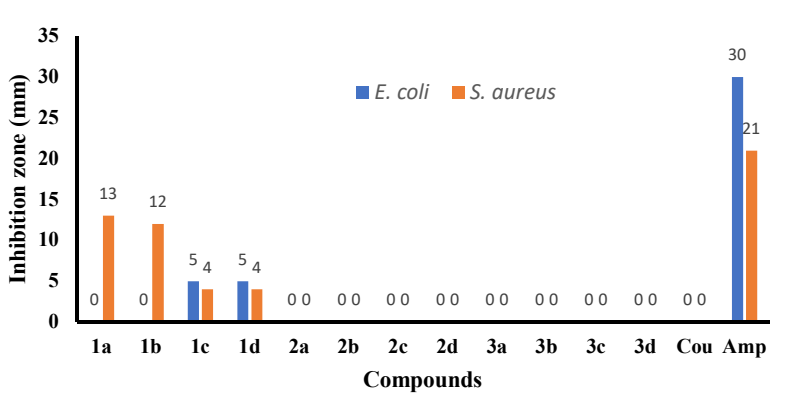

Figure 4. Inhibition activities of **1a-d**, **2a-d**, and **3a-d** against *E. coli* and *S. aureus*

Based on the results, all the synthesized azo **1a-d** showed inhibition activities against *S. aureus*. Among them **1a-b** demonstrated excellent activities on Gram positive bacteria (12-13 mm), while **1c-d** showed bacterial inhibition against both *E. coli* (5 mm) and *S. aureus* (4 mm), respectively. The bacterial inhibition activities of **1a-d** contributed to the presence of the N=N and halogens in the molecular network. The azo has the ability to protonate in acidic conditions and interact with the phosphate group on the peptidoglycan layer of bacteria, thus hindering the formation of the cell wall [6&33]. The biological activities of azo are well known for their ability to inhibit the DNA gyrase enzyme [34]. Additionally, azo can undergo tautomerization enabling it to act as both hydrogen bond acceptor and donator [24&35-36], hence increasing the biological activity. The presence of the OH group has also contributed to the inhibition activity of **1a-d** due to its ability to form hydrogen bond interaction with the biological target receptor [37-38].

The subsequence one pot cyclization of coumarin **2a-d** and **3a-d** via Knoevenagel condensation, however, reduced the inhibition activity against both bacteria strains. The compounds were inactive due to the competitive resonance and reduced electrophilicity of the lactone with the presence of azo group [9]. The formation of lactone further increases the lipophilicity of the compound, decreasing the compound permeability [39]. Poor dissolution properties of a compound could also contribute to the reduces antibacterial activity [40]. The combined interaction of hydrophilic and lipophilic characteristics in molecule structure plays a significant role in antibacterial activities [41-42].

Conclusion

The synthesis of coumarin-azo derivatives bearing halogens **2a-d** and **3a-d** has been successfully synthesized with great yield from **1a-d** *via* MW assisted Knoevenagel condensation followed by hydrolysis. Microwave-assisted synthesis promotes green chemistry by using less solvent and reaction times compared to the conventional heating method. Molecular docking evaluation of **2a-d** and **3a-d** showed higher binding affinity (-7.5 to -7.9 kcal/mol) than ampicillin (-7.2 to -7.3 kcal/mol) which indicates the potential ligands to affect enzyme activity and inhibit bacterial growth. The azo intermediate **1a–d** showed moderate inhibition activity with **1a** depicted the highest inhibition zone of 13 mm against *S. aureus*, whereas **1c-d** gave 5 mm against *E. coli* due to involvement of electron

delocalization and resonance stability. Nevertheless, the **2a-d** and **3a-d** showed no inhibition to the bacterial growth against *E. coli* and *S. aureus*. The halogenated azo intermediates exhibited a better binding tendency with target proteins as compared to the coumarin-azo derivatives. This research is essential in pharmaceutical industry for the drug development of lead chemicals.

Abstract

Domoic acid (DA) molecular imprinted polymers (MIP) were successfully synthesized by a bulk polymerization method using 2-hydroxyethyl methacrylate (HEMA) as a functional monomer and ethylene-glycol dimethacrylate (EGDMA) as a cross-linker. Non-imprinted polymers (NIP) were also synthesized using similar procedures, but without the addition of template molecules (DA). The presence of DA templates in MIP and the absence of DA templates in NIP was proven by Fourier-Transform Infrared (FT-IR) Spectroscopy, Brunauer, Emmett, and Teller (BET) method, and Scanning Electron Microscopy (SEM) analysis. All MIP analyses were done using a UV-Vis spectrophotometer. Binding efficiencies of MIP with domoic acid were determined using batch rebinding experiments, where the optimum mass and time obtained were 5 mg and 15 minutes, respectively. The correlation coefficients (R^2) of NIP and MIP were 0.8989 and 0.9933, respectively. The calculated limit of detection (LOD) was 1.418 ppm, and the limit of quantification (LOQ) was 4.2983 ppm. An adsorption isotherm experiment indicated that the Freundlich isotherm model yielded a better fit towards the equilibrium adsorption data. The MIP was successfully applied in the determination of DA in shellfish tissues of cockles and mussels, where the percentage recovery obtained for the spiked samples was 95.88% for cockles and 82.71% for mussels.

Keywords: molecularly imprinted polymer, domoic acid, shellfish, binding efficiency, marine neurotoxin

Abstrak

Polimer tercetak molekul (MIP) domoik asid (DA) telah berjaya disintesis melalui kaedah pempolimeran pukal menggunakan 2-hidroksietil metakrilat (HEMA) sebagai monomer berfungsi dan etilena-glikol dimetakrilat (EGDMA) sebagai penghubung silang. Polimer tidak tercetak (NIP) juga disintesis melalui kaedah yang sama tetapi tanpa penambahan templat molekul (DA). Kehadiran templat DA didalam MIP dan ketidakhadiran templat DA didalam NIP dibuktikan melalui analisis Fourier-Transform Infrared (FT-IR) Spectroskopi, kaedah Bruneaur, Emmett and Teller (BET) dan mikroskopi pengimejan elektron (SEM). Semua MIP dianalisa menggunakan UV-Vis spektrofotometer. Kecekapan pengikatan MIP dengan domoik asid ditentukan melalui ujikaji pengikatan semula secara berkelompok dimana berat dan masa optima yang diperolehi adalah 5 mg dan 15 minit masing-masing. Pekali korelasi (R^2) bagi NIP serta MIP adalah 0.8989 dan 0.9933 masing-masing. Pengiraan had pengesanan (LOD) adalah 1.4148 ppm dan had kuantiti (LOQ) adalah 4.2983 ppm. Ujikaji isoterma penjerapan menunjukkan bahawa model isoterma Freudlich menghasilkan data keseimbangan penjerapan yang lebih sesuai. MIP ini telah berjaya diaplikasikan dalam penentuan DA dalam

tisu kerangan iaitu kerang dan kupang dimana nilai peratusan pemulihan yang diperolehi bagi sampel yang dipaku adalah 95.88% bagi kerang dan 82.71% bagi kupang.

Kata kunci: molekul polimer tercetak, domoik asid, kerangan, kecekapan pengikatan, neurotoksin marin

Introduction

Domoic acid (DA) is a type of marine neurotoxin that is responsible for Amnesic Shellfish Poisoning (ASP). It was first documented in 1987, where consumers reportedly fell ill after consuming DA contaminated blue mussels harvested from eastern Prince Edward Island [1]. ASP can cause several illnesses such as diarrhea, degeneration of the nervous system in brain, and short-term memory loss [2]. In the human body, DA is known as an agonist to the glutamate receptor in the brain, where it causes disruption of the flow of mineral ions (Ca, Mg, Zn) across the cell membranes, thus affecting the hippocampus and amygdale glands in the human brain [3]. The DA toxin can be transferred to humans through the food chain via the consumption of toxic microalgae accumulated in seafood [4]. DA bio-accumulation in shellfish is aided by filtration of toxic species of red algae diatom, *pseudo-nitzschia* [5,6]. The DA molecule (shown in Figure 1), though unstable due to the oxidation of the conjugate double bond, has a strong UV chromophore, marking it as one of the most easily detected toxins [7].

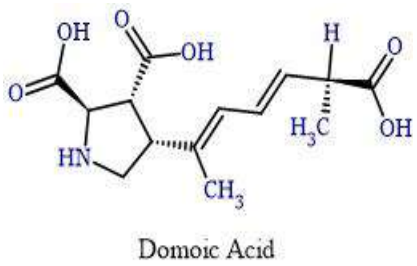

Figure 1. Chemical structure of DA

In order to protect consumers from DA poisoning, i.e., ASP, relevant permitted levels of DA concentration are established by many regulatory authorities, such as in the EU and USA, which is 20 µg of DA concentration per gram (g) shellfish meat [8, 9]. The outbreak of DA poisoning in shellfish tissue typically relates to the red tide phenomenon, which occurs during harmful algae blooms [10]. These blooms can be associated with cool and high nutrient water discharge from freshwater reservoirs [11]. Over 52 known species of *Pseudo-nitzschia* have been recorded globally, and 27 of these species are known to produce DA toxins [12]. In Malaysia, two types of DA producer algae have been recorded: *Nitzschia navis varingica*, which was discovered in peninsular Malaysia [13], and *Pseudo-nitzschia cuspidata*, which was discovered in Borneo [14].

Researchers have been using many means of analysis to detect DA in seafood. Instruments such as HPLC, GC-MS, and LC-UV are known as the established instruments used for the accurate and precise analysis of DA [15, 16]. However, these methods of analysis are time consuming and expensive. Therefore, in order to provide an alternative sensing method for DA detection, molecular recognition using imprinting polymers is being studied.

Molecularly imprinted polymers (MIPs) are specially designed sorbents that exhibit enhanced selectivity towards a specific structure [17, 18, 19]. They are able to obtain high affinity, robust and stable artificial receptors for the analyte of interest in harsh chemical and physical conditions [20, 21, 22]. The template binds with cross-linkers, monomers, and initiators to produce a set of imprinted memories for the target molecule [23]. The working mechanism of MIPs used in this study is shown in Figure 2. Template molecules (DA), monomer (HEMA), cross-linker (EGDMA), initiator (BPO), and solvent (DMSO) were used for the synthesis of MIPs.

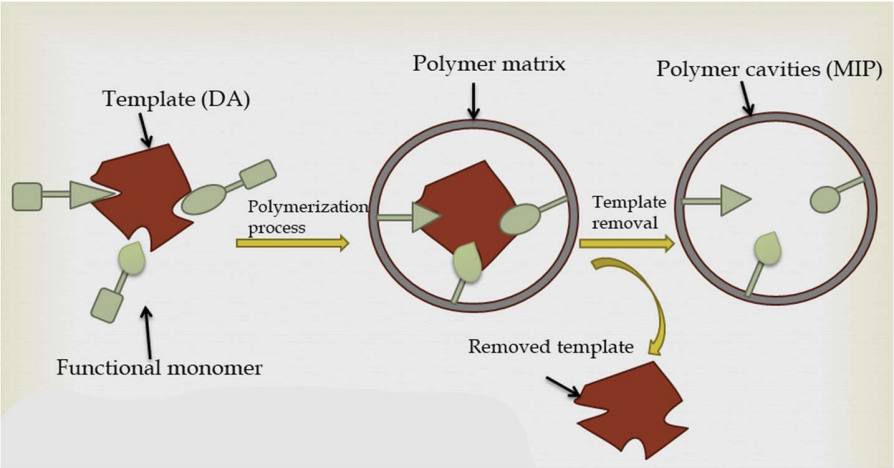

Figure 2. The schematic diagram for the working mechanism of MIP

The pre-polymerized solution was refrigerated for 1 hour in order to slow down the interaction between existing compounds in the solution with oxygen [24]. The polymerization of the MIP was conducted under low temperature conditions ranging from 40°C to 60°C. The cavities were formed by a washing method where the MIP was immersed in methanol/acetic acid (9:1, v/v) to remove the template (DA) [25]. The cavities provide a set of imprinted morphologies and memories capable of selectively binding the template. The imprinted polymer formed after template removal was used in this study to determine the adsorption capacity of MIP with DA.

Materials and Methods

Chemicals and samples

Domoic acid (DA), ethylene glycol dimethacrylate (EGDMA, 98%), hydroxyethyl methacrylate (HEMA, 98%), and benzoyl peroxide (BPO) were purchased from Merck. All other chemicals used in polymer synthesis including acetic acid, methanol, dimethyl sulfoxide (DMSO), and acetone were all analytical grade, and were purchased from Sigma Aldrich. Shellfish samples (cockle and mussel) were purchased from local fishermen and grocery stores.

Instrumentation

The characterization of MIPs and NIPs was conducted using Scanning electron microscopy (SEM), Fourier Transform Infrared (FTIR) spectrometry, and Brunauer, Emmett, and Teller (BET) Analysis. Meanwhile, the DA detection analysis was performed using Ultraviolet-Visible (UV-VIS) Spectrophotometer.

Synthesis of molecularly imprinted polymers

DA MIP was synthesized by a non-covalent bulk polymerization method. 313.3 µL DA template molecule and 520 µL of monomer (HEMA, 98%) were added into a beaker containing 4.9ml of DMSO. The solution mixture was allowed to stand for 5 minutes. Then, 3.96 mL of cross linker (EDGMA, 98%) was added into the solution, followed by 0.20g of benzoyl peroxide, to initiate the polymerization process. The solution was sonicated for 20 minutes and cooled at -20˚C for 1 hour. Then, the polymerization process of MIP was allowed to occur at 40 ˚C - 60˚C for 24 hours using a water bath. The polymers obtained were then filtered and dried for 6 hours at 50˚C in an oven. Meanwhile, NIP was synthesized with the same procedure as MIP, but without the addition of a template molecule.

Removal of DA template molecule from MIP

A template removal process was conducted to remove the imprinted DA molecule from the polymer matrix. A successive immersion technique was implemented for the removal of the template. The imprinted polymer was immersed in methanol/acetic acid (9:1, v/v) and shaken using an orbital shaker at 160 RPM for 24 hours at room temperature. The supernatant was filtered and analyzed

to confirm the removal of DA from the MIP. The template removal procedure was conducted until no DA was present in the collected supernatant. The MIP powder was then washed with methanol to remove excess acetic acid. Lastly, the polymer particles were washed with distilled water to remove the remaining solvents. The end product was dried in an oven at 50˚C for 6 hours.

Characterization of MIP and NIP

MIPs and NIPs were characterized before and after the template (DA) removal. Morphology and physical characterization studies were carried out using Scanning electron microscopy (SEM), Fourier Transform Infrared (FTIR) spectrometry, and Brunauer, Emmett, and Teller (BET) Analysis.

Batch rebinding experiment

Batch rebinding experiments were conducted to evaluate the performance of MIP binding capacity with DA. Mass and reaction time data was collected using UV-VIS spectrophotometer analysis. The data was analyzed using the Langmuir and Freudlich isotherm model in order to determine the heterogeneity and binding affinity of the MIP with DA.

Reproducibility and Reusability of MIP

Three batches of synthesized MIP were analyzed for their reproducibility by testing their responses with DA analyte for five times. The reusability of MIP was also tested by measuring several detection responses of DA analyte with the same MIP. This involved the repeated processes of reacting, re-washing, and re-reacting MIPs with DA analyte for five reusability cycles. The absorptivity of DA was measured and recorded, and the percentages of relative standard deviations (%RSD) were calculated for the reproducibility and reusability performance of MIP.

Analysis of real samples

The 20g of shellfish tissue and viscera was blended in 25 mL of distilled water and extracted by immersing 10 mL of pureed shellfish samples with 40 ml of methanol/distilled water (1:1; v/v) in a centrifuge tube. The sample mixture was shaken with a vortex and filtered using a filter paper. The remaining filtered mussel puree was removed and the supernatant collected was labeled as shellfish samples. Spiked and non-spiked samples were prepared by injecting 5ppm of DA for the spiked samples. The spiked and non-spiked shellfish samples were poured into clean vials, labeled, and refrigerated for storage at 4-5°C for further use.

Results and Discussion

Synthesis of MIP and NIP

The MIP and NIP were successfully synthesized through a non-covalent approach using the bulk polymerization method. The functional monomer, HEMA was used in the polymerization process for its neutral functionality, stability, and resistant bond strength [26]. Previous research by Ceolin et al. [27] has proven that the highest imprinting factor for MIPs can be achieved by using the molar ratio of 1:3.5:19.5 for templates, monomers, and cross-linkers. The MIP was synthesized using a 1:4:20 molar ratio of DA template to HEMA monomer to EGDMA cross-linker to provide an MIP with the highest affinity sites, higher selectivity, and adsorption capacity towards analogous compounds [28]. According to Cormack, the ratio of 1:4 of template to functional monomer is commonly used in non-covalent polymerization in favor of the template for the formation of imprinted binding sites. Large amounts of functional monomer will influence the adsorption effect and pore volume of the MIP. Additionally, the molar ratio of template to cross linker (EGDMA) used in the polymerization process is 1 to 20. The polymer to cross-linkers ratio in excess of 80% is often used in the polymerization method. The amount of EGDMA in MIP was studied by Zhao et al., proving the significant effect of cross-linkers dosage on the recognition and adsorption ability of the imprinted polymers. A low amount of EGDMA will cause poor stability and deformation of the polymer cavity, wherein, a high amount of EGDMA will affect the removal process of the template molecule. The polymerization process of MIP was initiated with the presence of BPO in DMSO. The final product obtained was in the form of white powder for both NIP and MIP [29, 30].

Characterization of MIP and NIP: Scanning electron microscopy

The structure and surface morphology of MIP and NIP were observed by using a Scanning Electron Microscope (SEM) at a magnification of 1000x. The NIP and MIP were synthesized in the form of white powder. The SEM micrographs for MIP and NIP are shown in Figure 3.

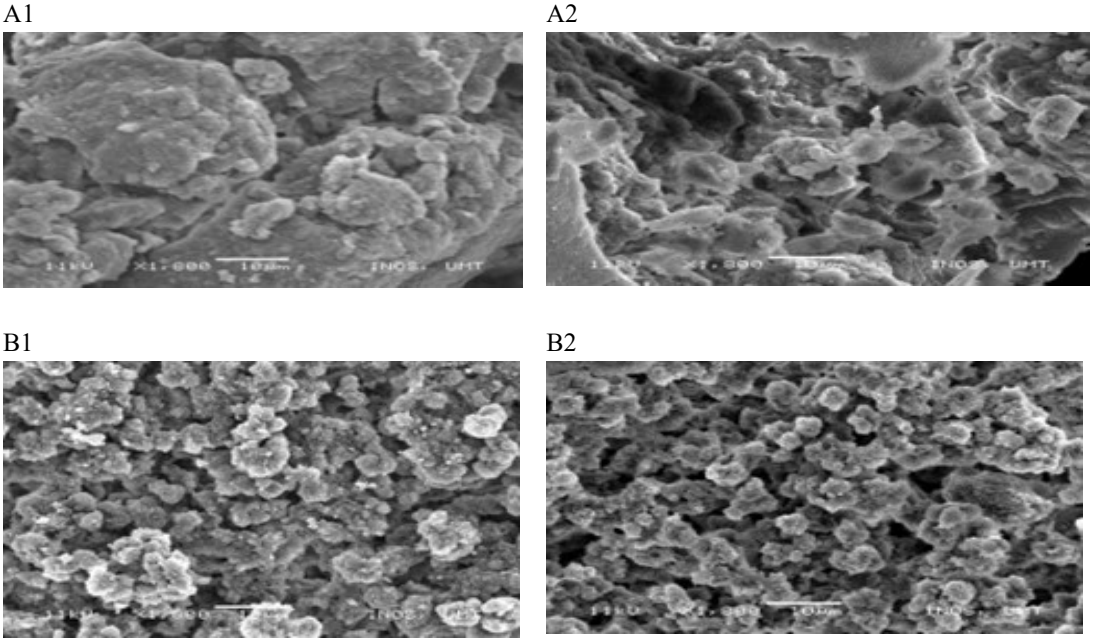

Figure 3. The morphology of MIP and NIP under SEM. A1 and A2 indicates the NIP before and after template removal. Meanwhile, B1 and B2 refer to the MIP before and after template removal

The NIPs before and after the template removal process (A1, A2) exhibit clean surface characteristics with no distinctive pores. The NIP was synthesized without the presence of a template (DA). The NIP after template removal (A2) shows a rougher surface characteristic, which was caused by the removal of unreactive substances from the polymer.

The MIP-DA complex can be seen in Figure 3 (B1 and B2). The pore diameter in B2 is clearer and more prominent when compared to B1. These pores in MIP are the cavities used for embedding the DA template molecule. After the template removal process, the MIP surface was cleaner as all the unreactive particles were flushed from the imprinted polymer, showing complex binding sites and a more distinctive shape than NIP. This difference may be caused by the stable interaction between DA and monomer, where the template was successfully imprinted onto the polymers during the pre-polymerization process. From Figure B1 and B2, it can be seen that both prepared polymer particles are non-spherical and not completely in uniform size and shape, as well as aggregation. This might be caused by the structure of monomer (HEMA) which is quite complicated and has a branched hydrocarbon tail when compared to other monomers such as methacrylic acid (MAA). Therefore, a homogenous spherical shape was unable to be maintained for both MIP and NIP. Another possible reason might due to the inconstant temperature setting (40 ˚C - 60˚C) utilized in the polymerization process. According to Mayes and Whitcombe (2005) [31], the polymerization temperature should be controlled to stabilize the interactions between template and monomer. Low polymerization temperature and low polarity solvents will favor the hydrogen bonding interactions.

Fourier transform infrared

The NIP, MIP-DA, and leached MIP were analyzed under FT-IR spectroscopy as shown in Figure 4. A wide OH stretch can be seen at 3471.68 cm^{-1}, which might indicate the presence of carboxylic acid from the ester group. The presence of imine group (-NH) can be seen at the wavenumber 3408.22 cm^{-1}, where a weak stretch in MIP-DA and MIP spectra exists. The intensity of the NH stretch in MIP is lower than MIP-DA; this might be due to the lack of DA presence in MIP after template leaching. The peak of sp^3 CH can be seen at 2954.95 cm^{-1}. The intensity of the sp3 CH stretch is almost similar for NIP and MIP-DA, while MIP shows a decrease in the peak intensity. The decrease of peak intensity in the leached MIP might indicate the successful removal of unreacted particles in polymers. At 1720.50 cm^{-1}, a peak of C=O stretching can be seen, with NIP and MIP-DA spectra exhibiting the highest intensity value, albeit MIP-DA spectra showing a slight decrease in intensity, due to the ester groups of EGDMA [32]. The decrease in intensity of C=O in MIP-DA might be due to the reaction of the cross-linker and DA in the polymer matrix. The low intensity of C=O functional group in MIP might be due to the successful removal of the template (DA). A peak of N-H bend at 1581.63 cm^{-1} can be seen in MIP-DA and MIP spectra, indicating the presence of DA in the imprinted polymer. The O-H bend of carboxylic acid was exhibited at 1444.68 cm^{-1} which can be seen present in all spectra. The presence of OH functional group denotes the esters of monomer and cross linkers in the polymer matrix. The stretching of C-O functional group was exhibited by all the spectra at 1188.15 cm^{-1} and 1139.93 cm^{-1}. The C-O peak of MIP shows a lower intensity than NIP and MIP-DA, as the unreactive particles were removed from the polymer during the leaching process. The sp2 CH bend of alkene can be seen at 991.34 cm^{-1} in the spectra of NIP, MIP-DA, and MIP.

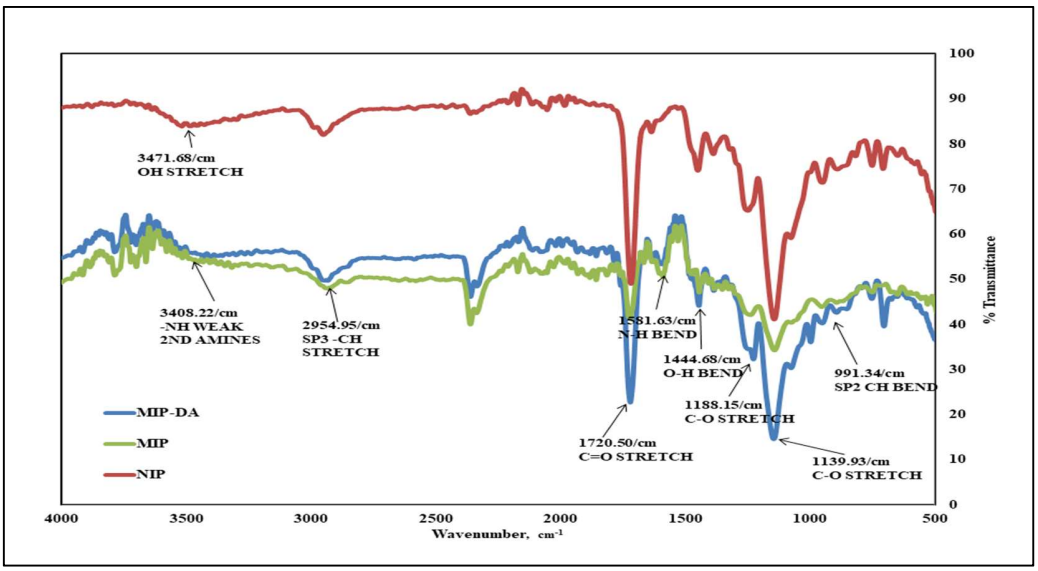

Figure 4. Infrared spectra of Non-Imprinted Polymer, NIP, Molecular Imprinted Polymer, MIP-DA, and MIP after template removal

BET porosity analysis

Figure 5 shows the adsorption-desorption isotherm analysis for NIP, MIP-DA, and MIP polymer matrix. The physisorption isotherm of all polymer matrices exhibits a type IV isotherm. Type IV isotherm is a monolayer-multilayer adsorption and capillary condensation with complete pore filling. The result indicates that the polymer matrix is mesoporous, with pores in the range of 1.5 – 100 nm. The type IV isotherm can be characterized by capillary condensation which occurs in mesoporous polymer structures that exhibit a hysteresis loop. In Figure 5 (A), the NIP exhibits H4

type, where polymer contains narrow slit pores including the pores in the micropores region, which conclude that no existing imprint is present in the NIP polymer matrix [33]. Figure 5 (B) and 5(C) prove that MIP was included in the H3 hysteresis type, indicating that the imprinted polymer structure is a non-rigid aggregate with slit shaped 'ink-bottled' pores [34]. Figure 5(C) shows a slightly wider adsorption and desorption region, which indicates an increase in the pore size of MIP after the template removal process. This can be further proven by Table 1, where the pore size of MIP before and after template removal is 11.7nm and 12.9nm respectively. The surface area and pore volume of NIP is 102 m^2/g and 0.29 cm^3/g respectively as shown in Table 1, which is smaller than MIP (a) and MIP (b). The result indicates that almost no imprint exists in NIP.

The resulting pore size of NIP might be due to swelling of non-rigid pores in the polymer matrix during the condensation process. The pore size of NIP, MIP(a), and MIP(b) is in the range of 0-100 nm, which verifies that the polymers are mesoporous.

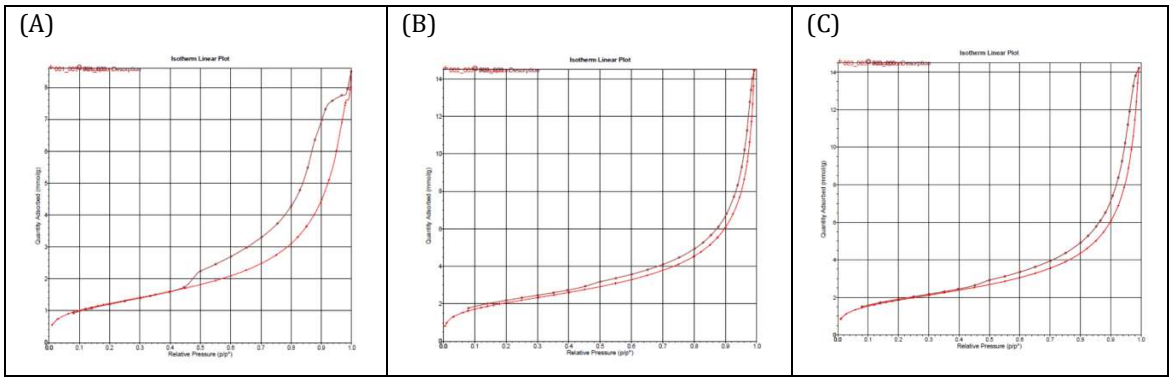

Figure 5. BET adsorption-desorption isotherm analysis of NIP (A), MIP-DA (B), and MIP after DA removal (C). Quantity adsorbed (mmol/g) versus relative pressure (p/p^o)

Table 1. Analysis of MIP and NIP porosity using BET

Sample	Surface Area (m^2/g)	Pore Volume (cm^3/g)	Pore Size (nm)
NIP	102	0.29	11.5
MIP a	170	0.50	11.7
MIP b	153	0.49	12.9

a: before template removal, b: after template removal

Validation study of DA standard solution

The standard solution of DA was validated using a UV-VIS spectrophotometer at wavelength of 242nm. The validation study was conducted for DA of various concentrations in distilled water. The absorbance value of domoic acid was used to construct a calibration plot as shown in Figure 6. The increasing absorbance value was clearly shown with increasing DA concentration. The regression correlation for the calibration curve is R^2=0.9888 with a slope value of 0.051. The limit of detection (LOD) and limit of quantification (LOQ) for DA was calculated using the formula,

$$\text{LOD} = \frac{3.3\sigma}{S} \quad (1)$$

$$\text{LOQ} = \frac{10\sigma}{S} \quad (2)$$

Where σ refers to the standard deviation of the response and S is the slope value from the calibration curve. The LOD and LOQ values calculated for DA using the formulas are 1.418 and 4.2983 ppm, respectively.

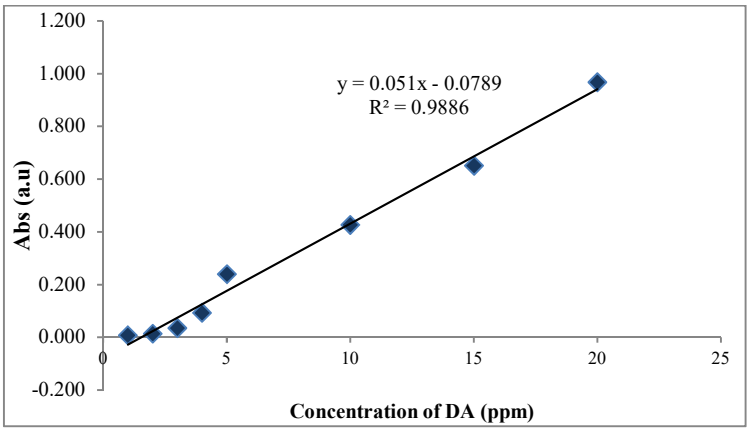

Figure 6. Calibration plot of absorbance (a.u) against concentration of DA (ppm)

Batch rebinding experiments: Adsorption capacity of DA with MIP

The effect of immersion time and mass of molecularly imprinted polymer over domoic acid adsorption capacity was investigated for optimization purposes. Figure 7 shows the graph of adsorption capacity, Q_e against immersion time of different masses of MIP with DA at fixed concentration. The binding capacity of MIP was calculated using formula 3.

$$Q_c = \frac{(C_i - C_f)V}{m} \quad (3)$$

Where Q is the adsorption capacity (mg/g), C_i and C_f indicate the initial and final concentrations of DA (ppm), V is the volume of the aqueous solution (ml), and m is the weight of the polymer (g).

The increasing trend of adsorption capacity (Q_e) values for MIP against time in different imprinted polymer weights from zero to fifteen minutes is shown. From 15 to 25 minutes of reaction time, no significant difference in Q_e values can be seen, indicating that the equilibrium concentration of DA in the system was achieved.

Meanwhile, the increasing mass of imprinted polymer shows a significant decrease in Q_e values of the MIP-DA reaction. In Figure 7, 5mg of MIP shows the highest adsorption value when compared to other masses of MIP used in the study, with a significantly large Q_e value. Low adsorption capacity shown in 10mg, 15mg, 20mg and 25mg of MIP was contributed by deep imprinted pores that cause the bleeding of excess templates in molecular imprinted polymer, resulting in the collapse of the equilibrium system [35]. The equilibrium adsorption capacity for MIP was achieved with the best reaction time and mass of MIP at 15min and 5mg, respectively. The optimum weight and reaction time obtained were 5mg and 15min, respectively.

Reaction response of DA with NIP and MIP

The study for reaction response of NIP and MIP with different concentrations of DA was conducted to determine the selectivity of the sensing system at equilibrium condition as shown in Figure 8 below. The adsorption capacity of DA from a concentration of 1 to 20 ppm shows increasing values for both MIP and NIP. The positive value of adsorption capacity for MIP shows an increasing trend from 1ppm to 20ppm. However, the Q_e value for MIP is not significantly large. The results might be due to the low imprinting effect of the MIP where weak imprinted complexes are formed due to the dominant role of the cross-linker during the pre-polymerization process [36]. The adsorption capacity of NIP during the adsorption study shows positive results

starting from 10ppm to 20ppm, which indicates the presence of non-selective binding sites on the surface of the polymer. This might be due to the swelling of polymer surface and the hydrogen bonding interaction between the COOH functional group of DA and the acidic non-specific binding sites of NIP [37].

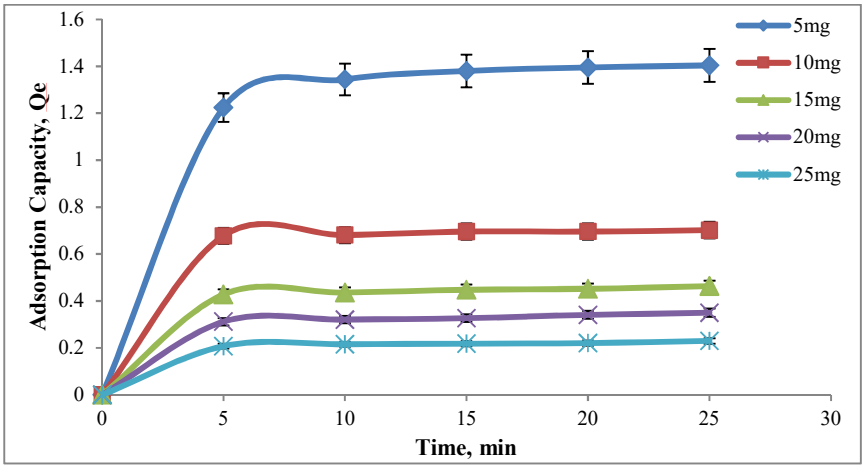

Figure 7. Optimization study of MIP with mass and time as the parameter

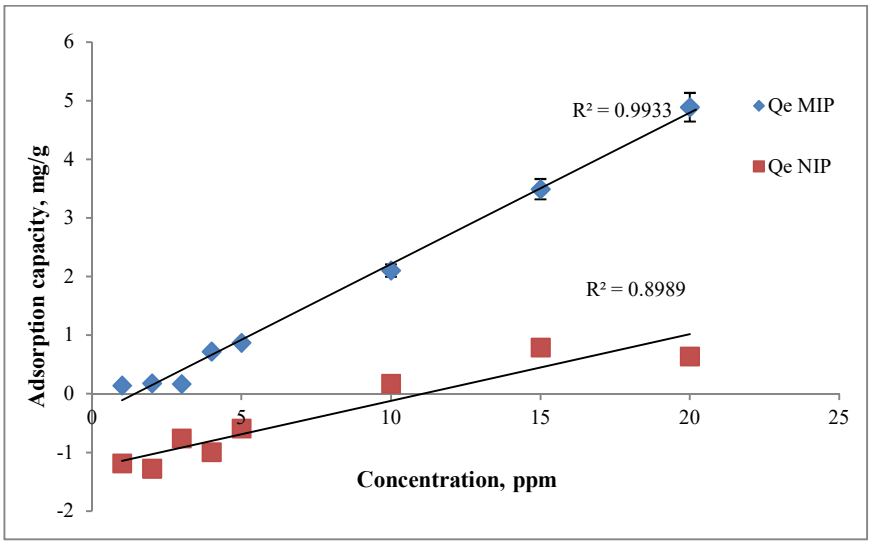

Figure 8. The adsorption capacity of NIP and MIP with various concentrations of DA in equilibrium condition

Adsorption isotherm study

Adsorption isotherm is described as the retention (release) of substances on a solid in various concentrations [38]. The Langmuir isotherm is defined as a system where homogenous adsorption of fixed, localized, identical sites project similar affinities to adsorbate, where no further reaction occurs approaching equilibrium saturation point [39]. The model can be linearized and non-linearized according to the formulas 4 and 5 shown below.

$$Qe = \frac{Q_O K_L C_e}{1+K_L C_e} \quad (4)$$

$$\frac{1}{Qe} = \left(\frac{1}{Q_O K_L}\right)\frac{1}{C_e} + \frac{1}{Q_O} \quad (5)$$

Where Q_e indicates the binding capacities at equilibrium (mg/g); Q_o denotes the maximum adsorption capacities of the adsorbate (mg/g); K_L refers to the Langmuir constant (L/mg); C_e is the concentration of domoic acid at equilibrium (ppm). The data was fitted into a Langmuir isotherm model of $1/C_e$ versus $1/Q_e$ as plotted in Figure 9(a). The separation factor, R_L of the Langmuir isotherm was calculated using formula 6.

$$R_L = \frac{1}{1+K_L C_O} \quad (6)$$

Where K_L indicates the Langmuir constant (L/mg) and C_O refers to the initial concentration of DA (ppm).

The Freundlich isotherm model is used to analyze the adsorption isotherm in order to define the surface heterogeneity and adsorption intensity of the adsorbate sites. The linear and non- linear equations of the model were indicated as shown in formula 7 and 8, respectively.

$$Q_e = K_f C_e^{\frac{1}{n}} \quad (7)$$

$$logQ_e = logK_f + \frac{1}{n} logC_e \quad (8)$$

Where K_f indicates the adsorption capacity (L/mg) and 1/n refers to the adsorption intensity. This isotherm model was fitted into a graph by plotting log C_e against log Q_e as shown in Figure 9(b).

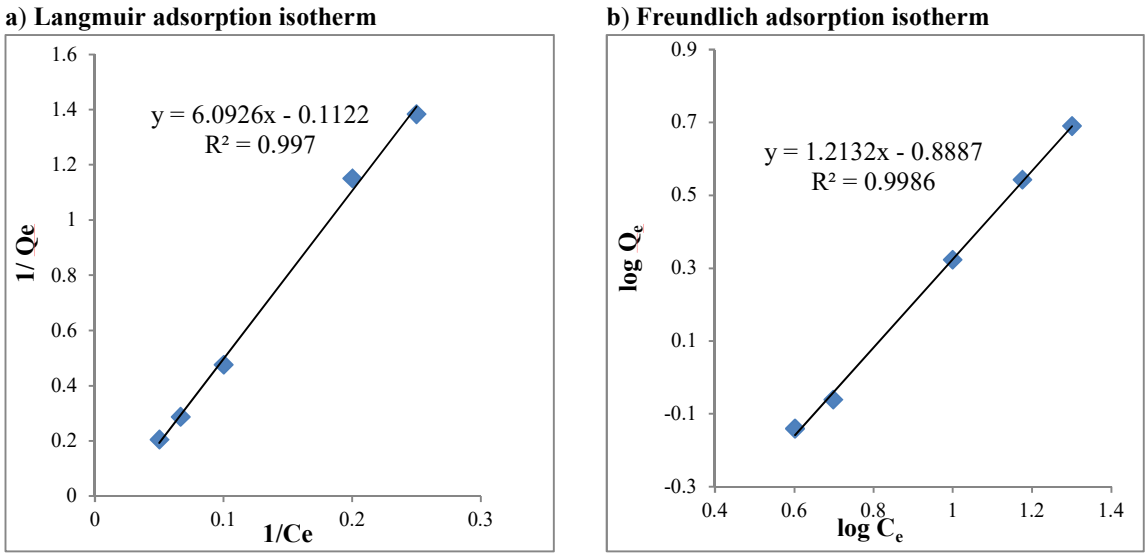

Figure 9. The graph of adsorption isotherm model study of MIP with DA where; a) Langmuir adsorption isotherm, b) Freundlich adsorption isotherm

The separation factor (R_L) value was used to conclude the favorability of adsorption. R_L values more than 1 indicate that an unfavorable adsorption occurs in the system. Linear adsorption occurs when R_L = 1, while irreversible adsorption occurs when R_L=0. However, 0 < R_L < 1 indicates favorable adsorption [40]. From table 2, the R_L values for the Langmuir isotherm were calculated, where R_L>1. It indicates unfavorable adsorption reactions occurring in the environment. The value of K_L is less than zero, which implies that a large surface area and pore volume of MIP results in a lower adsorption capacity [41].

The experimental data was fitted into the Freundlich isotherm model in order to define the surface heterogeneity and adsorption intensity of the adsorbate

sites. Meanwhile, for the Freundlich isotherm model, the value of 1/n that represents the adsorption intensity is more than 1, indicating cooperative adsorption between DA and MIP.

The R^2 of the Freundlich model is 0.9986 which is approaching 1 compared to the Langmuir model where the R^2 is 0.997. From R^2 values, the Freundlich model isotherm is better fitted for DA and MIP binding systems rather than the Langmuir isotherm model. The result suggests that multilayer chemisorption occurs for DA in MIP [42]. The calculated data for parameters representing the Langmuir and Freundlich isotherm models is tabulated in Table 2.

Table 2. Constant parameters of Langmuir and Freundlich Isotherm model for MIP

Isotherm Model	Langmuir	Freundlich
Equation	y = 6.0936x- 0.1122	y =1.2132x-0.8887
Q_o (mg/g)	-8.9126	-
K_L (L/mg)	-0.0184	-
R_L	1.1013	-
1/n	-	1.2132
n	-	0.8243
K_f (mg/g)	-	0.4112
R^2	0.997	0.9986

Reproducibility of MIP

This study was conducted to analyze the effectiveness and practicability of the preparation method and whether it can be reproduced in its entirety under changing conditions [43]. Five batches of MIP were synthesized in triplicates under optimized conditions. The data collected was analyzed, and a graph was constructed (as shown in Figure 10) to exhibit the reproducibility of the MIP sensing system. The five (5) batches of MIP showed no significant difference in absorbance values. The %RSD for the reproducibility of MIP was calculated, with the value ranging from 3.22% – 5.19% (n=5). The low values of %RSD reflect the good performances of MIP in DA determination.

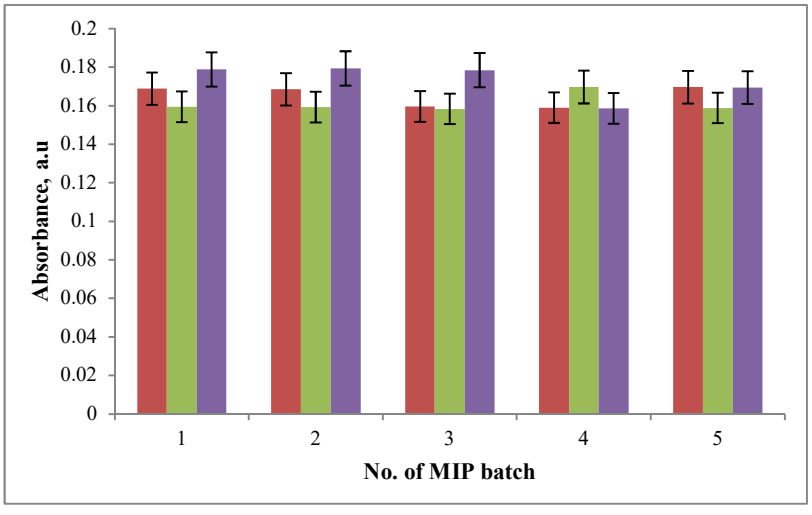

Figure 10. The reproducibility study of MIP in optimized condition

Reusability of MIP

Reusability is defined as repeat measurements made on the same subject under identical conditions. The reusability study was conducted by using one (1) set of MIP for five cycles of DA adsorption. The MIP was re-washed and re-used to reflect the reusability of the sensing system. The absorbance values for each cycle in the reusability analysis are shown in Figure 11. From Figure 11, cycles 1 to 3 show no difference in absorbance values, indicating the stability in DA detection. However, the fourth cycle shows a high value of DA present in the system. This condition might occur due to the bleeding of un-leached template molecules that are retained in the MIP from the first three cycles. The %RSD value calculated for the reusability test is 2.97% (n=5), which indicates the suitability of MIP as a disposable sensor for the detection of DA, which can be used three times.

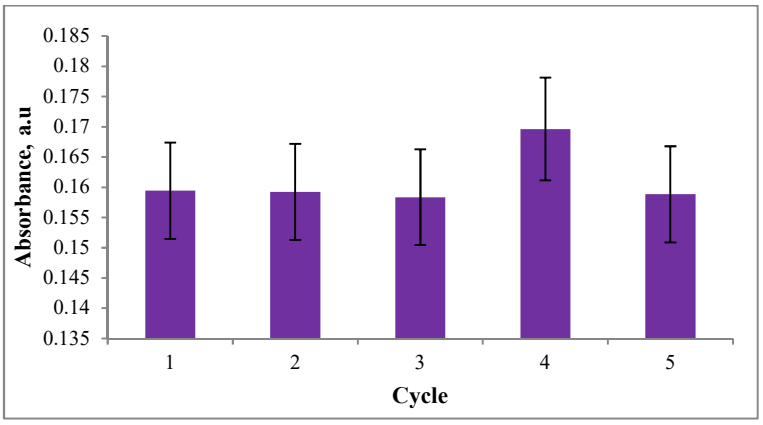

Figure 11. The reusability of MIP for adsorption of DA in 5 cycles

Application of MIP with real samples

The selected shellfish (cockle and mussel) used for this study were purchased from local fishermen and grocery stores. Table 3 shows the final concentration and percentage recovery for spiked and non-spiked cockle and mussel samples.

Table 3. Spike and recovery results of domoic acid in cockle and mussel tissue

Types of Shellfish	Non-spiked	Spiked (5 ppm)	
		Final Concentration, ppm	% Recovery
Cockle	Undetected	4.79	95.88
Mussel	Undetected	4.13	82.71

From the initial concentration (5ppm) of DA used, 4.79ppm and 4.13ppm were recovered from the spiked tissue of cockle and mussel, respectively, using the MIP sensing system. The percentage recovery for cockle and mussel was calculated to be 95.88% and 82.71%, respectively. However, no DA was presence was detected from non-spiked samples when analyzed using UV-VIS spectrophotometry.

Conclusion

In this study, a selective and sensitive MIP sensing system was successfully synthesized using non-covalent bulk polymerization techniques. The lower values of %RSD for reproducibility and reusability of MIP indicate better performances for the sensing system. From the adsorption isotherm analysis, the Freudlich isotherm model was found to be a better fit for analyzing the binding affinity of MIP with DA. The MIP sensing

system for DA was successfully applied to real samples (cockle and mussel).

Abstract

Magnesium-modified biochar (MB) is used to recover phosphate (PO_4^{3-}) from urine by struvite precipitation. Pyrolysis of sawdust (SD) at 700°C and subsequent impregnation with MgO_2 produced MB. Virgin and spent MB were characterized for proximate analysis, surface morphology, elemental composition, specific surface area, and functional groups using thermogravimetric analysis (TGA), scanning electron micrography (SEM), energy dispersive X-ray (EDX) analysis, surface area analysis, and Fourier transform infrared (FTIR) spectroscopy, respectively. The batch sorption experiments were conducted on MB using artificial human urine (AHU), where residual PO_4^{3-} was quantified by colorimetry. Sorption data were analyzed using various isotherm (i.e., Langmuir and Freundlich) and kinetic models (i.e., pseudo-first and pseudo-second-order) for elucidation of sorptive potential and mechanism. Pyrolysis of SD produced porous sawdust biochar (SB) with a high surface area. However, modification with MgO_2 decreased the surface area of MB, possibly due to the loss of micropores from oxidation and deposition of struvite as confirmed by SEM-EDX analysis. FTIR analysis showed that polar functional groups such as carboxylate (1641 cm^{-1}), phenolate (1300 cm^{-1}), and amide (1674 cm^{-1}) were mainly involved in the Mg^{2+} and PO_4^{3-} adsorption. The PO_4^{3-}sorption capacity for MB was 8967 mg/g at a sorbent/solution ratio of 0.1 g/L after 120 min of contact time. Sorption of PO_4^{3-} occurred on a heterogeneous MB surface with a possible multilayer adsorption mechanism. The kinetic study suggested that the sorption of PO_4^{3-} by MB was a chemisorption process. The presence of Mg in MB aided the formation of struvite in MB and enhanced the recovery of PO_4^{3-} from

AHU. Spent MB exhibited higher ability in immobilizing soil Pb compared to ground magnesium limestone (GML) at a similar application rate (5% w/w). Spend MB can be recovered as fertilizer or immobilizing heavy metals such as lead in soil.

Keywords: oxidized biochar, magnesium peroxide, struvite, phosphate recovery, human urine

Abstrak

Biochar yang diubah suai dengan magnesium (MB) digunakan untuk memulihkan fosfat (PO_4^{3-}) daripada air kencing melalui pemendakan struvite. Pirolisis habuk papan (SD) pada 700°C dan impregnasi seterusnya dengan MgO_2 menghasilkan MB. Kedua-dua MB mentah dan terpakai dicirikan pada analisis proksimat, morfologi permukaan, komposisi unsur, luas permukaan spesifik dan kumpulan berfungsi telah dijalankan menggunakan penganalisis termogravimetrik (TGA), pengimbasan mikrografi elektron (SEM), analisis sinar-X penyebaran tenaga (EDX), penganalisis luas permukaan, dan spektroskopi Inframerah transformasi Fourier (FTIR), masing-masing. Eksperimen jerapan telah dijalankan pada MB menggunakan air kencing manusia tiruan (AHU), di mana sisa PO_4^{3-} ditentukan dengan teknik kolorimetri. Data jerapan dianalisis menggunakan pelbagai model isoterma (iaitu, Langmuir and Freundlich) dan kinetik (iaitu, pseudo-tertib-pertama and pseudo-tertib-kedua) untuk penjelasan potensi dan mekanisme jerapan. Pirolisis SD menghasilkan biochar (SB) berliang dengan luas permukaan yang tinggi. Walau bagaimanapun, pengubahsuaian dengan MgO_2 mengurangkan luas permukaan MB, mungkin disebabkan oleh kehilangan mikropori daripada pengoksidaan dan pemendapan struvite seperti yang disahkan oleh analisis SEM-EDX. Analisis FTIR menunjukkan kehadiran kumpulan berfungsi polar seperti karboksilat (1641 cm^{-1}), fenolat (1300 cm^{-1}), dan amida (1674 cm^{-1}) terlibat terutamanya dalam penjerapan Mg^{2+} dan PO_4^{3-}. Kapasiti penyerapan PO_4^{3-} untuk MB ialah 8967 mg/g pada nisbah sorben/larutan 0.1g/L selepas 120 minit masa sentuhan. Penyerapan PO_4^{3-} berkemungkinan berlaku pada permukaan MB heterogen dengan mekanisme penjerapan berbilang lapisan. Kajian kinetik menunjukan bahawa proses penjerapan PO_4^{3-} oleh MB adalah melalui proses kimia. Kehadiran Mg dalam MB membantu pemendakan struvite dalam MB, dan meningkatkan prestasi pemulihan PO_4^{3-} daripada AHU. MB terpakai lebih cekap dalam imobilisasi plumbum di dalam tanah berbanding dengan batu kapur magnesium terkisar (GML) pada kadar penggunaan yang sama (5 % w/w). MB terpakai boleh dikitar semula sebagai baja atau merawat tanah yang tercemar dengan logam berat seperti plumbum.

Kata kunci: biochar teroksida, magnesium peroksida, struvite, pengambilan semula fosfat, urin manusia

Introduction

Phosphorus is a macronutrient that occurs naturally in the orthophosphate (PO_4^{3-}) form and is essential for all living organisms [1]. According to the Malaysian Department of Environment, the permissible level of PO_4^{3-} in effluent discharge is 5 mg/L [2]. Excessive PO_4^{3-} in aquatic environments may cause eutrophication. Human urine is managed through a modern sewer system and treated biologically to effectively remove PO_4^{3-} [3]. Despite the abundance of PO_4^{3-} in human urine, its recovery is associated with the risk of pathogen infection and adverse effects of residual pharmaceutical products. Despite the challenges, human urine is a renewable source of PO_4^{3-} that can be recovered for crop production [4]. Adsorption is an energy-efficient and low-cost technique for recovering PO_4^{3-} from human urine [5]. Furthermore, the yield of PO_4^{3-} recovery can be improved by slightly increasing the pH value of human urine [6].

Biochar is a sorbent commonly used for the removal of pollutants from the environment. Pyrolysis of agricultural biomass at a high temperature (i.e., >500 °C) and anoxic conditions can produce carbon-rich and porous biochars [7]. The surface of low-temperature biochars often contains plenty of polar functional groups (i.e., phenol and hydroxyl [8]. A slightly alkaline condition allows deprotonation of the polar functional groups and may be used for adsorbing pollutants that possess a net positive charge [9]. Moreover, biochar is considered a recalcitrant organic carbon that can withstand microbial decomposition. The application of biochar allows the storage of carbon in the soil, reduces greenhouse gas emissions, and helps combat climate change [10]. The improvement of soil fertility by the addition of biochar helps the greening and reclamation of the polluted land and increases the capacity for holding cationic nutrients [11].

Residual minerals in biochar consist mainly of oxides of alkaline (i.e., K_2O) or earth alkaline metals (i.e., CaO, MgO), providing an alkaline condition that can improve

electrostatic attraction and precipitation of PO_4^{3-} ions [12]. Moreover, polar functional groups may react with Ca^{2+} or Mg^{2+} cations to acquire a positively charged surface and become a medium for binding PO_4^{3-} ion [13]. However, the CaO content in biochars may be insufficient for effectively recovering PO_4^{3-} from human urine. Various methods have been used for artificially introducing Ca and Mg into biochar. Magnesium chloride ($MgCl_2$) and oxide (MgO) were commonly used for modifying biochar [14]. An activation of biochar with MgO has successfully increased the surface functional group, porosity, surface area, and PO_4^{3-} removal [15]. The introduction of Mg is often associated with a high PO_4^{3-} removal due to the precipitation of struvite, which is formed with the addition of phosphate into a portion of ammonium and magnesium at equal ratio concentrations [16].

Even though the pyrolysis process at high temperature produces porous biochar, possible decarboxylation may cause a net loss of polar functional groups such as carboxylate and phenolate groups [17]. The presence of the negative-charged polar organic functional groups on the biochar surfaces is crucial for its function in soil fertility, including the retention of essential cations such as Mg^{2+} [18]. Oxidation can be introduced to improve the negative surface of high-temperature biochars. Recent studies have shown the great potential of combining electro-oxidation for improving the porosity and capacity of biochar to retain Mg for recovering PO_4^{3-} [19]. Alternatively, biochar can be chemically oxidized and impregnated with Mg simultaneously using magnesium peroxide (MgO_2). The oxidation and subsequent Mg-deposition can be controlled by decreasing and increasing the solution pH, respectively. The slow dissolution of MgO_2 in slightly acidic water at room temperature allows the slow release of dissolved oxygen for minimizing damage to the microporous structure of the biochar during oxidation. Upon complete dissolution of MgO_2, the adsorption and precipitation of soluble Mg^{2+} can be enhanced by slowly increasing the solution pH. In this study, sawdust is a widely available solid waste from the sawmill and was used as the precursor for the production of biochar.

Materials and Methods

Preparation of sawdust (SD) and sawdust biochar (SB)

About 10 kg of SD was collected from a furniture processing plant at Klang, Selangor. The SD was washed with tap water and oven-dried overnight at 105 °C. Then, the SD was pulverized using a mixer grinder and sieved to a particle diameter of <150 μm. About 500 g of the SD was converted into SB through slow pyrolysis at 700 °C in a furnace with nitrogen gas at a flow rate of 10 L/min. The pH value of the resulting SB was measured with a pH meter at SB/DI water mass ratio of 1:10 [20]. The SB was washed further with warm DI water until it reached a pH value of 8. The SB was then placed in the lid-covered metal crucibles and allowed to dry in a dehydrating cabinet at 60 °C for 24 h.

Modification of SB with MgO_2

The preparation of MgO_2-modified biochar (MB) followed the method described by Tan et al. [21] and is optimized at 5% w/v MgO_2 concentrations. Thirty millilitres of each MgO_2 solution were mixed with 1.0 g SB. The solution was adjusted to a pH value of 2 by adding 65% HNO_3 drop by drop using an auto titrator. The mixture was agitated for a few minutes until the effervescence ceased, and then agitated for a further 30 min. The mixture was allowed to rest overnight at room temperature (25°C). The pH of the biochar was adjusted to a pH value between 6.0 and 6.5 by adding 1.0 M NaOH using an auto titrator and then agitated for 4 h with a magnetic stirrer at room temperature. Then, MB was collected after filtration, oven-dried at 90 °C, and then pulverized to a desired particle size of 0.20–0.45 mm [21].

Chemical characterization for SD, SB, and MB

Surface morphology and elemental composition were investigated using scanning electron microscopy (SEM) with energy dispersive X-ray spectroscopy (EDX) (Hitachi TM3030plus). About 1 mg of sample was coated with a thin layer of carbon and mounted on a copper stub using double-stick carbon tape. Thermal degradation analysis was conducted on the as-receive SD (10 mg) using a thermogravimetric analyzer (TGA) (Setaram Setsys Evolution TGA-DTG/DSC High Temperature (2400) instrument at a heating rate of

10℃/min, and a peak temperature of 900 ℃ in a nitrogen atmosphere. The TGA and differential thermogravimetric (DTG) data were analyzed using AKTS Thermokinetics software. Major inorganic elements were determined using the Association of Official Analytical Chemists (AOAC) method of acid digesting the samples (1.0 g) for multi-elemental analysis by ICP-OES. The presence of functional groups on samples was studied using Fourier transform infrared (FTIR) spectroscopy. About 5 mg of sample was mixed with potassium bromide KBr at approximately 0.1% w/w and pressed into pellets. The spectra of the samples were collected using an FTIR spectrometer (Perkin Elmer) by averaging 32 scans in the range of 400 to 4000 cm^{-1}. The baseline of spectra was corrected, and the curve of spectra was smoothened. The surface area was determined with 0.5 g of SB or MB samples using N_2 sorption isotherms run on Macromeritics ASAP 2010, USA. The samples were degassed at 200 °C for 8 h prior to analysis.

Chemical characterization for soil

The soil samples were air-dried and pulverized with an agate mortar to pass a 200 μm (80 mesh) sieve. The cation exchange capacity (CEC) was determined using the sodium acetate method [22]. The pH and electrical conductivity (EC) were measured on a soil slurry with a solid/solution ratio of 1:10, using a calibrated pH meter and EC meter respectively.

Sorption of MB with artificial human urine (AHU)

For the batch sorption experiment, AHU that contains 30 g PO_4^{3-}/L was prepared according to the method described by [23] (Table 1). The pH value of AHU was adjusted to the 6.0-6.5 pH range with 1.0 N HCl and 1.0 N NaOH. Stock AHU was stored in a plastic container at 4°C. The AHU stock was warmed to room temperature before being used. Finally, 100 mg of albumin and 4.0 g of creatinine were slowly mixed into the 2.0 L of the AHU solution.

Table 1. Properties and Composition of Artificial Human Urine [23]

Property and Composition	Amount
pH	6.0 - 6.5
Specific gravity (g/mL)	1.020
Osmolality (mOsm/kg)	861
Urea (mM)	416
NaH_2PO_4 (mM)	17.60
NaCl (mM)	154.00
NH_4Cl (mM)	48.00
Na_2SO_4 (mM)	21.10

Batch adsorption experiments were conducted by studying the effect of Mg content in MB, MB dosage, contact time, and initial concentration of AHU on adsorption of PO_4^{3-} MB. Various amount of MB (i.e., 0.005, 0.01, 0.05, and 0.10 g) was weight and agitated with 30 mL of stock AHU in 50 mL centrifuge tubes using a rotator at 100 rpm at room temperature for 4 h. Blanks containing AHU without MB were also included in the same experiments. After 4 h of agitation, the residual AHU solutions were filtered with a 0.45 μm syringe filter, and the concentration of PO_4^{3-} was determined by colorimetry using a UV-VIS spectrophotometer and a combined reagent (i.e., potassium antimony tartrate solution, ammonium molybdate solution, and ascorbic acid solution). Thirteen millilitres of combined reagent were added to 1.0 mL of residual AHU solution in a 25 mL volumetric flask, topped to the mark with DI water, and shaken thoroughly. It was then allowed to stand for 30 min for colour development. The absorbance was measured at 880 nm in a 1-cm quartz cuvette. A calibration curve was prepared by plotting the absorbances of PO_4^{3-} standards with various concentrations and was then used to determine the concentration of PO_4^{3-} in AHU.

The PO_4^{3-} removal percentage and uptake were calculated using equations 1 and 2, respectively. The dosage of MB that gives the highest removal percentage

(i.e., 0.10 g) was chosen for the next sorption experiments.

$$\text{Removal percentage (\% w/w)} = \frac{\text{P}_{\text{initial}} - \text{P}_{\text{final}}}{\text{P}_{\text{initial}}} \times 100\ \% \quad (1)$$

$$\text{Uptake, } q_e \text{ (mg/g)} = \frac{(P_{initial} - P_{final})V}{M} \quad (2)$$

Where $P_{initial}$ and P_{final} (mg/L) are the initial and equilibrium concentrations of PO_4^{3-}. V is the volume of the AHU (L), and M is the mass of dry MB (g).

For the sorption isotherm experiment, 10 g of MB were agitated with 30 mL AHU at various PO_4^{3-} concentrations (i.e., 66.8, 93.1, 237, 520, 683, 734, 1636, 2472, and 3038 mg/L) in closed 50 mL centrifuge tubes using a rotator at 100 rpm and room temperature for 4 h. For sorption kinetic study, 10 g of MB was agitated at 100 rpm with 30 mL AHU (initial PO_4^{3-} concentration 374 mg/L) in a 50 mL centrifuge tube at room temperature for 4 h. All residual AHU solutions were filtered through a 0.45 µm syringe filter, and the concentration of PO_4^{3-} was determined by colorimetry. The PO_4^{3-} uptake by MB was calculated using equation 2 and studied using non-linear Langmuir (Equation 3) and Freundlich (Equation 4) isotherm models as well as non-linear pseudo-first-order (Equation 5) and pseudo-second-order (Equation 6) kinetic models.

Langmuir isotherm model:

$$q_{\text{e}} = \frac{q_{\text{max}} \cdot K_{\text{L}} \cdot C_{\text{e}}}{1 + K_{\text{L}} \cdot C_e} \quad (3)$$

Freundlich isotherm model:

$$q_{\text{e}} = K_{\text{F}} \cdot C_{\text{e}}^{1/\text{n}} \quad (4)$$

Where q_e (mg/g) is the PO_4^{3-} uptake, and C_e (mg/L) the concentration of PO_4^{3-} in residual AHU solution at equilibrium. K_L is the equilibrium constant for the Langmuir model. Lastly, K_f [(mg g^{-1})(mg L^{-1}) ^{n}] is the Freundlich constant that is related to adsorption capacity, and n is the Freundlich constant related to adsorption intensity. Graphs of q_e versus C_e were plotted to determine Langmuir and Freundlich parameters. Then the parameters were compared to determine the isotherm model that best fit the sorption data.

The pseudo-first-order model:

$$q_{\text{t}} = q_{\text{e}} \left(1 - e^{-k_1 t}\right) \quad (5)$$

The pseudo-second-order model:

$$q_{\text{t}} = \frac{k_2 \cdot q_e^2 \cdot t}{1 + K_2 \cdot q_{\text{e}} t} \quad (6)$$

Where q_e (mg/g) is the uptake of PO_4^{3-} at equilibrium and q_t (mg/g) is the amount of phosphate from AHU adsorbed at time, respectively. Next, t is the contact time in minutes, and the adsorption rate constants, k_1 (1/min) is the rate constant for the pseudo-first-order model, while k_2 (g/[mg.min]) is the rate constant of the pseudo-second-order model. Parameters for both kinetic models were determined by plotting a graph of q_t (mg/g) versus t (min).

Leaching tests

The leaching test followed the method described by [24] with several modifications. Calcium chloride solution (0.01M, pH = 7) was used to fill up the 50 mL syringe columns that were then irrigated on MB in the syringe column. Lead-contaminated soil was collected from a shooting range located in Universiti Pertahanan Nasional Malaysia (UPNM). The 50 mL syringe columns of MB were irrigated with $CaCl_2$ using a flow rate that represents the average distribution of rainfall intensity in Peninsular Malaysia (i.e., >10 mm/h) [25]. The total duration of the experiment was 36 h. The leachate produced by each column was sampled in 10 mL volume intervals. The samples were collected in acid-washed 50 mL centrifuge bottles and stored at 3.9 °C until analysis. A tip at the bottom was used to direct the outflow into sampling containers. The 50 mL syringe columns had a diameter of 3.0 cm and were filled with soil and MB to a height of 7.35 cm according to the weight ratio in Table 2. At the bottom of the 50 mL syringe columns, a 1 mm mesh-sized gauze was attached to hold the soil in place. Untreated shooting range soil and ground magnesium limestone (GML)-treated soil

were also subjected to leaching tests as the negative and positive control, respectively.

Modified selective sequential extraction (SSE)

Soil samples were incubated with GML or MB at two application rates of 1.0% w/w and 5.0% w/w (Table 2). Soil samples that were not incubated with any material were compared as control. About 1.0 g of treated soil samples were air-dried, crushed to <2 mm diameter using an agate mortar, and transferred into 50 mL polypropylene centrifuge tubes. Referring to Table 3, the extraction began from step 1 (exchangeable fraction), until step 5 (residual fraction). The supernatants were separated by centrifugation at 1,400 rpm for 10 min. Each liquid fraction was filtered through a 0.45 µm syringe filter, and the Pb content was determined in each of the five extracts of soil samples using ICP-OES [26].

Table 2. The weight (g) of shooting range soil (Soil), Mg-modified biochar (MB), and ground magnesium limestone (GML) of treated soil samples at 1.0 % (w/w) and 5.0 % (w/w) application rates for leaching test and selective sequestration extraction (SSE) experiments

Soil Amendment	**Weight (g)**	
	1.0% (w/w)	**5.0 % (w/w)**
Control	10.0 g Soil	10.0 g Soil
MB	9.9 g Soil + 0.1 g MB	9.5 g Soil + 0.5 g MB
GML	9.9 g Soil + 0.1 g GML	9.5 g Soil + 0.5 g GML

Table 3. Modified selective sequential extraction procedures

Step	**Fraction**	**Reagent**	**Conditions**
1	Exchangeable (E)	8.0 mL of 1.0 M $MgCl_2$ (pH 7)	1 h, 25°C
2	Carbonate (C)	8.0 mL of 1.0 M NaOAc (pH 5)	5 h, 25°C
3	Fe-Mn oxide (FM)	20 mL of 0.04 M $NH_2OH.HCl$ in 25% HOAc (v/v)	6 h, 96ºC
4	Organic (O)	3.0 mL of 0.02 M HNO_3 + 5.0 mL of 30% H_2O_2 (pH 2)	2 h, 85ºC
		3.0 mL of 30% H_2O_2	3 h, 85ºC
		5.0 mL of 3.2M NH_4OAC + 20% HNO_3 (v/v)	30 min, 25°C
5	Residual (R)	HNO_3-HCl digestion	

Results and Discussion

Chemical characterisation for SB, MB, and Spent MB

The elemental composition of SB, MB, and spent MB are shown in Table 4. The overall content of C in SB was relatively low possibly due to the low cellulose content in SD [27]. The pyrolysis process at high temperature (i.e., >500 °C) intensifies the degree of carbonization and increased the C content in SB to 69.03% [28]. Modification with MgO_2 introduced Mg and has slightly decreased C content in MB [29]. Soluble Mg may have been dehydrated to form MgO on the surface of MB [30]. The N content in the Spent MB content after sorption with AHU. Besides the PO_4^{3-}, urea is also present in AHU and it is naturally decomposed by microbes to form ammonium ions (NH_4^+). Possible precipitation of struvite and its attachment onto the surface of the spent MB exhibited a higher P content [31].

Figures 1 (a), (b), and (c) show the surface of SD, MB, and Spent MB, respectively. The surface of SD was originally smooth with a compact, non-porous structure. Upon pyrolysis, the surface of SB was uneven with more pores formed on its surface and with a much higher C content. A larger pore size was observed in SB compared to that for SD. Pyrolysis at a higher temperature may have allowed more removal of volatile matter from SD and developed a larger pore in SB. The quantity of micropores in SB may have increased in diverse ranges [32]. Meanwhile, The SEM images in Figure 2 show that pores were smaller, and the surface was coarser after SB was modified with MgO_2. The average pore diameter

decreased from 3 nm to 1 nm after the Mg impregnation process due to the blockage of pores in biochar by Mg compounds [33]. Figure 1 (d) shows the presence of PO_4^{3-}. Figure 2 further indicates that elemental P was associated with N, and Mg, possibly due to the formation of struvite crystals. The increasing P% in Spent MB coincides with decreasing content of Mg% and C%. The result was predictable as the low content of C% might be due to the phenolic hydroxyl and carboxylic groups on the surface of Spent MB being preoccupied with PO_4^{3-} and NH_4^+ through the ion exchange mechanism [34]. Both Na and Cl were the most obvious in Figure 2, indicating that NaCl was also co-precipitated with struvite on the surface of Spent MB. Other Mg compounds (i.e., $Mg_3(PO_4)_2$, $MgHPO_4$, or $Mg(H_2PO_4)_2$) may also be present in Spent MB but may be significant in quantity [35].

Table 4. Elemental composition of SD, SB, MB, and Spent MB

Element	Composition (wt.% d.b.)			
	SD	SB	MB	Spent MB
C	45.15	69.03	52.08	25.35
O	26.66	3.19	5.37	20.55
Mg	-	-	1.19	0.06
Si	-	-	1.50	0.06
Ca	0.00	0.00	2.36	0.22
S	0.00	0.00	1.77	1.41
N	28.19	27.78	2.27	17.35
Cl	0.00	0.00	0.00	33.89
P	0.00	0.00	0.00	1.11
Au	-	-	33.46	-

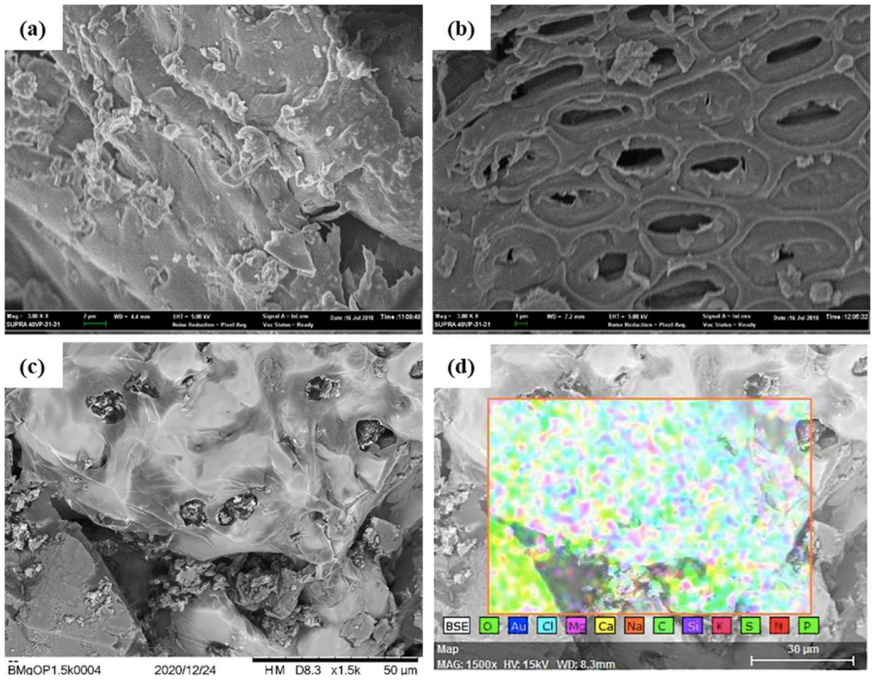

Figure 1. Scanning electron micrograph (SEM) images of (a) sawdust (SD), (b) Mg-modified biochar (MB), (c) Spent MB, and (d) combined elemental map for Spent MB

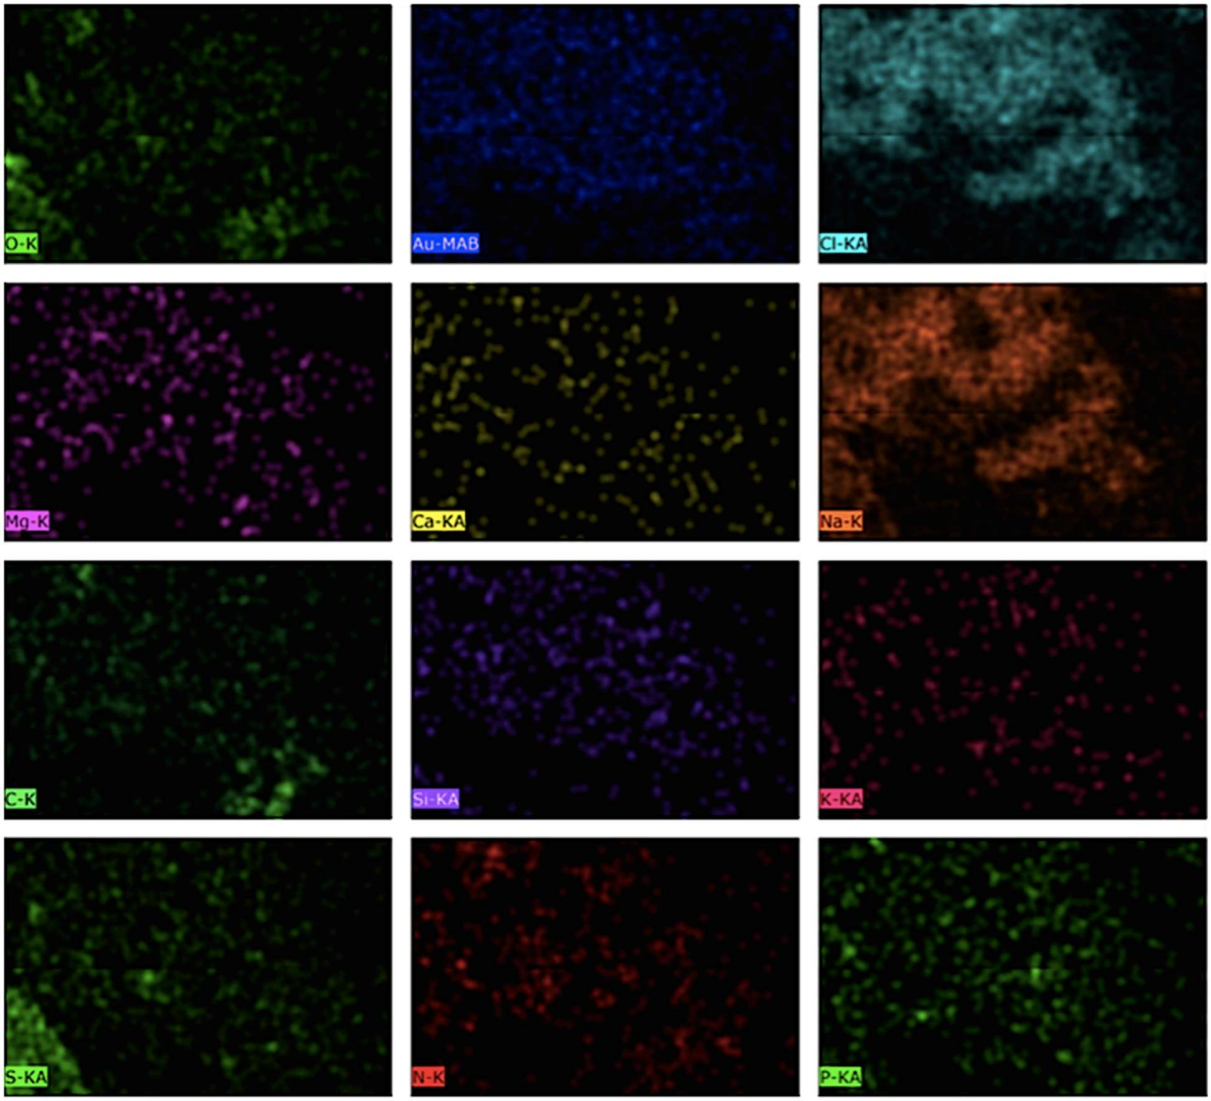

Figure 2. Elemental map of O, Au, Cl, Mg, Ca, Na, C, Si, K, S, N, and P for Spent MB

The BET surface areas and pore width of SB and MB are shown in Table 5. The high pyrolysis temperature at 700 °C allowed the formation of porous SB with a high BET surface area (145 m^2/g). This could be due to the formation of micropores when the pyrolysis temperature is greater than 500 °C [36]. Pyrolysis at a high temperature removed the volatile matter and pore-blocking tar from SD, leading to the greater formation of micropores and an increase in the BET surface area and pore volume [37]. However, the modification process with MgO_2 has also decreased the BET surface area value from 145 m^2/g to 5.05 m^2/g. This could be due to the excessive chemical oxidation by MgO_2 that converts micropore to macropore in MB [38]. The increase in average pore width (nm) in MB corroborates this hypothesis. The possible formation of Mg nanoparticle in the inner pores of MB may also cause blockage and leads to a decrease in the BET surface area [39]. During the dehydration process of MB, a higher amount of Mg concentration leads to Mg becoming hydrated thus forming an excess MgO that blocks the pores of MB [40].

Table 5. The BET surface areas (m^2/g), average pore width (nm), and CEC of sawdust biochar (SB) and Mg-modified biochar (MB), and Spent MB

Parameter	SB	MB	Spent MB
BET surface area (m^2/g)	145	5.05	-
Average pore width (4V/A) (nm)	11.62	14.88	-
CEC (cmol/kg)	0.757	1.034	1.015

The CEC values for SB, MB, and Spent MB are shown in Table 5. Modification of MB with MgO_2 marginally increased CEC values from 0.7569 cmol/kg to 1.034 cmol/kg. The CEC value for Spend MB (1.015 cmol/kg) is also similar to that of MB. The surface of MB may have been slightly oxidized by MgO_2. The insignificant increase in CEC value may also be due to a possible formation of a strong Mg-O bond that prevents deprotonation of the polar functional groups. Similarly, a potential PO_4^{3-} adsorption and precipitation of struvite did not cause further oxidation and the amount of polar functional group remains the same as that of MB. The formation of struvite may have occupied the pores and neutralized the negative charge of the polar functional groups on the surface of MB [41].

Figure 3 illustrates the vibration bands for SB, MB, and Spent MB. The hydroxyl group (-OH) is present in cellulose, hemicelluloses, and lignin which is also responsible for the binding of Mg [42]. The hydroxyl band is not observed in SB, where there was a possibility that most of the cellulose, hemicellulose and lignin degraded due to the high pyrolysis temperature. The vibration bands at 828 cm^{-1} are related to the aromatic C-H in MB, indicating that the added Mg was adsorbed [43]. The presence of the NH_4^+ band is shown at 1463 cm^{-1}-1465 cm^{-1} [44]. Furthermore, the NH_2 stretching bands for spent MB are shown at 3453 cm^{-1}. Bands at 1090-1096 cm^{-1} were due to the P-O stretching vibration of PO_4^{3-} [45]. Bands at 1641-1674 cm^{-1} are the stretching vibrations for C=O carboxylate (1641 cm^{-1}) and C=O amide (1674 cm^{-1}). The wavenumber at 1389-1467 cm^{-1} corresponds to the sp3 C-H bending vibration [46]. The presence of phenolate (1300 cm^{-1}) along with carboxylate and amide were mainly involved in the Mg and PO_4^{3-} adsorption.

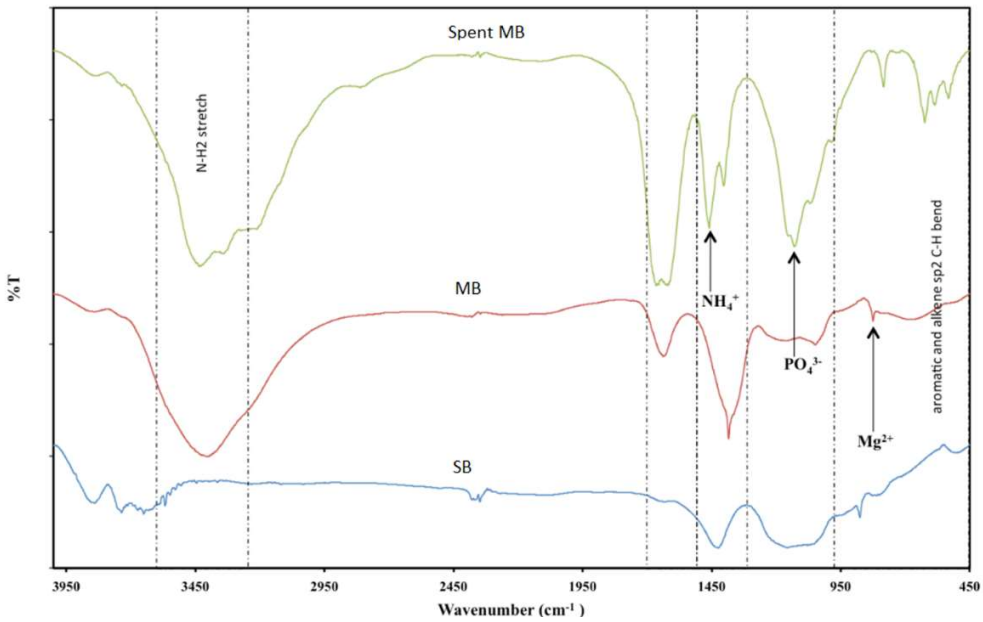

Figure 3. Stacked FTIR spectra of sawdust biochar (SB), Mg-modified biochar (MB), and Spent MB

Figure 4 shows the TG and derivative curve (DTG) thermogram of SD, MB, and Spent MB. Thermal decomposition was characterized by four different mass loss phase that has been separated by the lines for specific temperature intervals. The first decomposition stage happened to all the samples at < 300 °C. Partial decrease in total mass was observed, possibly due to the evaporation of water, and minor de-volatilization [47]. The weight loss that took place between 300 and 500 °C refers to the degradation of cellulose [48]. There were two decomposition stages between 250 °C and 350 °C at phase 2 that correspond to the sharp peak of DTG at 350 °C for MB. This indicated that the first decomposition was due to the weight loss of residual water, while the second decomposition stage could be due to the degradation of the Mg hydrates along with the third stage showing a formation of magnesium hydroxychloride (MgOHCl) [49]. Meanwhile, the second phase for Spent MB showed no peak with a flat decomposition stage starting at 250 °C. This could be due to the bonding of PO_4^{3-} from AHU. The Mg^{2+} ion forms struvite and this may lead to the absence of free $MgCl_2$ hydrates. Lastly, stage 3 and 4 thermal decompositions at 450 °C and 800 °C, respectively were attributed to the slow decomposition of residual solids that contributed to the formation of char [50].

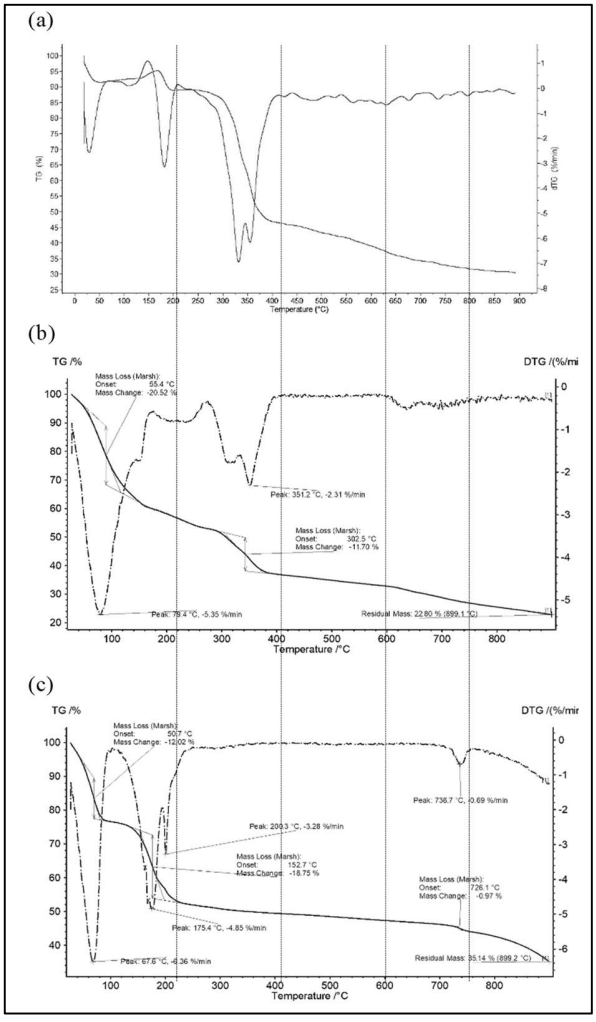

Figure 4. TGA and DTG of (a) sawdust (SD), (b) Mg-modified biochar (MB), and (c) spent MB at heating rate of 3°C/min

Batch sorption of PO_4^{3-} from AHU: Effect of initial concentration of PO_4^{3-}

The PO_4^{3-} sorption capacities of MB increased from 668 mg/g to 9554 mg/g when the initial PO_4^{3-} concentrations of AHU were increased from 6.68 mg/L to 304 mg/L. A higher concentration allows greater diffusion rates and contact of PO_4^{3-} in the aqueous phase with the surface of MB. Thus, more PO_4^{3-} can bind with polar functional groups and increase sorption capacity [51]. Adsorption isotherm parameters in Table 6 show that the PO_4^{3-} adsorption of MB fits better with the Freundlich model (i.e., R^2 = 0.827) [52]. This shows that adsorption of PO_4^{3-} occurred on heterogeneous active sites on the surface of MB. The Langmuir maximum sorption capacity for MB was 8967 mg/g.

Table 6. Parameters of isotherm (Langmuir and Freundlich) and kinetic models (pseudo-first-order and pseudo-second-order) of PO_4^{3-} sorption by MB

Isotherm Models		**Kinetic Models**	
Langmuir		**Pseudo-first-order**	
q_{max} (mg/g)	8967	k_1 (g/[mg.min])	0.053
K_L (L/mg)	0.029	q_e (mg/g)	114.5
R^2	0.773	R^2	0.850
Freundlich		**Pseudo-second-order**	
K_F	944	k_2 (g/[mg.min])	0.0762
n	2.456	q_e (mg/g)	9.937
R^2	0.827	R^2	0.903

Effect of contact time on uptake of PO_4^{3-}(mg/g)

The uptake of PO_4^{3-} by MB reached the first equilibrium in the 10th minute with PO_4^{3-} uptake of 81.1 mg/g. The second sorption equilibrium was observed in the 75th minute with a PO_4^{3-} uptake of 127 mg/g. The surface sites for binding PO_4^{3-} become limited and saturated when contact time was prolonged to two hours [53]. Removal of PO_4^{3-} from AHU may be higher if contact time is allowed to extend for a month. Precipitation and crystallization of Mg minerals may take place. Moreover, MB has an enhancement of negative-charged polar functional groups on its surface, and the main sorption sites for magnesium (i.e., phenolic and carboxyl groups) were deprotonated to allow free Mg^{2+} ions to precipitate as MgO [54]. Kinetic parameters of PO_4^{3-} sorption data analysed using non-linearised pseudo-first-order and pseudo-second-order models for MB are shown in Table 9. Adsorption of PO_4^{3-} occurred rapidly within 15 min of contact time with more than 70 mg/g of uptake. The PO_4^{3-} adsorption by MB was better described by the pseudo-second-order kinetic model with a higher correlation coefficient (i.e., 0.903) than that of the pseudo-first-order model (i.e., 0.85). This outcome suggests that the adsorption process may involve the formation of strong chemical bonds between PO_4^{3-} and the polar functional group on the surface of MB [55].

Modified selective sequential extraction

Figure 5 illustrates the percentage of Pb in the five fractions of the selective sequential extraction (SSE) for soils incubated with GML, and spent MB at 1 and 5% w/w application rate. The first fraction is the exchangeable Pb that easily reacts with the ionic content in water and becomes soluble [56]. This form of Pb is considered available and may cause adverse effects on living organisms. The percentage of exchangeable Pb (first fraction of the SSE procedure) is shown in Figure 6. Exchangeable Pb in unamended soil was the highest (0.33%). Complete immobilization of exchangeable Pb (0 %) was achieved by treating the soil with 0.5 g of spent MB (5% w/w MB). Soil treated with spent MB has a decrease of Pb in fraction 1, but an increase in fractions 2 and 3. This shows that Pb was converted to a relatively less available form that is not readily taken up by plants [34]. This could be due to the chemical reaction between soluble Pb^{2+} ions with PO_4^{3-} from spent MB, forming the insoluble Pb minerals such as $Pb_3(PO_4)_2$.

The second fraction generally refers to the Pb that is likely to bind with carbonate and is susceptible to pH alterations. Immobilization of Pb in the carbonate fraction could be due to the bonding with hydroxide ions, and the precipitation process of Pb with PO_3^{-4} or CO_2^{-3} that were abundant in spent MB [57]. According to Tessier [26], a decrease of soil pH to 5.0 in the second fraction would solubilize Pb which is particularly adsorbed in the carbonate-bound fraction. In this study, spent MB was alkaline with a pH value of 12. The alkaline nature was due to the presence of struvite and alkaline minerals in spent MB which includes hydroxides and oxides of potassium and calcium [58]. For high Pb in fraction 4 (i.e., bound to organic matter), Tessier reported that some organic matter may eventually be released into the environment as biomass may deteriorate, causing it to release the soluble Pb under certain oxidizing conditions in natural waters [26]. Fortunately, the biochar component in the spent MB is more stable than biomass and this was proven as treatment of 1 and 5% w/w of Spent MB gave the least percentage of Pb in fractions 4 of 7.3 % and 12.7 %, respectively. This may be due to the less complexation of Pb with the stable organic structure with struvite bound to MB. Most of the exchangeable Pb were probably precipitated with struvite and ash originated from SB. This shows that treatment of shooting range soil with Spent MB promoted Pb immobilization and minimizes the health risk [59].

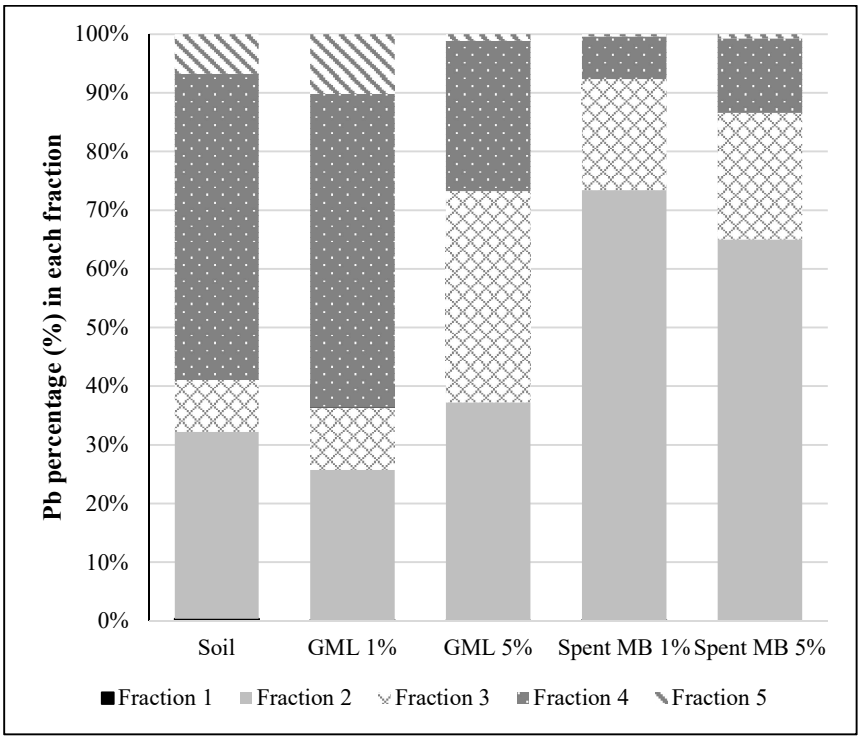

Figure 5. Percentage of lead (Pb) (% w/w) in fractions of the selective sequential extraction experiment for soil treated with GML and spent MB at 1 and 5 % w/w application rate.

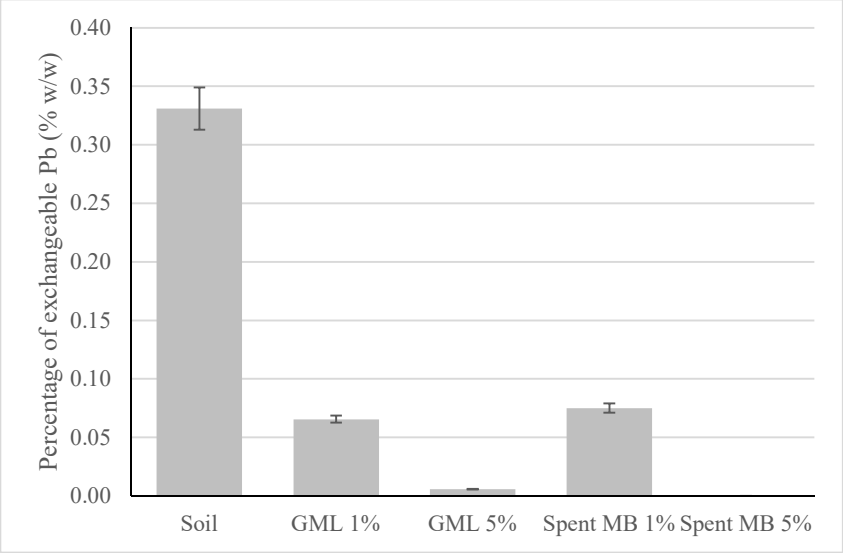

Figure 6. Percentage of exchangeable lead (Pb) (% w/w) for soil treated with ground magnesium lime (GML), and spent modified biochar (MB) at 1 and 5 % w/w application rate.

Leaching rate of Pb from soils modified with Spent MB, and Ground Magnesium Lime (GML)

Figure 7 shows the variations in the available Pb concentration of leachates from soils treated with MB and GML over the volume of 0.01M $CaCl_2$. For the untreated soil column, the concentration of Pb in leachate had increased slightly during the initial stage of the leaching process. The concentration of Pb drastically increased until it reached the maximum Pb concentration of 5.96 mg/L. Then, the Pb concentration decreased gradually to 2.40 mg/L. The overall trend for soil column leaching was gradually decreased from high concentrations of Pb compared to other samples. However, the Pb concentration in leachates coming from soil columns treated with GML and Spent MB were similar and remained constant below 1.63 mg/L. This shows that amendment with MB can mitigate Pb leaching from soil and the performance is comparable to the commercial liming agent of GML. The mechanism of Pb immobilization by struvite-modified magnesium biochar can be explained by the dissolution of PO_4^{3-} to the aqueous phase followed by the precipitation process of hydroxypyromorphite $Pb_{10}(PO_4)_6(OH)_2$ [60]. The reaction equation is represented as follows:

$$MgNH_4PO_4 \cdot 6H_2O + 2H+ \leftrightarrow Mg^{2+} + NH_4^+ + H_2PO_4 + 6H_2O + 10Pb^{2+} + 6H_2PO_4 + 2H_2O \leftrightarrow Pb_{10}(PO_4)_6(OH)_2\downarrow + 14H^+$$
$$+ Pb^{2+} + HPO_4^{2-} \leftrightarrow PbHPO_4\downarrow$$

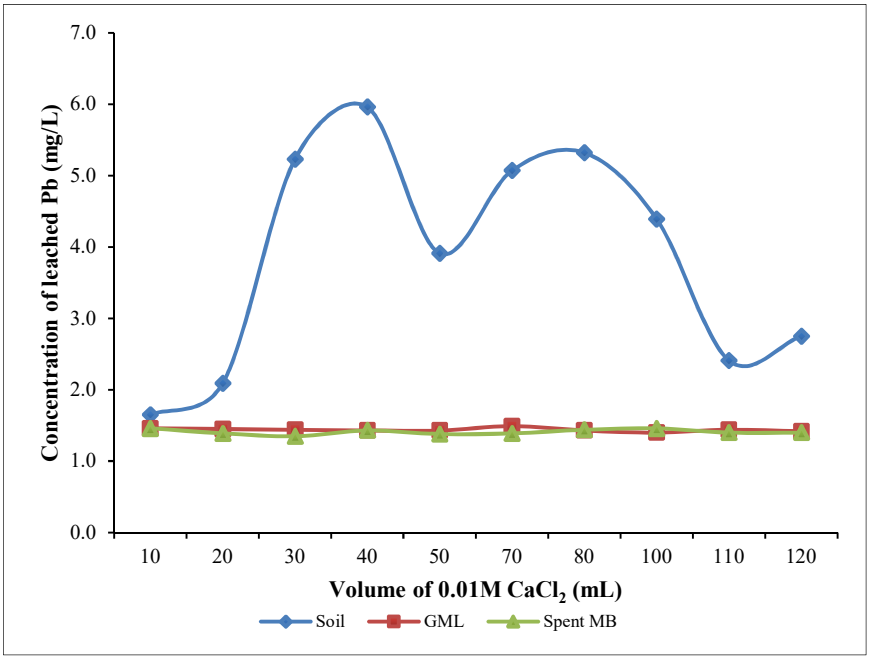

Figure 7. The concentration of Pb in leachates (mg/L) as a function of the volume of 0.01 M $CaCl_2$ solution of soil columns treated with 1 % w/w Spend MB, ground magnesium lime (GML).

Conclusion

This research exhibited the application of SB, MB, and Spent MB as adsorbents because of their features that were easily available, not harmful to the environment, its oxygenated functional groups on biochar surfaces, and the potential for higher sorption capacity. The modification process of MgO_2 seemed able to improve PO_4^{3-} uptake of SB. The SEM-EDX analysis showed that pyrolysis has helped develop macropores in SB and is still retained MB after modification with MgO_2. However, due to possible over oxidation, the microporous structure of MB was not retained. Fortunately, the modifications with MgO_2 led to additional negative-charged polar functional groups for the adsorption of Mg and the subsequent PO_4^{3-} from AHU. Although struvite crystal was successfully precipitated from AHU using MB, a significant amount of NaCl was also present in the Spent MB. Long-term application of Spent MB may introduce Na and may damage soil structure due to an increase in salinity. Even so, Spent MB has shown greater potential to immobilize Pb in soil than GML. Based on the batch adsorption study, modification of MgO_2 has produced MB with a high Langmuir maximum sorption capacity for PO_4^{3-} (i.e., 8967 mg/g), and is higher than that of biochar modified with only $MgCl_2$ (i.e., 8026 mg/g) [61]. Adsorption isotherm analysis indicated that the uptake of PO_4^{3-} by MB was best described by the Freundlich model, with an assumption that several layers of adsorption mechanism occurred on a heterogeneous surface of MB. Kinetic study results suggested that the entire adsorption process for MB was dominated by the chemisorption process via an ion-exchange mechanism. While the small amount of Mg did have some significant effect on adsorption of PO_4^{3-} onto MB. Lastly, the Pb immobilization test results for the three samples have indicated that Spent MB exhibited higher immobilization ability for Pb compared to soil with GML. Thus, amendment with the Mg-impregnated biochar can mitigate Pb leaching from soil to improve PO_4^{3-} utilization.

Abstract

Sensitivity and reliability have become focal points in the analysis of contaminants in wastewater. The optimisation using liquid chromatography mass spectrometry triple-quadrupole (LCMS-QQQ) and carbamazepine microextraction parameters were investigated. The optimisation of gas flow, nebuliser, fragmentor voltage, and collision energy in LCMS-QQQ were examined. Carbamazepine microextraction parameters for extraction methods, extraction tools, various solvents, and solvent volume ratios were investigated. The optimised LCMS-QQQ conditions were 11 L/min gas flow, 25 psi nebuliser, 80 V fragmentor voltage, as well as 35 eV (179.1 m/z) and 15 eV (194.1 m/z) collision energy. For microextraction analysis, liquid-liquid extraction (LLE) yielded a higher carbamazepine average recovery percentage of 96±26%–100±10% than solid phase extraction (SPE) at 4 ±0%–8±1%. The sonicator and separatory funnel similarly showed a high average recovery percentage of carbamazepine at 96±26%–100±10%, but the sonicator saves time and human resources. The average recovery percentage for carbamazepine in solvents at 100±10% was higher compared to water at 26±4%. Statistically, there was no significant difference between the various solvents used in LLE. The optimised solvent volume-ratio LLE was 1.25. This study is vital for the analysis of carbamazepine in the environment and the development of an emerging pollutants monitoring database.

Keywords: carbamazepine, liquid chromatography mass spectrometry triple-quadrupole, optimisation, microextraction

Abstrak

Sensitiviti dan kebolehpercayaan telah menjadi tumpuan dalam analisis bahan cemar dalam air sisa. Oleh itu, pengoptimuman menggunakan kromatografi cecair spektrometri jisim tiga-caturkutub (LCMS-QQQ) dan parameter pengekstrakan mikro karbamazepin telah dikaji. Pengoptimuman aliran gas, nebuliser, voltan serpihan, dan tenaga perlanggaran untuk LCMS-QQQ telah diperiksa. Parameter pengekstrakan mikro karbamazepin untuk kaedah pengekstrakan, alat pengekstrakan, pelbagai pelarut, dan nisbah isipadu pelarut telah disiasat. Keadaan optimum LCMS-QQQ ialah aliran gas 11 l/min, nebuliser 25 psi, voltan serpihan 80 V, serta tenaga perlanggaran 35 eV (179.1 m/z), dan 15 eV (194.1 m/z). Untuk analisis pengekstrakan mikro, pengekstrakan cecair-cecair (LLE) menghasilkan purata peratusan pemulihan karbamazepin yang lebih tinggi pada 96 ± 26%–100 ± 10% daripada pengekstrakan fasa pepejal pada 4 ± 0%–8 ± 1%. Sonikator dan corong pemisah menunjukkan keputusan yang sama, purata peratusan pemulihan yang tinggi bagi karbamazepin pada 96 ± 26%–100 ± 10% tetapi sonikator menjimatkan masa dan sumber manusia. Purata peratusan pemulihan untuk karbamazepin dalam pelarut pada 100 ± 10% adalah lebih tinggi berbanding dengan air pada 26 ± 4%. Pelbagai pelarut yang digunakan dalam LLE tidak menunjukkan perbezaan yang signifikan secara statistik. Nisbah isipadu pelarut LLE yang optimum ialah 1.25. Kajian ini adalah penting untuk analisis karbamazepin dalam alam sekitar dan pembangunan pangkalan data pemantauan bahan pencemar yang muncul.

Katakunci: karbamazepin, kromatografi cecair spektrometri jisim tiga-caturkutub, pengoptimuman, pengekstrakan mikro

Introduction

Carbamazepine is a pharmaceutical compound used as an anti-epileptic drug for suppressing seizures. It is a tricyclic compound that is persistent in the environment. The compound is not completely metabolised in the liver [1]. A total of 1% is excreted through urine and faeces into the sewage system and enters the wastewater treatment plants [2]. Current treatments in wastewater treatment plants are unable to remove carbamazepine because it is not designed to degrade stable contaminants, including carbamazepine [3]. Consequently, treated wastewater with carbamazepine flows into the water stream, accumulates, and causes adverse effects on human health, aquatic organisms, and the environment [4]. Long-term exposure to low concentrations of carbamazepine disrupts the human endocrine system [5]. Carbamazepine also disturbed the growth and development of zebrafish embryos and larvae [6]. In the environment, plants uptake carbamazepine, which accumulates and exposes human and aquatic organisms to risk [7]. Therefore, developing a method for isolating and analysing trace carbamazepine concentrations in wastewater is critical for improving water quality and safety for humans, aquatic organisms, and the environment.

Liquid chromatography mass spectrometry triple-quadrupole (LCMS-QQQ) has been used for the analysis of pharmaceutical compounds, industrial chemicals, and pesticides in the environment due to its high sensitivity and selectivity. Hence, it is suitable for screening and quantifying the trace concentration of carbamazepine in wastewater. Kruglova et al. [8] reported the detection of trace carbamazepine at 0.4 ± 0.1 μgL^{-1} using ultra-performance liquid chromatography/tandem mass spectrometry (UPLC-MS/MS). In the study by He et al. [9], 53.8 μgL^{-1} carbamazepine was analysed using LCMS-QQQ. Although the published methods of detection and quantitating carbamazepine can be used as a reference in the analysis of carbamazepine, optimisation of the method needs to be conducted. This is because assay performance and optimal conditions vary among different instruments and sample matrices [10].

The wastewater containing carbamazepine also has a high concentration of organic matter, microorganisms, and inorganic compounds [11]. Therefore, carbamazepine requires pre-treatment through microextraction before LCMS-QQQ analysis. The most widely used carbamazepine microextraction methods are liquid-liquid extraction (LLE) and solid-phase extraction (SPE). LLE involves the partitioning of compounds based on the solubility of the mixture in two different solvents [11]. Meanwhile, SPE uses a solid phase and a liquid phase to isolate and concentrate compounds from a solution [12]. In comparison to SPE, which requires expensive equipment and accessories,

LLE is a low-cost microextraction method suitable for research with limited funding [11, 12]. In LLE, microextraction tools, types of solvents, and solvent volume ratio are important optimisation parameters in determining the highest average recovery percentage of carbamazepine for high sensitivity and reliable results.

The objectives of this study are to optimise LCMS-QQQ through gas flow, nebuliser, fragmentor voltage, and collision energy, and to optimise microextraction methods, microextraction tools, types of solvents, and solvent volume ratio.

Materials and Methods

Chemicals and standard solutions preparation

The pharmaceutical compound carbamazepine ≥ 98% purity used was purchased from Sigma Aldrich. HPLC and LCMS grade acetonitrile, methanol, ethanol, and acetone were used in the microextraction and LCMS analysis of carbamazepine. A 500 mgL^{-1} carbamazepine stock solution was prepared by dissolving 5 mg of carbamazepine in 10 mL of methanol.

LCMS-QQQ set-up for carbamazepine analysis

A liquid chromatography system (Agilent 1200 Series, Agilent Technologies, USA) equipped with a quaternary pump, an autosampler, a column thermostat, an inline degasser, and a Zorbax Extend-C18 (100 x 2.1 mm, 1.8 µm) column was coupled to the triple quadrupole (QQQ) mass spectrometry (Agilent 6410, Agilent Technologies, USA) with an electrospray ionisation interface (ESI) MS source. The column oven and flow rate were set to 40°C and 0.2 mL/min, respectively. A 2 µL of 1 mg/L^{-1} carbamazepine was injected into the system. A binary gradient mobile phase consisting of ultrapure water (UPW) and acetonitrile (ACN) was prepared and identified as A and B solvents. Both solvents were added with 0.1% formic acid. The gradient profile was set up at initial conditions of 20%:80% (A:B, v/v) and brought to 95%:5% (A:B, v/v) for the first 2 minutes, changed to 20%:80% (A:B, v/v) for 5 minutes, and restored to 95%:5% for 7 minutes. Ionization was performed using the ESI positive mode ion polarity. During optimisation, two mass transitions for carbamazepine, 237.3 → 179.1 m/z and 237.3 → 194.1 m/z were set in multiple-reaction monitoring mode (MRM) [13]. Samples of 1 mgL^{-1} carbamazepine were prepared in triplicates. This experiment used a single factor at a time optimisation design. The optimisation parameters of carbamazepine for gas flow, nebuliser, fragmentor voltage, and collision energy were investigated according to Table 1. Identification and quantitation analysis were performed using Mass Hunter Quantitative Analysis software (Version B.03.01, Agilent Technologies, USA).

Table 1. Optimisation parameters of carbamazepine using LCMS-QQQ

Optimisation Parameters			
Gas Flow (L/min)	**Nebuliser (psi)**	**Fragmentor Voltage (V)**	**Collision Energy (eV)**
10.5	20	80	5
11.0	25	100	10
11.5	30	120	15
	35	140	20
	40		25
			30
			35
			40

The optimised parameters were used to construct the calibration curve. A series of desired carbamazepine standard solutions at 0.001 mgL^{-1} to 1 mgL^{-1} were prepared in triplicates using the 500 mgL^{-1} prepared carbamazepine stock solution. The limits of detection (LOD) and quantification (LOQ) were calculated as in Equations 1 and 2:

$$LOD = 3.3\left(\frac{SD}{S}\right) \quad (1)$$

$$LOQ = 10\ (\frac{SD}{S}) \quad (2)$$

where *SD* is the standard deviation of the response and *S* is the slope of the calibration curve.

Microextraction optimisation

The optimisation design used for microextraction optimisation was a single factor at a time, and the samples were prepared in duplicate. The microextraction methods used were LLE and SPE, followed by optimisation of the microextraction tools, and solvent versus water as in Table 2. The optimisation was further examined with various solvent combinations and solvent volume ratios as shown in Table 3. The methods were adopted from Mohamad-Nasir et al. [11]. In LLE (A), 2 mL of the 0.5 mgL^{-1} carbamazepine standard solution were added to 11 mL of methanol and 9 mL of acetonitrile. The samples were mixed for 5 minutes. For SPE (B), the cartridges were equilibrated using 2 mL of methanol. A total of 2 mL of the 0.5 mgL^{-1} carbamazepine standard solution was eluted into the cartridge, followed by 11 mL methanol and 9 mL acetonitrile. Next, samples extracted from LLE and SPE were rotavapor (IKA, Model: RV06-ML, Germany), filtered with a 0.22 µm syringe filter, and analysed using LCMS-QQQ. The LLE method was repeated under similar conditions, using the microextraction tools of a separatory funnel and sonicator for 5 minutes. Then, the experimental designs for A and B were repeated using methanol and water. After that, various solvent combinations and solvent volume ratios were examined (Table 3). The recovery percentage and average recovery percentage of carbamazepine were calculated using Equations 3 and 4, respectively.

Table 2. Optimisation of carbamazepine microextraction on microextraction methods, tools, and types of solvents

Solvents (mL)	A = LLE				B = SPE

Results and Discussion

LCMS-QQQ set-up for carbamazepine analysis

Table 4 shows the results of the optimisation parameters of LCMS-QQQ for carbamazepine analysis, such as gas flow, nebuliser, fragmentor voltage, and collision energy. The optimised parameters were 11 l/min for gas flow, 25 psi for the nebuliser, 80 V for fragmentor voltage, and 35 eV (179.1 m/z) and 15 eV (194.1 m/z) for collision energy. These conditions are selected because they provide the highest abundance, sharp peak shapes, and consistent retention times as shown in Figure 1. The highest abundance reflects the highest count of carbamazepine [14]. While sharp peak shapes signify the purity of carbamazepine, they reduce faulty results [15]. These outcomes lead to better sensitivity. Consistent retention time indicates the reliability of the optimisation of LCMS-QQQ.

Table 4. Optimisation parameters for carbamazepine analysis for LCMS-QQQ

Optimised Conditions	**Abundance**	
1. Gas flow (l/min)		
10.5	104922	
11.0	**125130**	
11.5	110205	
2. Nebuliser (psi)

*ND: Not detected

Figure 1 shows the spectrum of counts versus acquisition time for carbamazepine concentrations. In this study, the retention time for carbamazepine was at the range of 6.01–6.20 minutes for carbamazepine at concentrations from 0.001 mgL^{-1} to 1 mgL^{-1}. From these carbamazepine concentrations, the average retention time was found to be 6.16 ± 0.0222 minutes. He et al. [9] reported an 8-minute short retention time for carbamazepine using a C_{18} column with a particle size of 2.6 µM. Generally, high particle size results in complete separation of carbamazepine in a minimum amount of time [17]. In this study, carbamazepine retention time

was shorter than He et al. [9], although they used a C18 column with a smaller particle size of 1.8 µM. This is due to the fact that optimising the LCMS-QQQ for carbamazepine analysis is vital for achieving high sensitivity, saving time, and decreasing the volume of solvents used in the LCMS-QQQ.

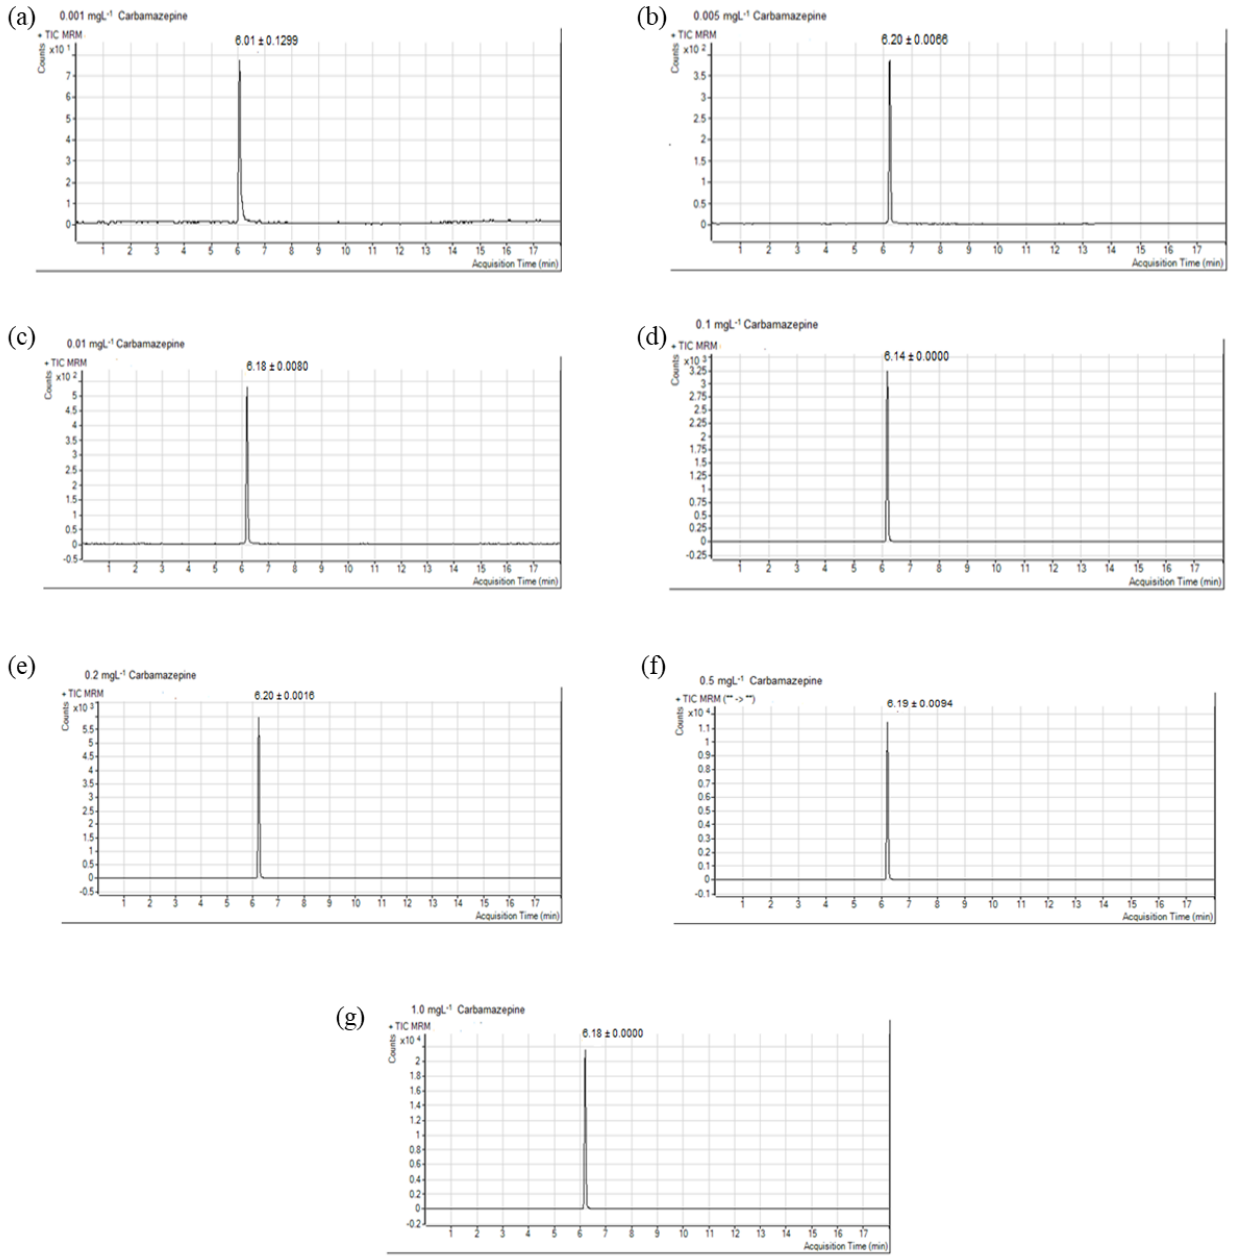

Figure 1. Carbamazepine spectrum of counts versus acquisition time for carbamazepine concentrations: (a) 0.001 mgL^{-1} carbamazepine; (b) 0.005 mgL^{-1} carbamazepine; (c) 0.01 mgL^{-1} carbamazepine; (d) 0.1 mgL^{-1} carbamazepine; (e) 0.2 mgL^{-1} carbamazepine; (f) 0.5 mgL^{-1} carbamazepine; (g) 1.0 mgL^{-1} carbamazepine

Figure 2 shows a graph of the calibration curve for carbamazepine. The equation of the graph was y = 79068x, and the value for the correlation coefficient (R^2) was 0.9940. High R^2 represents an excellent linear relationship. The linearity of the calibration curve signifies the suitability of the chromatographic method over a wide range of concentrations for the studied pharmaceutical [18]. From this study, the LOD and LOQ obtained were at 0.04 mgL^{-1} and 0.13 mgL^{-1}. These results are highly reliable, as the retention time for carbamazepine concentrations was less than 15%. Previous studies for carbamazepine analysis using LCMS-QQQ for the type of column, LOD, LOQ, and linearity are shown in Table 5. The use of column C18 with a particle size of 1.8 µm improved the efficiency of separation, resulting in better LOD, LOQ, and linearity. This confirms that the optimisation of LCMS-QQQ conducted in this study is suitable for the analysis of carbamazepine.

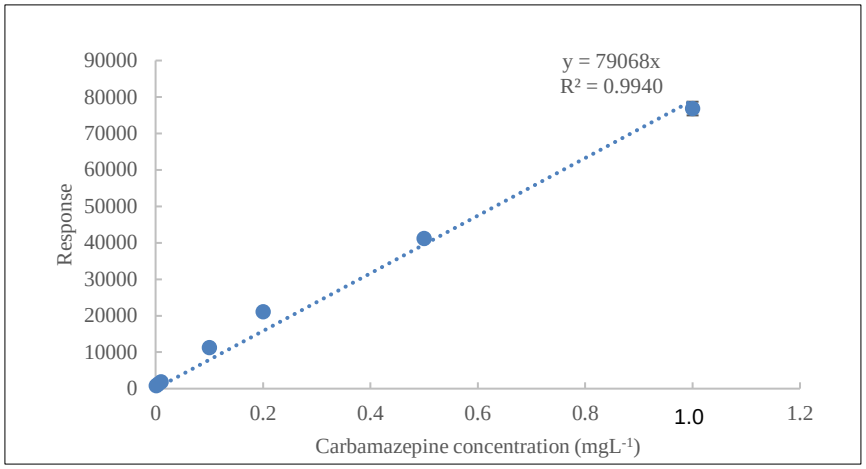

Figure 2. Calibration curve of carbamazepine

Table 5. Type of column, LOD, LOQ, and linearity of carbamazepine

Application	Type of Column and Size	LOD	LOQ	Linearity (R^2)	Reference
Quantification and screening CBZ in surface and drinking water	C_{18} 100 x 2 mm, 3 µM	0.2 ngL^{-1}	*NM	0.9900	[17]
Forensic toxicology cases	C_{18} 100 x 2.1 mm, 1.7 µM	0.12 mgL^{-1}	0.30 mgL^{-1}	0.9989	[18]
Quantification and screening CBZ in wastewater	C18 100 x 2.1 mm, 1.8 µm	0.04 mgL^{-1}	0.13 mgL^{-1}	0.9940	This study

Microextraction optimisation

Figure 3 depicts a graph of the microextraction methods LLE and SPE with the average carbamazepine recovery percentage. The average recovery percentage of carbamazepine in LLE for A1 and A2 at 96 ± 26% and 100 ± 10% respectively, higher than SPE for B1 and B2 at 8 ± 1% and 4 ± 0%, respectively. Mohamad-Nasir et al. 2021 also support these results, where the 98.9% average recovery percentage of carbamazepine was higher than SPE at 16.1% [11]. The high average recovery percentage of carbamazepine in LLE was due to the direct methanol interaction with carbamazepine through mixing with the second solvent, acetonitrile [19]. Meanwhile, the low average recovery percentage of carbamazepine in SPE is associated with carbamazepine that is slightly polar, resulting in poor elution on the sorbent [21]. The use of a separatory funnel (A1) and sonicator (A2) yielded high average recovery percentages of 96 ± 26% and 100 ± 10%, respectively. Vigorous mixing increases the interaction of methanol molecules with carbamazepine. Sonicator offers the advantages of less time and human resources. For LLE (A1 and A2), solvent methanol and acetonitrile yield a higher average recovery percentage of carbamazepine at 96 ± 26%–100 ± 10% than solvent methanol and water at 36 ± 12%–26 ± 4%. In addition, Zhang et al. [20] also supported the findings that carbamazepine has low solubility in water at 0.00001 (mole fraction). The average recovery percentages of carbamazepine in SPE for solvent methanol and acetonitrile and solvent methanol and water were neglected due to their low average recovery percentages. This further confirms the effectiveness of the LLE method.

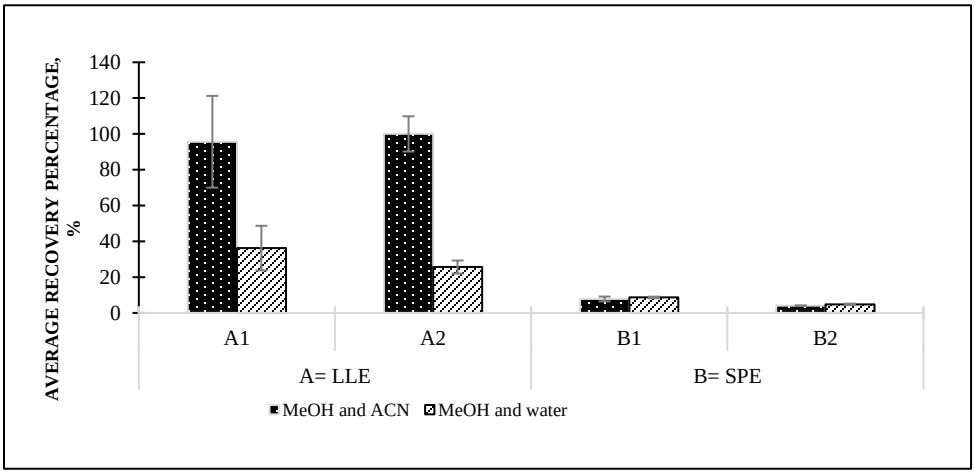

Figure 3. Average recovery percentage of carbamazepine for microextraction methods. A1: Separatory funnel; A2: Sonicator; B1: Select HLB; B2: Envi 18

Figure 4 illustrates the use of various solvents and the solvent volume ratio in LLE with the average recovery percentages of carbamazepine. The average recovery percentages of carbamazepine in methanol and acetonitrile, methanol and ethanol, and methanol and acetone were 100 ±13%, 100 ±1%, 100 ±12%, respectively. The optimum solvent volume ratios for methanol and acetonitrile, methanol and ethanol, and methanol and acetone were all at 1.25. An increase in solvent polarity resulted in an increase in carbamazepine affinity. Thus, methanol in combination with these solvents at the optimum solvent volume ratio caused maximum interaction of carbamazepine and prevented excessive use of solvents. Overall, microextraction optimisation is important in the carbamazepine analysis because it prevents contamination that damages the analytical column of LCMS-QQQ, improves accuracy, and minimises the risk of false results.

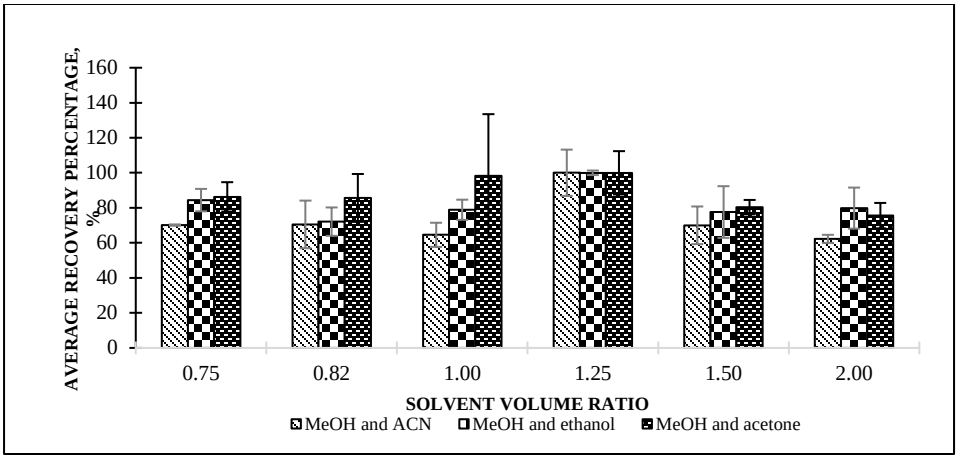

Figure 4. Average recovery percentage of carbamazepine for solvent type and solvent volume ratio

Conclusion

The optimisation parameters of LCMS-QQQ and microextraction methods for carbamazepine analysis were successfully investigated. The optimum gas flow, nebuliser, fragmentor voltage, and collision energy were at 11 l/min, 25 psi, 80 V, 35 eV (179.1 m/z), and 15 eV (194.1 m/z). For the microextraction methods, the LLE resulted in a higher average recovery percentage of carbamazepine at 96 ± 26%–100 ± 10% compared to the SPE at 4 ± 0%–8 ± 1%. The use of a sonicator and a separatory funnel yielded a high average recovery percentage at 96 ± 26% to 100 ± 10%. But, a sonicator has the advantage of saving time and human resources. The use of solvents resulted in a higher average recovery percentage of carbamazepine at 100 ± 13% compared to water at 26 ± 4%. For various solvents used in LLE, methanol and acetonitrile, methanol and ethanol, and methanol and acetone have average recovery percentages of carbamazepine of 100 ± 13%, 100 ± 1%, and 100 ± 12%, respectively. The optimal solvent volume ratio for various solvents in LLE was 1.25. The low-cost microextraction method LLE is suitable to be used in the study as it offers the advantages of simple apparatus, easy operation conditions, short time, and minimum resources used. This ensures reliable and consistent results in carbamazepine analysis for monitoring databases and policy development for emerging pollutants.

Abstract

Heparin is a well-known anticoagulant drug commonly utilized in medical practice. Nevertheless, foreign impurities may contaminate heparin extract; thus, molecular imprinting technology is introduced to purify and separate the anticoagulant. In this study, an epitope heparin imprinted polymer was prepared using low molecular weight heparin (LMWH) as a template model in three different functional monomers: (3-aminopropyl) trimethoxysilane (APTMS), (3-mercaptopropyl) trimethoxysilane (MCPTMS), and 3-(2-aminoethylamino) propyltrimethoxysilane (AEAPTES). Meanwhile, tetrarthoxysilane (TEOS) was used as a cross-linker for the sol-gel process. The prepared epitope heparin imprinted polymer was characterized using Fourier transform infrared spectroscopy (FTIR) and scanning electron microscope (SEM). The AEAPTES-MIP demonstrated the best imprinting effect towards heparin (IF = 3.10) due to the high stability and dual functional group created strong hydrogen bonding, in comparison to APTMS-MIP (IF = 2.18) and MCPTMS-MIP (IF = 0.13). Moreover, the epitope heparin imprinted polymer exhibited higher selectivity towards macromolecule heparin than LMWH, indicating the successful identification and selection of macromolecule fragments to determine the biological activities.

Keywords: epitope imprinted, heparin, molecular imprinted polymer, sol-gel process

Abstrak

Heparin adalah ubat anti-gumpalan yang terkenal dan biasa digunakan dalam amalan perubatan. Walau bagaimanapun, ekstrak heparin berisiko tinggi bercampur dengan bahan cemar asing. Oleh itu, teknologi pencetakan molekul diperkenalkan untuk penulenan dan pengasingan heparin. Di sini, polimer bercetak epitop heparin telah dihasilkan dengan menggunakan berat heparin molekul rendah (LMWH) sebagai model templat dalam tiga monomer berfungsi berbeza yang dikaji iaitu (3-aminopropil) trimetoksisilana (APTMS), (3-merkaptopropil) trimetoksisilana (MCPTMS) dan 3-(2-aminoetillamino) propiltrimetoksisilana (AEAPTES) manakala, Tetrartoksisilana (TEOS) digunakan sebagai penyambung silang di dalam proses sol-gel. Polimer tercetak epitop heparin yang disediakan telah dianalisis menggunakan spektroskopi inframerah transformasi Fourier (FTIR) dan mikroskop

elektron pengimbasan (SEM). AEAPTES-MIP mempunyai kesan cetakan terbaik terhadap heparin dengan nilai faktor pencetakan tertinggi (IF=3.10) berbanding APTMS-MIP (IF=2.18) dan MCPTMS-MIP (IF=0.13) kerana kestabilannya yang tinggi dan kumpulan dwi berfungsi yang diwujudkan mengukuhkan ikatan hidrogen. Selain itu, polimer tercetak epitope heparin menunjukkan selektiviti tinggi terhadap makromolekul heparin berbanding LMWH. Ini membuktikan bahawa MIP berjaya digunakan sebagai pengenalpastian dan pemilihan serpihan makromolekul untuk menentukan peranan aktiviti biologinya.

Introduction

Heparin is a linear polysaccharide of repeating disaccharide units comprising 1,4-linkage of glucosamine and uronic acid. This drug is a popular anticoagulant for diseases such as deep vein thrombosis (DVT) and pulmonary embolism (PE), extracorporeal (hemodialysis), and surgery [1]. Heparin is derived from animal sources [2], mainly pig intestines and bovine lungs, leading to a high risk of contamination by foreign impurities [3]. Thus, an effective extraction and purification method is essential to produce pure heparin by removing impurities. Heparin extraction and purification are currently performed using capillary electrophoresis, affinity chromatography, and polyacrylamide gel electrophoresis (PAGE). Nevertheless, these techniques demonstrated multiple drawbacks, including time consuming, high maintenance, and regeneration [4, 5]. Therefore, molecular imprinting technology has been proposed as a sustainable heparin extraction and purification alternative.

Molecular imprinting is a technology that produces artificial recognition sites in polymeric matrices complementary to the template in size, shape, and chemical functionality. The functional monomer is polymerized with a template in the presence of a cross-linker. Once the template is removed, cavities are imprinted on the molecular imprinting polymer (MIP). The MIP is produced as a highly selective polymer towards a particular template [6]. Furthermore, MIP manufacturing is simple and cost-effective, with high chemical and physical robustness, and highly resistant in harsh environments, such as drastic changes in temperature, pressure, and pH [7]. Therefore, MIP is extensively applied for separation and purification. For example, MIP can separate small compounds such as enzyme lysozyme from aqueous egg white [8], Congo red dye from water [9] and purify large macromolecular compounds such as protein [11], DNA acrydite [12] and acetoside from *Cistanche tubulosa* [10].

Several methods are utilized for MIP preparation, including radical and hydro-gel processes. Nonetheless, the sol-gel method is relatively superior due to the simplicity, time efficiency, and hydrophilicity of the protein template [13]. The sol-gel process involves the condensation of a colloidal solution (sol) to form a cross-linked solid (gel) in the presence of solvent and catalyst [14]. Previously, multiple MIPs had been developed using various techniques (bulk, precipitation, and surface imprinting), but these methods share similar weaknesses, such as poor and less selective adsorption performance in recapturing large molecule structures (e.g. protein). Therefore, epitope surface imprinting techniques are introduced due to the low cost, high template utilization efficiency, and high selectivity towards the target molecule, particularly large molecules. This technique involves the imprinting of the epitope template at the material surface. The epitope template functions as a pseudo-template to replace the macromolecule and polymerizes with monomers in the presence of a cross-linker to produce MIP films. Resultantly, highly selective cavities are formed in the MIP film once the epitope template is removed, similar to the normal macromolecule MIP film. Thus, a highly selective MIP is produced to recognize and bind to the targeted macromolecule [15].

In this study, the epitope imprinted polymer for capturing large molecule heparin was developed. The low molecular weight heparin (LMWH) was used as an epitope template to capture the large heparin macromolecule, while tetraethyl orthosilicate (TEOS) acted as the cross-linker for the epitope surface imprinting in the sol-gel process. Three functional monomers, (3-aminopropyl)trimethoxysilane (APTMS), (3-mercaptopropyl)trimethoxysilane

(MCPTMS), and 3-(2-aminoethylamino) propyl]trimethoxysilane (AEAPTES), were selected to investigate the interaction of heparin adsorption in this study.

Materials and Methods

Materials

The silica-gel (230 – 400 mesh) was purchased from Merck (Germany). The heparin, 98% (for medical purposes), was purchased from AinMedicare (Malaysia). The commercial LMWH), 98%, was purchased from Easybuyer Ltd. (Shanghai, China). The three functional monomers, APTMS, MCPTMS, and AEAPTES, were purchased from Sigma-Aldrich (Germany). Meanwhile, the cross-linker, TEOS, was purchased from Acros Organics (Germany). Hydrochloric Acid (HCl), 37%, was purchased from Fisher Scientific (Germany), while ethanol, 95%, and methanol, 99.98%, were obtained from HmbG (Germany).

Activation of silica gel

The silica gel was first activated to increase the silanol group and remove metal oxide and nitrogen-containing impurities [16]. Subsequently, the silica gel was dried to remove and reduce the silica gel particle size, thus, increasing the surface area and adsorption capacity [17]. The silica gel (15 g) was then immersed in 120 mL of concentrated 6 M hydrochloric acid (HCl) and refluxed for 10 h with constant stirring. The resulting mixture was filtered, washed thoroughly with deionized water, and centrifuged at 4000 rpm for 10 min. The washing steps were repeated until the mixture became neutral (pH 7.0). Lastly, the silica gel was oven dried at 70 °C overnight.

Preparation of epitope heparin imprinted polymer by sol-gel process

A total of 0.45 g LMWH (0.05 mmol) was first dissolved in 40 mL of distilled water before adding 0.0524 of APTMS (0.1 mmol) and sonicated for 5 min. Subsequently, 0.706 g TEOS (1.8048 mmol) was added into the solution and sonicated for another 5 min. Activated silica-gel (4 g) and 0.4 mL of 0.012 M HCl were added sequentially while stirring at 100 rpm, and the suspension was later polymerized at 40 °C for 24 h. The imprinted polymer was filtered, washed with 50 mL ethanol, and neutralized with 50 mL of distilled water thrice. Similarly, the non-imprinted polymer (NIP) was prepared using the same protocol but without the template LMWH. The process was repeated using the two remaining monomers: 0.1 mmol MCPTMS and 0.1 mmol AEAPTES. Once completed, the template LMWH was extracted from the imprinted polymer via sonication for 15 min with a 50 mL mixture of methanol and hydrochloric acid (10% in water) at a ratio of 1:1. Sonication was performed for another 15 minutes with 50 mL of methanol followed by 50 mL of water. The washing steps were repeated thrice. The supernatant from every washing was tested using UV-Vis spectroscopy at 230 nm, and the washing continued until no LMWH was detected. Finally, the MIP was obtained through filtration and dried at 80 °C overnight. A similar protocol was repeated for other imprinted polymers with different monomers and NIP.

Batch rebinding experiment

The MIP and NIP (50 mg) of different monomers were placed in 15 mL centrifuge tubes, followed by adding 5 mL of 0.25 mg/mL heparin or 0.25 mg/mL LMWH solution. Subsequently, the centrifuge tubes were placed horizontally on the shaker for 4 hours at 100 rpm under room temperature. In the adsorption binding test, different concentrations of the prepared mixtures were utilized (0.0625 mg/mL to 1.0 mg/mL). Similarly, the kinetic binding analysis was performed at a constant concentration of heparin of 0.50 mg/mL, except the time measurement was evaluated from 10 min to 240 min. Once the binding has completed, the tubes were centrifuged at 4000 rpm for 10 minutes to remove the imprinted residual from the supernatant. The supernatant was then filtered from the imprinted polymers using a nylon syringe filter (0.45 μm). The LMWH and heparin concentrations in the supernatant were measured by UV–Vis spectrometer at 230 nm or 202 nm, respectively.

Characterization of the Imprinted Polymers

A scanning electron microscope (SEM) was used to study the morphology and texture of the imprinted polymers. The MIP, NIP, and silica gel were coated with platinum for 90 seconds before being observed under

high vacuum conditions at 5 kV and 3 mA current in SEM. The MIP and NIP were examined at 1000×, 5000×, and 10,000× magnifications. The MIP, NIP, and silica gel were also analyzed using the Perkin Elmer Spectrum 100 Series Fourier-transform infrared (FT-IR) spectroscopy using the KBr pellet method. The polymer (100 mg) and 200 mg of KBr powder were mixed using mortar and pestle and pressed for 2 min at 8 kPa to form transparent pellets. Finally, the pellets were placed in the FT-IR sample holder and observed at wavenumbers between 400 and 4000 cm^{-1}

Results and Discussion

FTIR Characterization of epitope heparin imprinted polymer

The FT-IR spectroscopy was used to prove the presence of amine-functional silane in the developed polymer. Figure 1 illustrates the FT-IR spectra of silica gel, APTMS-MIP, MCPTMS-MIP, AEAPTES-MIP, and APTMS-NIP. Spectra that included silica gel, MIP, and NIP exhibited similar peaks. The strong peaks at 3234.61 cm^{-1} to 3436.78 cm^{-1} corresponded to OH-group vibrations, resulting from the moisture absorbed by the imprinted polymer. Meanwhile, the peaks at 1631.92 cm^{-1} to 1671.75 cm^{-1} indicated the C-C stretching vibration of alkane. The peaks from 1022.38 cm^{-1} to 1100.75 cm^{-1} are associated with the Si-O-Si stretching. The Si–O vibration was identified at the peaks between 747.30 cm^{-1} and 806.36 cm^{-1}.

The developed polymers demonstrated unique FTIR spectra; small peaks were detected at 1410.37 cm^{-1} for APTMS-MIP, 1460.53 cm^{-1} for MCPTMS-MIP, and 1444.48 cm^{-1} for AEAPTES-MIP, representing the N-H peaks of primary amine. In addition, the N-H peaks of secondary amine were identified in AEAPTES-MIP at 1560.87 cm^{-1}. The peak of the S-H thiol group in MCTMS-MIP was observed at 2683.61 cm^{-1}, which slightly deviated from the literature (2600 cm^{-1} – 2550 cm^{-1}). These peaks indicated that the monomers had been imprinted on the silica support, hence, the successful production of epitope heparin imprinting polymer compared to silica gel.

Previously, Eskandarloo [18] synthesized (3-aminopropyl) triethoxysilane (3-APTES)-functionalized halloysite nanotubes (HNTs) by using heparin as a template to enhance the capacity of MIP binding selectivity. In contrast, the current study utilized LMWH as a template to capture large heparin, thus, known as the epitope imprinted technique. Moreover, the three types of silane groups selected for this study belonged to the trimethoxysilane group, contrary to the triethylxysilane group detected at 2900 cm^{-1} used by - Eskandarloo. The study also claimed that small peaks were detected at 1476 cm^{-1} and 2928 $cm^{-1,}$ represented by the C-N and N-H stretch, which was absent in the presence of a silane coupling agent.

SEM characterization of epitope heparin imprinted polymer

The surface morphology of silica, epitope heparin imprinted polymer, and the non-imprinted polymer was studied using SEM at 5000x magnification (see Figure 2). The silica gel [Figure 2(a)] exhibited a highly rough surface compared to other epitope imprinting and non-imprinting heparin [Figure 2 (b) - (e)], owing to the abrasive nature of silica particles. Furthermore, the imprinting polymers, APTMS-MIP [Figure 2 (b)], MCPTMS-MIP [Figure 2 (c)], and AEAPTES-MIP [Figure 2 (d)] demonstrated porous surfaces, representing the cavities resulting from the template removal. These pores can speed up the adsorption process towards the template and improve adsorption kinetic than NIP. Apart from that, this observation indicated that the epitope heparin had been imprinted on the silica gel, hence, the successful preparation of the epitope heparin polymer [19]. Conversely, the non-imprinting polymer in Figure 2 (e) manifested a clear, smooth surface without forming three-dimensional pores due to the non-template polymerization.

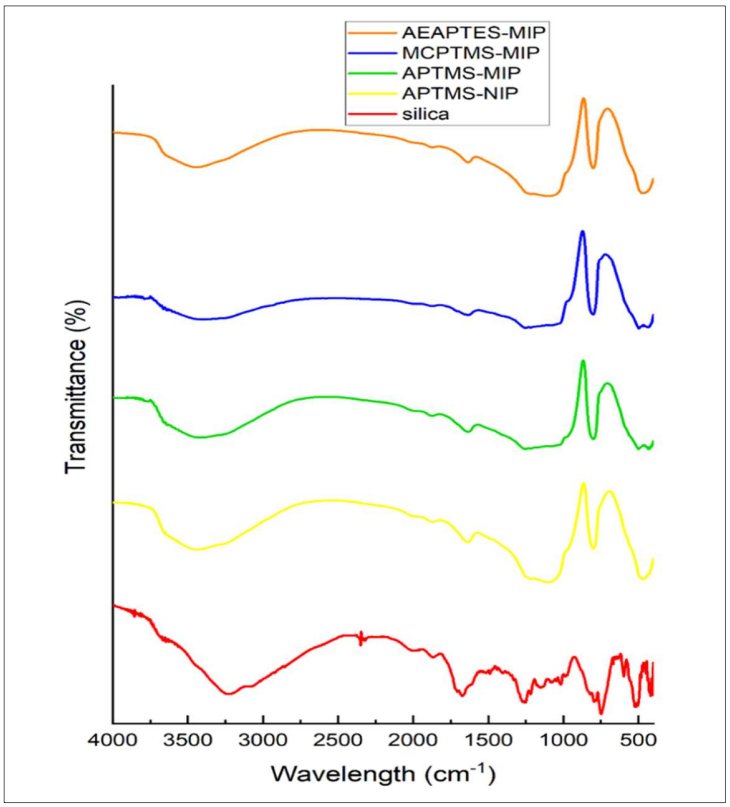

Figure 1. The FT-IR spectra of silica gel (red), APTMS-NIP (yellow), APTMS-MIP (green), MCPTMS-MIP (blue), and AEAPTES-NIP (orange)

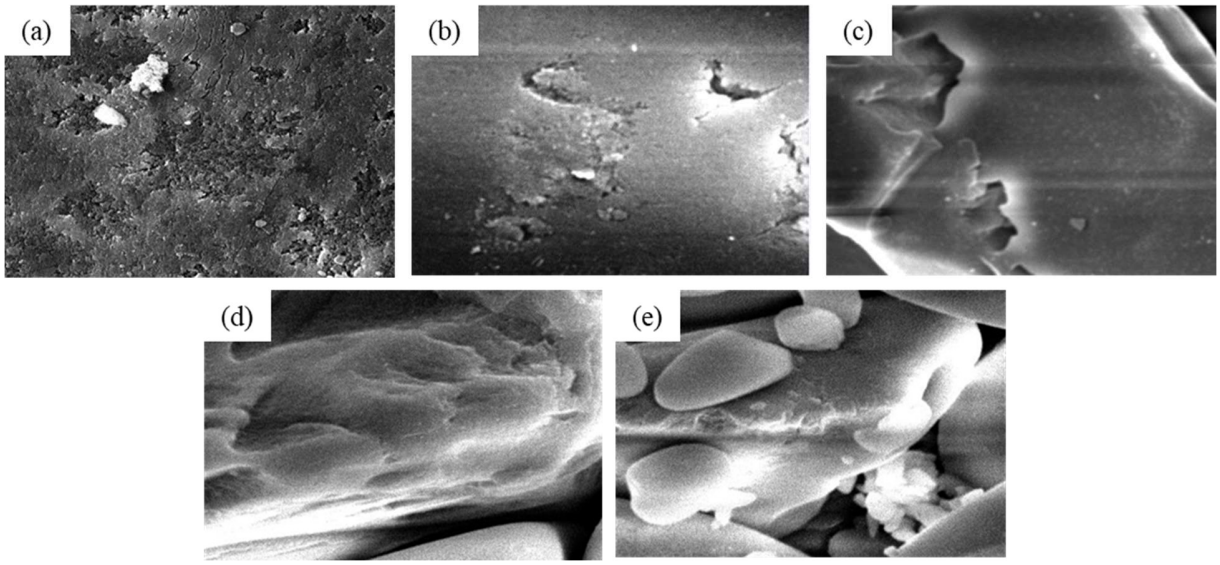

Figure 2. The SEM images of silica (a) APTMS-MIP, (b) MCPTMS-MIP, (c) AEAPTES-MIP, (d) and (e) NIP at 5000x magnification

Gossypol imprinted on silica surfaces via sol-gel surface imprinting [20] exhibited similar findings to the present study. The SEM images of gossypol-MIP illustrated rougher surfaces than gossypol-NIP and silica, indicating a successfully imprinted polymer. In addition, the silica gel surface was distinctly smoother than gossypol-MIP and gossypol-NIP.

Interactions between the functional monomer with heparin and LMWH

The present study tested three monomers, APTMS, MCPTMS, and AEAPTES, to identify the best functional monomer for the heparin imprinted polymer. The selectivity of epitope heparin imprinted polymer with different monomers was represented as an imprinting factor (IF). The comparison graphs of different monomers are plotted in Figure 3 for heparin rebinding and Figure 4 for LMWH rebinding. Generally, the monomers recorded higher IF values for heparin rebinding than LMWH rebinding, with the highest binding capacity of 23 mg/g for heparin and 9 mg/g for LMWH. The epitope MIP binding of macromolecule heparin was double that of LMWH, indicating higher adsorption towards the former than the latter. Thus, the findings supported epitope MIP utilization to capture macromolecule heparin. Similarly, Gupta et al. [21] reported that epitope-imprinted iron-binding MIP for detecting fbpA protein on *Neisseria meningitidis* bacteria demonstrated high selectivity towards the template fbpA protein (IF = 12.27 $ngmL^{-1}$). The protein epitope polymer was synthesized using the amino sequence fbpA epitope as the template. This finding suggested that the small epitope molecule could recognize macromolecules. Apart from that, Yoshimi et al. [22] used epitope surface imprinting heparin-imprinted nanoparticles for grafting on unfractionated heparin (UFH) or LMWH-immobilized glass beads, indicating that the epitope heparin imprinting polymer could capture macromolecule heparin by epitope surface imprinting.

Table 1 shows that AEAPTES recorded the highest IF values for heparin and LMWH rebinding, followed by APTMS and MCPTMS. Therefore, heparin and LMWH selectivity were the highest in AEAPTES, followed by APTMS and MCPTMS. This observation could be explained by the presence of double amine groups in AEAPTES; the primary and secondary amine established stable amine-functionalized surfaces. Resultantly, the interactions between the functional monomer and sulphate group in macromolecule heparin by hydrogen bonding increased in AEAPTES compared to APTMS with a single amine group. Meanwhile, the sulphydryl functional group (SH-group) in MCPTMS exhibited low interaction with macromolecule heparin. An earlier study by Zhu et al. [23] reported that AEAPTES had the highest thickness than other functional silanes, such as 3-aminopropyltriethoxysilane (APTES), APTMS, N-(2-aminoethyl)-3-aminopropyltrimethoxysilane (AEAPTMS), and N-(6-aminohexyl)aminomethyltriethoxysilane (AHAMTES). Moreover, AEAPTES is a more sterically hindrance of intramolecularly catalyzed hydrolysis, potentially improving the hydrolytic stability. As AEAPTES has low sensitivity to water, the polymer can generate a more reproducible silane group. Lastly, AEAPTES possess a unique structure that allows the formation of a cyclic intermediate through the coordination between the secondary amine group and the silicon atom.

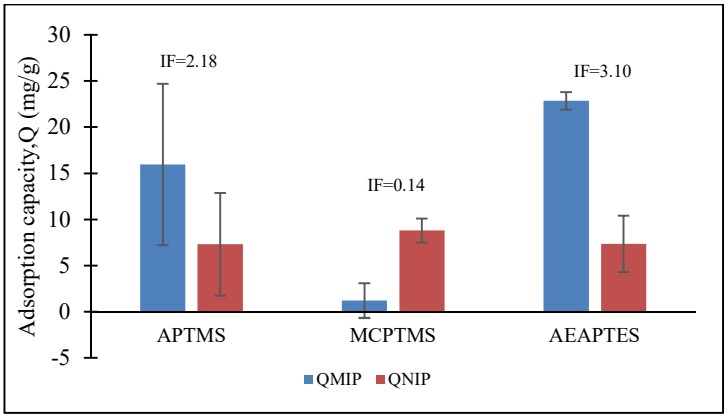

Figure 3. Heparin rebinding of different monomers

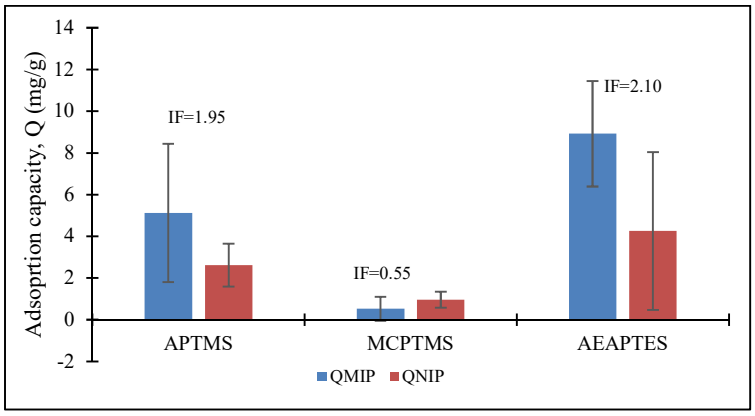

Figure 4. The LMWH rebinding of different monomers

Table 1. Heparin and LMWH rebinding performance of epitope heparin imprinted polymer with different monomers

Sample	Heparin			LMWH		
	Q_{MIP}	Q_{NIP}	IF	Q_{MIP}	Q_{NIP}	IF
APTMS	15.965	7.311	2.18	5.121	2.624	1.95
MCPTMS	1.203	8.789	0.13	0.529	0.96	0.55
AEAPTES	22.843	7.357	3.10	8.919	4.257	2.09

Q_{MIP} = MIP binding capacity, Q_{NIP} = NIP binding capacity, and IF = Imprinting factor

Adsorption and kinetic binding capacity towards heparin

Figure 5 shows the adsorption capacities of AEAPTES-MIP towards different concentrations of heparin (0.062 mg/mL - 1.0 mg/mL). There was a surge in AEAPTES-MIP and AEAPTES-NIP adsorption capacities when the heparin concentration increased from 0.0625 mg/mL to 0.5 mg/mL and remained constant thereafter. As the heparin concentration (target) increased, more heparin was available to adhere to the binding sites, increasing the heparin adsorption and binding capacities. The polymer became saturated at the equilibrium point (0.5mg/mL) as all the binding sites were occupied by heparin [24]. Based on Figure 5, AEAPTES-NIP adsorption capacity was slightly lower than AEAPTES-MIP. Meanwhile, the highest binding capacities for AEAPTES-MIP and AEAPTES-NIP were 38.19 mg/g and 35.51 mg/g, respectively. This outcome was aligned with a study by Dai et al.[22], which recorded similar adsorption capacities for the structural analogues of

AEAPTES-MIP and AEAPTES-NIP. Conversely, NIP could not produce proper binding sites that are highly complementary to the target due to the absence of a template, resulting in non-specific adsorption. Therefore, NIP adsorbed less template molecule than MIP, leading to lower adsorption capacities.

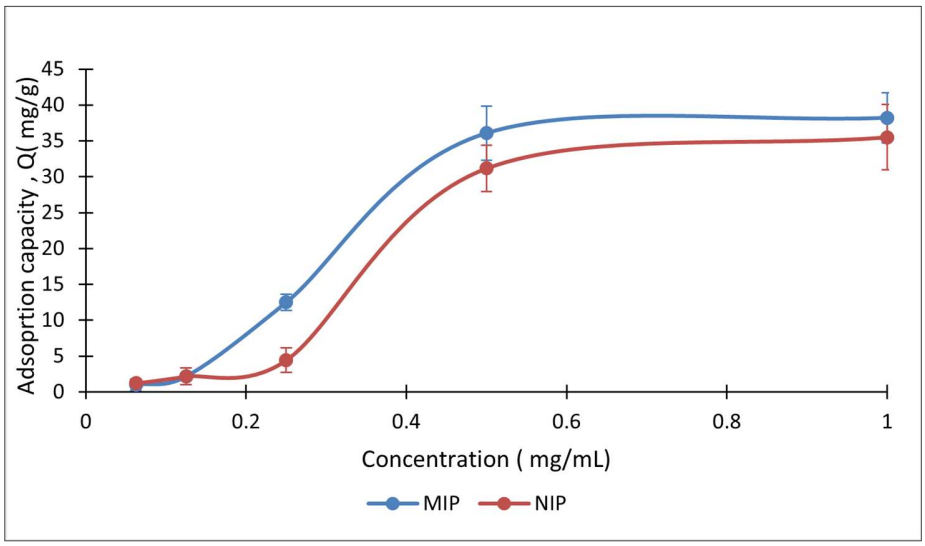

Figure 5. Batch binding test of heparin towards AEAPTES-MIP and AEAPTES-NIP

The AEAPTES-MIP and AEAPTES-NIP adsorption behaviors were determined using Langmuir and Freundlich, isotherm models. The AEAPTES-MIP is best suited to Freundlich isotherm with a linear regression coefficient (R^2) value of 0.8968. This outcome indicated that the heparin adsorption was multilayered and reversible, and the heat adsorption distribution was non-uniform on the AEAPTES-MIP heterogeneous surface. Meanwhile, AEAPTES-NIP followed the Langmuir isotherm model with an R^2 value of 0.9375. This finding suggested the reversible and energetically equivalent heparin adsorption at the homogenous site of the AEAPTES-NIP monolayer surface.

Figure 6 details the kinetic binding of heparin adsorption at 0.5mg/mL onto AEAPTES-MIP and AEAPTES-NIP between 10 to 240 minutes. The polymers adsorption capacities spiked during the first 10 to 120 minutes and decreased gradually until equilibrium was achieved. The rapid initial heparin adsorption could be explained by the abundance of polymer binding sites exposed to the target, which continued to rise with time. At 60 minutes, the binding sites became saturated, and resistance occurred between heparin and the polymer surface, making it harder to retain heparin in empty binding sites. Consequently, the adsorption rates declined and reached adsorption equilibrium [25]. The AEAPTES-NIP recorded a slightly lower adsorption capacity than AEAPTES-MIP, with the highest binding capacity of 17.1556 mg/g for the former and 18.4478 mg/g the latter.

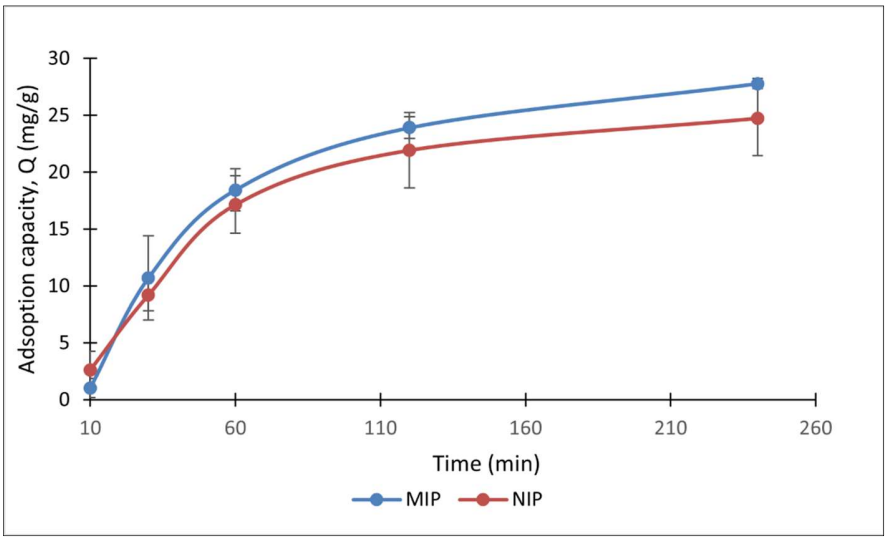

Figure 6. Kinetic binding analysis of heparin on AEAPTES-MIP and AEAPTES-NIP

The AEAPTES-NIP could not bind properly to a highly complementary target without a template, resulting in non-specific adsorption. Consequently, NIP adsorbed less template molecule than MIP, reducing adsorption capacities [26]. Furthermore, AEAPTES-MIP and AEAPTES-NIP were best suited to the pseudo-first-order with R^2 values of 0.9996 and 0.9870, respectively. These results indicated that the rate of change of heparin uptake with time is directly proportional to the difference in concentration of saturation and the amount of heparin uptake with time.

Conclusion

The prepared epitope heparin MIP samples were characterized using FT-IR and SEM in this study. The FT-IR results identified unique functional groups in the epitope heparin polymers: 1) amine group in APTMS-MIP, 2) thiol group in MCPTMS-MIP and 3) secondary amine group in AEAPTES-MIP. Meanwhile, the SEM findings indicated that all MIP exhibited rough surfaces compared to NIP, thus, confirming that the functional monomer and epitope heparin were successfully imprinted on the silica gel. Among the three selected monomers, AEAPTES-MIP demonstrated the best imprinting effect toward heparin (IF = 3.10). This functional monomer exhibited high stability and dual functional groups to create strong hydrogen bonding. Furthermore, the produced epitope heparin was proven to have high adsorption and specificity towards the macromolecule heparin template due to the higher adsorption toward heparin than LMWH. In conclusion, this study demonstrated that MIP could be synthesized using simple and fast methods, such as the proposed epitope surface imprinting and sol-gel method. These approaches can overcome the limitations of MIP and produce high selectivity heparin imprinted polymers.

Abstract

The present study describes the utilization of simple and commercially available iodine and tetraphenylphosphonium salt as leaching agents to recover palladium (Pd) from waste. This study employed a model reaction assay that utilized Pd(0) metal powder to stimulate palladium leaching from spent automotive three-way catalyst (TWC). The palladium complexes, $(Ph_4P)_2[Pd_2I_6]$, obtained were characterized with Fourier-transform infrared (FT-IR), ultraviolet-visible (UV-Vis) spectroscopy, nuclear magnetic resonances (NMR), thermogravimetric analysis (TGA), and elemental analysis. The recovered Pd complexes demonstrated excellent catalytic activity towards the methoxylation of benzo[*h*]quinoline. Furthermore, a lower to moderate product yield was recorded for the ethoxy- and isopropoxylation of benzo[*h*]quinoline. The C-H functionalization of 8-methylquinoline catalyzed by the obtained palladium complexes also documented a moderate product yield (< 65%) after 6 hours of reaction. The antibacterial activities of the $(Ph_4P)_2[Pd_2I_6]$ were evaluated through a disk diffusion test, minimum inhibitory concentration (MIC), and minimum bactericidal concentration (MBC) assays. Among the gram-positive and -negative bacteria evaluated, *Klebsiella pneumoniae* exhibited the highest sensitivity to the synthesized $(Ph_4P)_2[Pd_2I_6]$ at all concentrations. The MIC concentrations for all assessed bacteria ranged from 0.156 to 1.25 mg/mL. Moreover, bacterial growth was detected in all MBC plates, thus indicating that the $(Ph_4P)_2[Pd_2I_6]$ possessed a bacteriostatic effect and not a killing attribute.

Keywords: recovered palladium, palladium catalyst, antibacterial activity

Abstrak

Kajian ini menghuraikan mengenai penggunaan iodin dan garam tetrafenilphosphonium yang mudah dan boleh didapati secara

komersial sebagai agen larut lesap dalam proses pemulihan paladium (Pd) daripada sisa terbuang. Kajian ini melaksanakan ujian berdasarkan model tindak balas yang menggunakan serbuk logam Pd(0) untuk merangsang proses larut lesap Pd dari pemangkin tiga hala automotif (TWC) terpakai. Spesies molekul kompleks Pd dipulihkan, $(Ph_4P)_2[Pd_2I_6]$, yang diperoleh dicirikan melalui Fourier-transform inframerah (FT-IR), spektroskopi ultra ungu-nampak (UV-Vis), resonans magnet nuklear (NMR), analisis termogravimetrik (TGA) dan analisis unsur. Kompleks Pd dipulihkan yang diperoleh tersebut menunjukkan aktiviti pemangkin yang sangat baik bagi ke arah metoksilasi benzo[*h*]kuinolin. Selain itu, hasil produk yang sederhana telah direkodkan bagi etoksi dan isopropoksilasi benzo[*h*]kuinolin. Kefungsian C-H sebagai pemangkinan 8-metilquinolin oleh kompleks Pd dipulihkan juga merekodkan hasil produk yang sederhana (< 65%) selepas tindak balas selama 6 jam. Aktiviti antibakteria $(Ph_4P)_2[Pd_2I_6]$ tersebut dinilai melalui ujian resapan cakera, kepekatan perencatan minimum (MIC), dan ujian kepekatan bakteria minimum (MBC). Antara kesemua bakteria gram-positif dan -negatif yang diuji, *Klebsiella pneumoniae* menunjukkan sensitiviti tertinggi kepada $(Ph_4P)_2[Pd_2I_6]$ pada semua kepekatan. Kepekatan MIC untuk semua bakteria yang diuji direkod dalam julat 0.156 hingga 1.25 mg/ml. Tambahan pula, pertumbuhan bakteria yang dikesan dalam semua plat MBC menunjukkan bahawa $(Ph_4P)_2[Pd_2I_6]$ mempunyai kesan bakteriostatik dan tidak membunuh.

Kata kunci: paladium dipulihkan, mangkin paladium, aktiviti antibakteria

Introduction

Palladium (Pd) is a limited and significant raw material due to its scarcity and economic value [1]. Consequently, the element possesses a considerable market demand, dominated by automotive catalytic converters and electronic equipment, which account for 90% of its global production [2]. Nonetheless, Pd is primarily mined in geopolitically-unstable countries, such as Russia and South Africa, which could affect supply and pricing [3]. Furthermore, Pd mining is an energy-intensive process that employs chemical reagents [4] that are exceptionally detrimental to the environment, including published harmful effects on water and air quality, biodiversity, and housing displacement [5-7]. Consequently, a practical and realistic approach is necessary for sustainable Pd utilization.

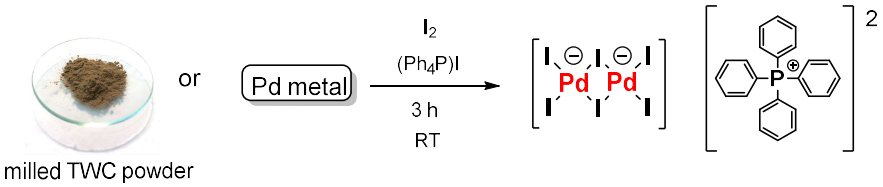
The Pd-containing waste from three-way catalytic converters (TWC) [8] and electric and electronic equipment (EEE) [9] has accumulated worldwide. The substance is a significant but underutilized source of potentially recoverable raw material. The most common techniques for recovering Pd from waste include pyro- and hydrometallurgical methods, where both are disadvantageous. The pyrometallurgical method consumes high energy and lacks Pd selectivity [10]. The more selective hydrometallurgical techniques rely on harmful reagents, such as potent oxidizing agents, including aqua regia and cyanide to leach Pd from spent TWC and EEE under mild conditions [11].

Available energy-efficient and sustainable recovery techniques produce molecular recovery products. Serpe and colleagues [12] demonstrated an excellent method of utilizing organic compounds, such as N,N'-dimethylperhydrodiazepine-2,3-dithione diiodine adduct ($Me_2dazdt{\cdot}2I_2$), to recover Pd from model spent catalytic converter under mild conditions. Nevertheless, the recovered Pd complexes $[Pd(Me_2dazdt)_2]I_6$ require an energy-intensive step that eliminates its ligands to procure metallic Pd as the end product [12].

An intriguing application was proposed by Wilton-Ely *et al*. to utilize the recovered Pd complex directly as a homogeneous catalyst in the C-H functionalization of benzo[*h*]quinoline and 8-methylquinoline [13]. Surprisingly, the $[Pd(Me_2dazdt)_2]^{2+}$ was catalytically active toward the proposed reaction, thus outperforming the conventionally mined $Pd(OAc)_2$ [14]. Nonetheless, the relatively expensive starting materials and Lawesson's reagent employed to install sulfur groups into the ligand designs diminished the economic and environmental benefits of the recovery process. Accordingly, a simpler, cheaper, and commercially available approach was sought to address the constraint. The impressive ability of organic triiodides, tetraphenylphosphonium $[Ph_4P]^+$, in the presence of iodine in the selective dissolution of Pd from spent TWCs was demonstrated by [15] (see Scheme 1).

The present study directly utilized the recovered Pd complexes, $(Ph_4P)_2[Pd_2I_6]$, as a homogeneous catalyst in the C-H functionalization of benzo[*h*]quinoline and

8-methylquinoline in ambient air, which required nitrogen as the only directing atom. The procedures were based on the work by [13]. The Pd loading, temperature, and time were varied to optimize the catalytic reaction. The lower temperature approach was focused on enhancing the green credential of the method. The results were compared to previous findings in studies utilizing different Pd catalysts obtained from commercial or secondary sources.



The recent emergence of antimicrobial resistance has become a critical issue worldwide [16]. Consequently, the demand to develop novel and efficient antimicrobial agents has also increased. Numerous studies have attempted to elucidate Pd compound potentials in combating human pathogens-caused illnesses [17–21]. Nonetheless, only very few studies reported the possible effects of recovered Pd against pathogenic bacteria. Thus, the present study explored the antibacterial attributes of the recovered $(Ph_4P)_2[Pd_2I_6]$ against common gram-positive and -negative bacteria.

Materials and Methods

All chemicals and solvents employed in the present study were purchased and utilized without further purification unless otherwise stated.

Synthesizing the $(Ph_4P)_2[Pd_2I_6]$ complexes

Serpe and co-workers [15] demonstrated the impressive ability of tetraphenylphosphonium $[Ph_4P]^+$ in the selective dissolution of Pd from spent TWCs (see Scheme 1). The Pd metal powder was employed as a proxy for the milled TWC mixed-metal powder to assess the Pd complex generated by the system. Tetraphenylphosphonium iodide (0.144 g, 0.31 mmol) was treated with iodine in acetone (30 mL) before adding Pd metal powder (33.1 mg, 0.31 mmol). The reaction mixture was stirred at room temperature for 3 hours until an abundant black crystalline product was precipitated. Subsequently, product re-crystallization was conducted by slowly diffusing diethyl ether into the concentrated acetone solution of the reaction mixture. The yield recorded in this study was 286 g (90%) [15].

Scheme 1. The synthesis of recovered Pd complexes [15]

Characterization of $(Ph_4P)_2[Pd_2I_6]$ complexes

The Pd complexes obtained in the current study were characterized via ^1H and ^{13}C nuclear magnetic resonance (NMR) with a JEOL JNM-ECZS 400 MHz spectrometer. A Varian Bruker AV300 spectrometer was also employed in attributing the ^1H NMR signals of the C-H functionalization catalysis reaction at 25 °C with deuterated chloroform ($CDCl_3$). Moreover, infra-red data were obtained with a Nicolet 6700 ATR spectrometer at 16 scans of 600–4000 cm^{-1} on solid samples. The specimens were also subjected to an ultraviolet-visible (UV-VIS) spectrometer (Perkin Elmer Lambda 25) to obtain the transmission and absorption spectra of the complexes within the 300–800 nm wavelength. Furthermore, elemental analyses (EA) were performed with CHNS/O Analyzer 2400 Perkin Elmer Series II, while thermogravimetric analysis (TGA) was conducted in a nitrogen atmosphere with a Mettler Toledo TGA/DSC 1LF/UMX.

The general C-H functionalization synthetic procedure

The C-H functionalization reaction in this study was performed with a Radley's Carousel 12 Reaction Station. The adaptable apparatus transforms a normal stirring hotplate into 12 parallel synthesizers capable of conducting parallel chemical reactions in an inert or ambient environment. First, individual reaction bottles (24 mm × 150 mm) were filled with alcohols, sacrificial oxidants, Pd catalysts, and substrates. The reaction

bottles were then installed on the Carousel 12 Reaction Station before the mixture was heated and stirred for 2, 4, and 6 hours. The operational temperature range of the heated base was 0–180°C at ±0.5 °C temperature precision. A single spinning magnetic field was also applied to ensure homogeneous stirring in each reaction bottle.

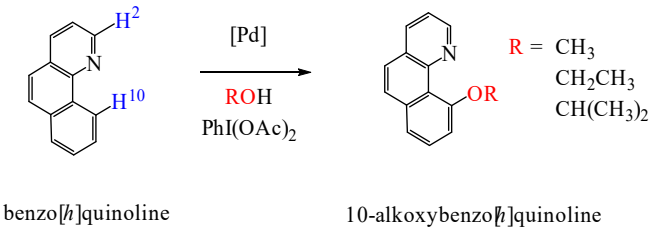


Figure 1. Radley's Carousel 12 Reaction Station

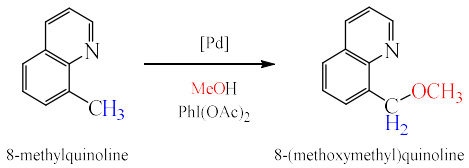
Synthesizing 10-alkoxybenzo[*h*]quinoline

Benzo[*h*]quinoline (50.0 mg, 0.28 mmol), (diacetoxyiodo)benzene (180.4 mg, 0.56 mmol), and $(Ph_4P)_2[Pd_2I_6]$ (between 1–2 mol% loads) were mixed in 2.5 mL alcohol [methanol (MeOH), ethanol (EtOH), or isopropanol and glacial acetic acid mixture] in a reaction bottle. Subsequently, individual reaction bottles were heated at 50 and 100 °C and stirred for 2, 4, and 6 hours. All solvent was then removed with a rotary evaporator, followed by the dissolution of the residue in a deuterated $CDCl_3$ for ^{1}H NMR analysis (see Scheme 2).

The ^{1}H NMR spectroscopic yield analysis was conducted by comparing the integration of the H_2 or H_{10} protons of benzo[*h*]quinoline at 9.30 and 9.05 ppm, respectively, to the peak of 10-alkoxybenzo[*h*]quinoline at 9.15 ppm. Another peak corresponding to the alkoxy group in the product was subjected to further evaluation at 4.19 (methoxy, CH_3; singlet), 1.63 and 4.45 (ethoxy, CH_2CH_3; triplet and quartet), and 1.54 and 4.76 [isopropoxy, $CH(CH_3)_2$; doublet and septet] ppm. All reactions were conducted a minimum of three times, and the yields were measured with ^{1}H NMR based on three independent experiments.



Benzo[*h*]quinoline (150.0 mg, 0.84 mmol), (diacetoxyiodo)benzene (541.2 mg, 1.68 mmol), and $(Ph_4P)_2[Pd_2I_6]$ (2 mol%) were treated in MeOH (7.5 mL) and heated at 50 °C for 2 hours for the isolated yield reaction. The products were then purified in a flash column (3:2 v/v ethyl acetate-to-n-hexane eluent) to procure 10-methoxybenzo[*h*]quinoline.

Scheme 2. The benchmark reaction for oxidative C-H functionalization

The synthesis of 8-(methoxymethyl)quinoline

A total of 42.5 mg of 8-methylquinoline (0.297 mmol), 103.3 mg of (diacetoxyiodo)benzene (0.321 mmol), and between 1–2 mol% loadings of $(Ph_4P)_2[Pd_2I_6)$ were mixed in 2.5 mL MeOH in reaction bottles. The individual reaction bottles were then heated at 50 °C and stirred for 2, 4, and 6 hours. Subsequently, the solvent was removed under reduced pressure, followed by the dissolution of the residue obtained in a deuterated $CDCl_3$ for ^{1}H NMR analysis. The product yield was determined by comparing the methyl integration (2.82 ppm) of 8-methylquinoline with the methylene (5.19 ppm) and methoxy group (3.57 ppm) in the 8-(methoxymethyl)quinoline resonances (see Scheme 3).

Scheme 3. The C-H functionalization of 8-methyl quinolone

Bacterial culture

Stock cultures of gram-negative, *Escherichia coli* (ATCC25922), *Salmonella typhimurium* (ATCC14028), *Klebsiella pneumoniae* (ATCC700603), and *Klebsiella aeruginosa* (ATCC13048), and gram-positive bacteria, *Bacillus cereus* (ATCC11778) and *Bacillus subtilis* (ATCC13124), were obtained from the Faculty of Applied Sciences, Universiti Teknologi MARA (UiTM), Shah Alam. The cultures were maintained on nutrient agar media at 37 ℃. Colony morphology observation and gram staining were performed in the present study to confirm the working strains.

Antimicrobial study: Disk diffusion method

The antibacterial activities of varying concentrations of $(Ph_4P)_2[Pd_2I_6]$ complex were screened against common gram-positive and -negative bacteria. Subsequently, the antibacterial activities of the samples were determined with the Kirby-Bauer disk diffusion method on a Muller-Hinton Agar (MHA) medium. For working cultures, 18–20 hours broth culture of each bacterium inoculum was compared with 0.5 McFarland standard (1×10^8 CFU/mL) and adjusted visually to obtain working cultures. A sterile cotton swab was dipped into the McFarland standardized inoculum, seeded and covered the MHA plate with the evenly swabbed inoculum. Next, sterile disks were placed onto each plate.

Before analysis, the $(Ph_4P)_2[Pd_2I_6]$ was dissolved in dichloromethane (DCM) into varying concentrations (1, 2, 3 and 4 mg/mL). An amount of 20 μL of each $(Ph_4P)_2[Pd_2I_6)$ concentration was pipetted onto the disks. Gentamicin (CN) (10 µg) and sterile distilled water were utilized as positive and negative controls, respectively. All of the plates were then incubated for 24 hours at 37 ℃. Following incubation, the inhibitory zone (in mm) was measured and recorded. All tests were performed in triplicate per condition.

The MIC and MBC

MIC was determined using Mueller–Hinton broth (MHB) macrodilution assays. Briefly, bacteria inoculum was prepared and adjusted to McFarland standard as before. Next, 1 mL of adjusted inoculum was transferred into 8 sterile test tubes. 1 mL of $(Ph_4P)_2[Pd_2I_6]$ complex dissolved in DCM was then added into the first tube, and 2-fold serial dilutions were performed to give the final concentrations of 10, 5, 2.5, 1.25, 0.625, 0.313, 0.156 and 0.078 mg/mL. Two additional tubes were prepared as positive growth control (MHB + bacteria) and negative control (MHB only). All tubes (in triplicate per condition) were incubated aerobically for 24 hours at 37 ℃, and MIC values were determined as the lowest concentration of the test compound that prevents microbial growth. For MBC, the MIC tubes that showed no visible apparent growth were subcultured onto the MHA plate and incubated for 24 hours at 37 ℃. No evidence of bacterial growth following incubation were confirmed as MBC values.

Statistical analysis

For antimicrobial analysis, data were statistically analyzed using GraphPrism 8.0. Results for the inhibitory zone were expressed as means ± standard error of the means (SEM). The results shown are the mean of three tested cultures plus SEM. Data were further analyzed with a two-way Analysis of Variance (ANOVA) followed by a Tukey's multiple comparison post-test. In all tests, p-values <0.05 and asterisks indicate statistically significant differences.

Results and Discussion

Transformation of recovered Pd complex from the recovery process

Scheme 1 illustrates selective Pd leaching from waste utilizing an organic triiodide salt in an organic solution

at room temperature. The peculiar features of the iodide/iodine mixture in the tetraphenylphosphonium iodide [(PPh_4)I] system could dissolve and quantitatively recover Pd from spent automotive TWC waste, generating a molecular $(Ph_4P)_2[Pd_2I_6]$ species [15]. Nonetheless, the procedure necessitates conventional thermal treatment to procure metallic Pd as the end product, thus making the technique less practical for recycling Pd. Consequently, the $(Ph_4P)_2[Pd_2I_6]$ complex obtained directly as a homogeneous catalyst for C-H activation and antibacterial agent against common pathogenic bacteria was suggested to solve the issue.

This study employed Pd metal powder as a proxy for milled TWC metal powder mix to generate the recovered Pd complex $(Ph_4P)_2[Pd_2I_6]$. Equimolar Pd powder with (PPh_4)I and iodine was dissolved in an acetone solution. The reaction mixture was stirred at room temperature for 3 hours. The resultant abundant black crystals formed were collected. The products were then re-crystallized by slowly diffusing diethyl ether (Et_2O) in a concentrated $(Ph_4P)_2[Pd_2I_6]$ acetone solution. A good yield of 90% was recorded. The infra-red and UV-Vis analysis of the $(Ph_4P)_2[Pd_2I_6]$ obtained in this study agreed well with the data reported by [15]. The complex was further characterized with NMR spectroscopy and elemental analysis to confirm the overall molecular formula.

The FT-IR analysis of the $(Ph_4P)_2[Pd_2I_6]$ chemical composition

The vibration frequencies of the $[PPh_4]^+$ counter ions remained virtually unchanged upon the Pd complex formation (see Figure 2). Furthermore, typical C-H and C-P stretching in aromatic phenyl absorptions were observed at 3049 and 1105 cm^{-1}, respectively. The aromatic C-H in-plane bending was also observed around the 1433 cm^{-1} region. The C-H bending for the monosubstituted absorption band was obscured within the 751–682 cm^{-1} band. The C=C and C-C stretching feature retentions in the infrared spectrum were observed at 1584 and 1479–1433 cm^{-1}, respectively [22]. The Pd-I stretching frequencies were not detected due to the absorption band occurring at a lower frequency region, while the other stretches agreed with a previous report [15].

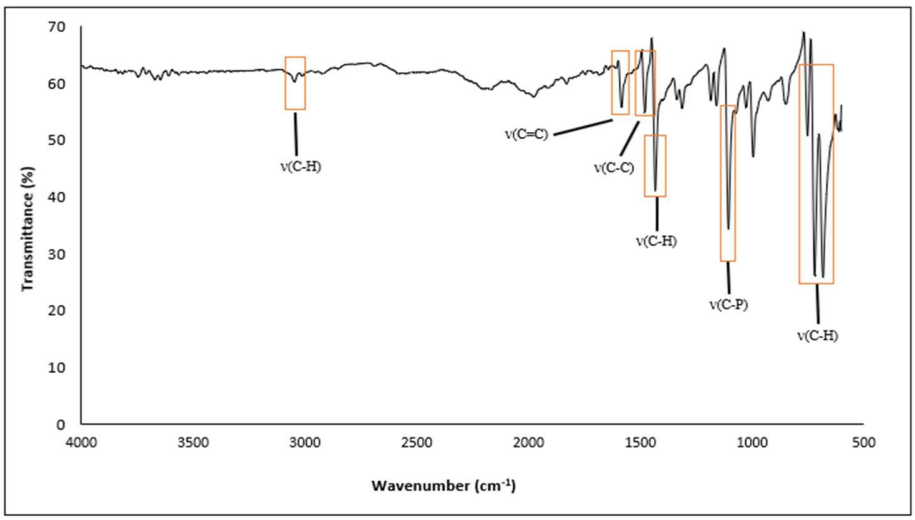


Figure 2. The FT-IR spectra of the recovered $(Ph_4P)_2[Pd_2I_6]$ complex

The $(Ph_4P)_2[Pd_2I_6]$ complexation analysis with UV-Vis spectra

Figure 3 illustrates the UV-Vis spectra of the Pd complexes procured in the current study. The presence of dimeric Pd complex, $[Pd_2I_6]^{2-}$, was confirmed by the absorption at 340 nm, while the peaks recorded at 426 and 524 nm supported the report by [15]. The absorption of PPh_4^+ was documented at approximately 260 nm, but

absorptions below 300 nm were indistinct and could not be appropriately determined [23].

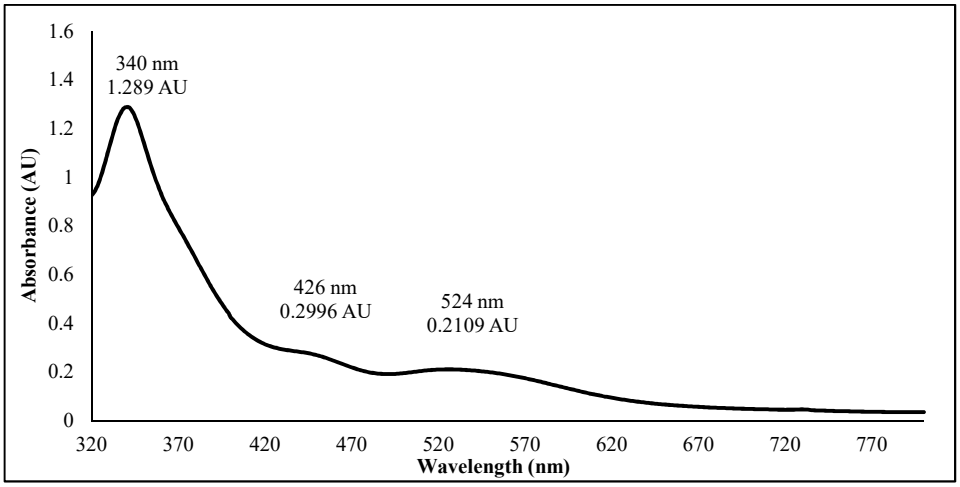

Figure 3. The UV-Vis spectra of the recovered $(Ph_4P)_2[Pd_2I_6]$ complex

The $(Ph_4P)_2[Pd_2I_6]$ molecular structure analysis via NMR spectroscopy

The NMR spectra of the $(Ph_4P)_2[Pd_2I_6]$ complex procured in this study were recorded in deuterated $CDCl_3$. The ^1H NMR analysis revealed diagnostic features of multiplet resonances at aromatic regions (7.66–7.95 ppm), which were attributed to the aromatic protons of the $[PPh_4]^+$ counter-ion phenyl groups. The carbon nuclei of $[PPh_4]^+$ counter-ions were almost unaltered compared to the precursors in the ^{13}C NMR spectrum. The ^1H NMR was set to 400 MHz, δ 7.95–7.66 ppm, while the ^{13}C NMR was at δ 117.0, 117.1, 131.0, 131.2, 134.7, 134.8, and 135.8 ppm.

The $(Ph_4P)_2[Pd_2I_6]$ organic matter composition analysis with CHNS/O analyzer

The composition of organic matter in the Pd complex [$C_{48}H_{40}I_6P_2Pd_2$ (Mw = 1653.06 g/mol)] obtained in the present study was determined with a CHNS/O analyzer. The results revealed experimental and calculated carbon and hydrogen percentages agreement, thus confirming the organic matter composition in the complex (see Table 1).

Table 1. Elemental analysis of the $(Ph_4P)_2[Pd_2I_6]$ complex

Element	Atomic Weight (g/mol)	Calculated Weight (%)	Experimental Weight (%)
C	12.011	$\frac{12.011 \times 48 \times 100}{1653.06} = 34.87$	34.9
H	1.008	$\frac{1.008 \times 40 \times 100}{1653.06} = 2.44$	2.4

Thermal stability analysis of the $(Ph_4P)_2[Pd_2I_6]$ with TGA

The thermal stability of the $(Ph_4P)_2[Pd_2I_6]$ complex from 30 to 750 °C was assessed at a 10 °C per minute heating rate (see Figure 4). The TGA isotherm exhibited slow mass declines within 30–300 °C before decreasing

significantly from 300 to 380 °C, indicating a 63% weight loss during the first stage of decomposition. The second stage of thermal decomposition was documented within 380–460 °C with a weight loss of approximately 17%. The loss in mass was relatively stable throughout the analysis. The stability of the complexes at high temperatures allowed the catalytic C-H functionalization reaction to be conducted at 100 °C.

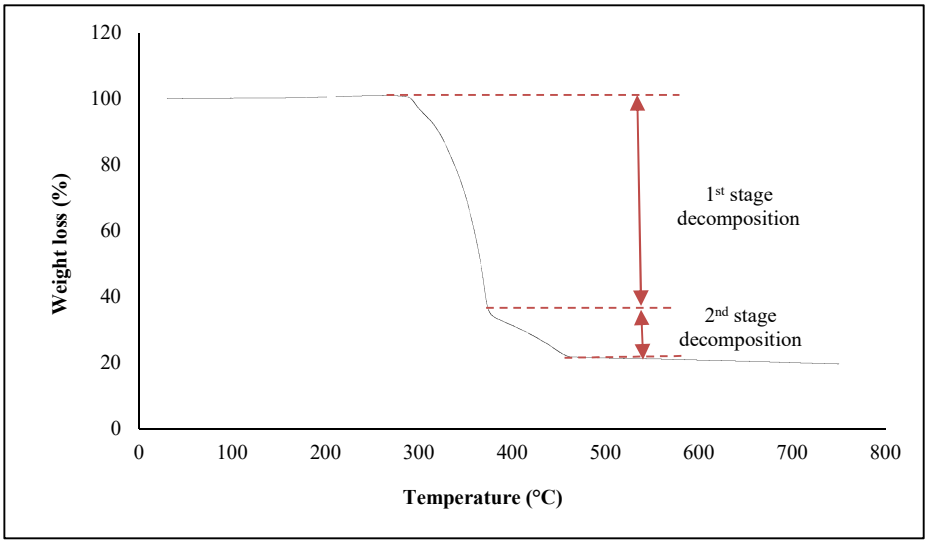

Figure 4. The TGA isotherm of the $(Ph_4P)_2[Pd_2I_6]$ complex

The catalytic activity of the $(Ph_4P)_2[Pd_2I_6]$ complex towards methoxylation of benzo[*h*]quinoline

The first comprehensive studies of Pd (II) complexes catalyzed C-H functionalization were published in the 2000s. A successful methoxylation of benzo[*h*]quinoline (see Scheme 2) in the presence of Pd acetate (1.1 mol%), the catalyst, and (diacetoxyiodo)benzene, the sacrificial oxidant, in MeOH was reported by Dick et al. [14]. Suitable high-pressure vials heated in an aluminium heating block to 100 °C were utilized in the study to yield a 95% product after 22 hours (see Table 2). In a similar manner, an 87% yield of 10-methoxybenzo[*h*]quinoline by employing recovered Pd complex, $[Pd(Me_2dazdt)_2]I_6$, (1 mol%) in 2 hours reaction time at 100°C was documented by Jantan et al. [13].

The present study slightly modified the procedure and utilized a Radley's Carousel 12 Reaction Station to investigate the catalytic activity of the recovered $(Ph_4P)_2[Pd_2I_6]$ complex towards methoxylation of benzo[*h*]quinoline (1 mol%, 2 hours, 100 °C). A quantitative product yield (90%) was obtained in 2 hours, which indicated that the reaction was more facile than the conditions documented in previous literature. The findings emphasized that the catalytic mechanism involved an oxidative addition step occured and resulted in the cyclopalladation of Pd (II) and oxidized Pd(II) to Pd(IV) before being followed by reductive elimination [14].

Table 2. Summary of catalytic activity various catalysts toward methoxylation of benzo[*h*]quinoline

Solvent	Temperature (°C)	Catalyst	Catalyst Loading (mol%)	Time (h)	NMR yield (%)
MeOH	100	$Pd(OAc)_2$	1.1	22	95
		$[Pd(Me_2dazdt)_2]I_6$	1.0	2	87
		$(Ph_4P)_2[Pd_2I_6]$	1.0	2	90

Heating MeOH (b.p. 65 °C) at 100 °C in a confined space, such as vials, could lead to potential dangers related to build-up pressure. Furthermore, energy consumption reduction from high-temperature heating is preferable. Consequently, the study decreased the reaction temperature (T) to 50 °C without changing other parameters to lower the catalytic reaction energy usage. Resultantly, a higher product yield (89%) was obtained in 2 hours of reaction time with the $(Ph_4P)_2[Pd_2I_6]$ (1 mol%) employed as a catalyst (see Figure 5). Elevating the reaction time to 6 hours also resulted in a slightly enhanced product percentage procurement (93%–96%). Moreover, an increased Pd loading by one-fold recorded a quantitative product yield of > 90%. Overall, the approach employed in this study involved milder and safer conditions and shorter reaction times.

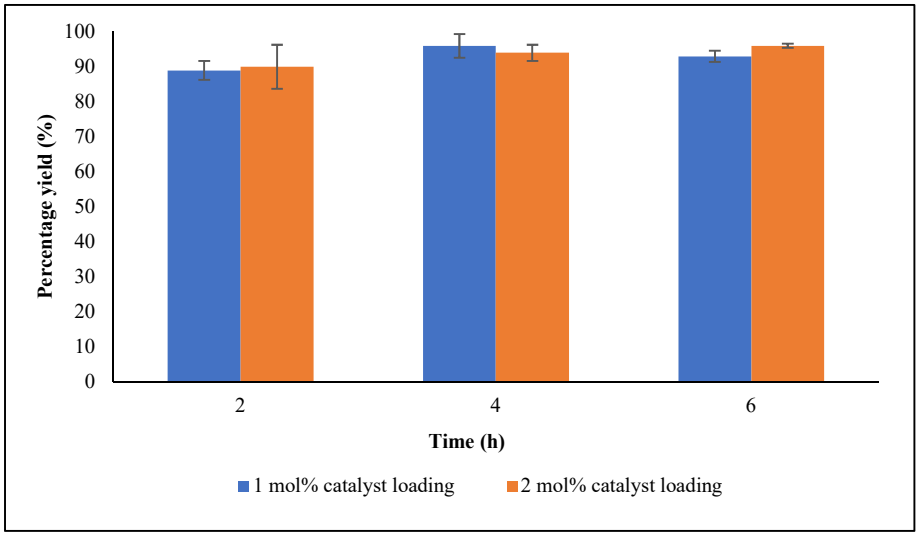

Figure 5. Methoxylation of benzo[*h*]quinoline with the $(Ph_4P)_2[Pd_2I_6]$ complex as a catalyst. Note: Solvent = MeOH, oxidant = $PhI(OAc)_2$, T = 50 °C, and t = 2, 4, and 6 hours

The successful formation of the product was further confirmed by analyzing the isolated yields of methoxylation of benzo[*h*]quinoline. The assessment was set to 2 hours of reaction time and 2 mol% of catalyst loading at 50 °C. The evaluation also validated the ^{1}H NMR integration yield. A brown oil was collected and purified in a flash column utilizing a 3:2 v/v ethyl acetate-to-hexane eluent. The pale-yellow solid isolated (154 mg, 88%) also agreed with the conversion determined in the ^{1}H NMR (90%).

Other alkoxylation of benzo[*h*]quinoline

The unexpectedly higher 10-methoxybenzo[*h*]quinoline procured at 50 °C resulted in the extension of the scope of this study into other alkoxylation of benzo[*h*]quinoline (see Scheme 2). In the assessment, the time and Pd loading were varied while the temperature was maintained at 50 °C. Furthermore, the alcohol solvent employed in the transformation was changed to ethanol and an isopropanol and acetic acid mixture, which yielded 10-ethoxybenzo[*h*]quinoline and 10-isopropoxybenzo[*h*]quinoline, respectively.

Figure 6 illustrates the experimental data of ethoxylation of benzo[*h*]quinoline at 50 °C. The 1 mol% catalyst loading produced a lower product yield (< 40%) even after 6 hours of reaction, hence implying that a temperature decrease reduces the chemical reaction rate. Nonetheless, elevating the catalyst loading to 2 mol% improved the reaction rate, which resulted in 79% yields of the desired products after 6 hours of reaction.

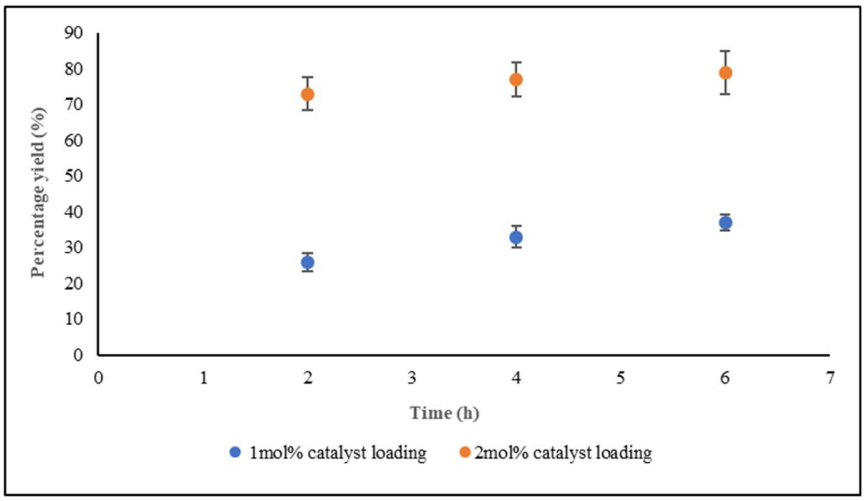

Figure 6. Ethoxylation of benzo[*h*]quinoline with the $(Ph_4P)_2[Pd_2I_6]$ complex as a catalyst. Note: Solvent = EtOH, oxidant = $PhI(OAc)_2$, T = 50 °C, and t = 2, 4, and 6 hours

A similar observation was recorded in the catalytic 10-isopropoxy benzo[*h*]quinoline reaction. Figure 7 indicates that a lower product yield (< 27%) was obtained when 1 mol% of catalyst loading was employed for reaction times between 2-6 hours at 50 °C. The results suggested that only a small proportion of benzo[*h*]quinoline molecules possess enough activation energy to react and generate a 10-isopropoxy benzo[*h*]quinoline at lower temperatures.

The increment of the catalyst loading to 2 mol% improved the reaction, which doubled the product yield. Nevertheless, a moderate 10-isopropoxybenzo[*h*]quinoline production (47%) was obtained compared to the 10-ethoxybenzo[*h*]quinoline (79%) derived after 6 hours when 2 mol% catalyst loading was employed at 50 °C. The results proved that the $(Ph_4P)_2[Pd_2I_6]$ was less catalytically active when the more sterically demanding reagent, the isopropanol and acetic acid mixture, was employed.

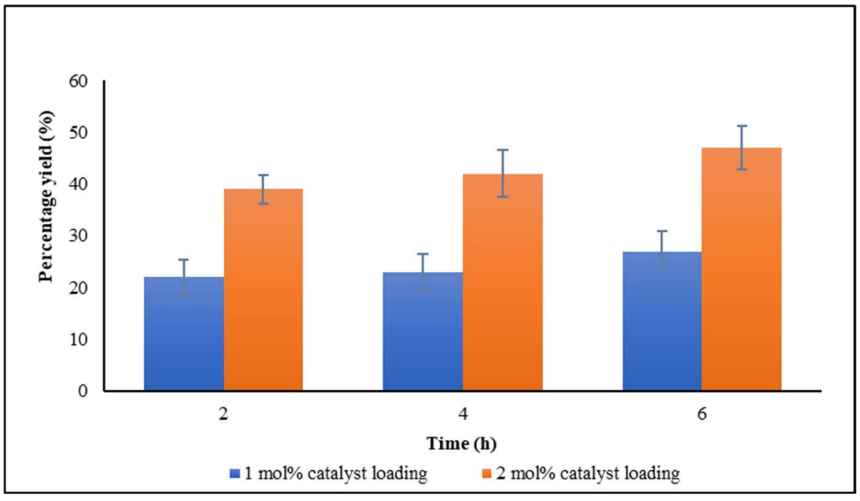

Figure 7. Isopropoxylation of benzo[*h*]quinoline utilizing the $(Ph_4P)_2[Pd_2I_6]$ complex as a catalyst. Note: Solvent = mixture of isopropanol and acetic acid, oxidant = $PhI(OAc)_2$, T = 50 °C, and t = 2, 4, and 6 hours

The C-H functionalization of 8-methylquinoline

The present study extended the catalytic alkoxylation of benzo[*h*]quinoline to synthesize 8-(methoxymethyl)quinoline (see Scheme 3). An energy-saving strategy by reducing the reaction temperature was adopted during the present study to continue building greener synthetic pathways and improve the efficiency of the required C-H functionalization. Nevertheless, the reaction of 8-methylquinoline with 1–2 mol% of the recovered $(Ph_4P)_2[Pd_2I_6]$ as the catalyst and $PhI(OAc)_2$ in methanol at 50 °C recorded a moderate yield (< 65%) after 2–6 hours of reaction time (see Figure 8). A possible explanation might be the presence of additional benzylic hydrogen atoms in the substrate, which are inert to deprotonation for directed C-H activation. Consequently, increasing the catalyst load or temperature while maintaining other reaction conditions might be required to lower the activation energy of the reaction for complete conversion.

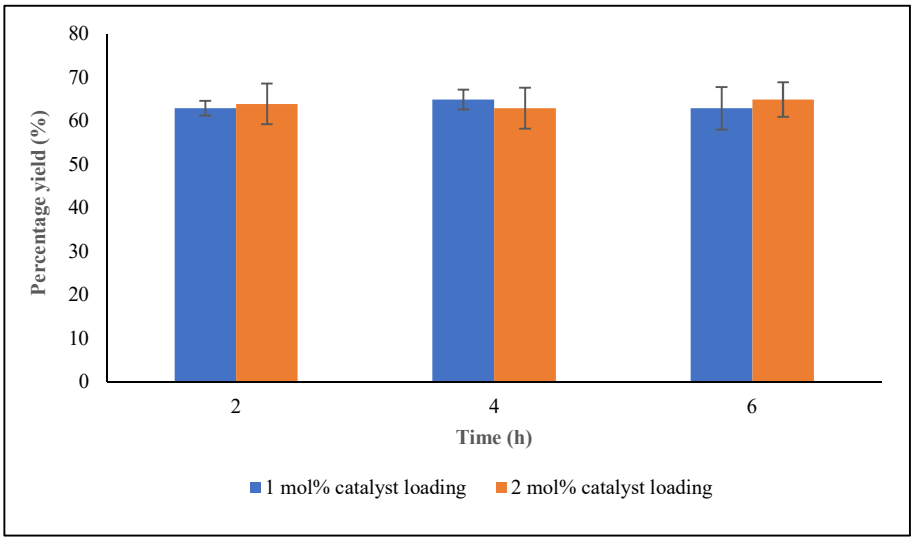

Figure 8. The C-H functionalization of 8-methylquinoline with the $(Ph_4P)_2[Pd_2I_6]$ complex as a catalyst. Note: Solvent = MeOH, oxidant = $PhI(OAc)_2$, T = 50 °C, and t = 2, 4, and 6 hours

Antibacterial activity

The antibacterial inhibition zone diameter means of the recovered $(Ph_4P)_2[Pd_2I_6]$ against six bacterial strains is demonstrated in Figure 9. The organisms evaluated in this study were sensitive towards the compound. Among the bacterial strains, *K. pneumoniae* recorded the highest inhibition zone in all $(Ph_4P)_2[Pd_2I_6]$ concentrations. *B. subtilis*, *S. typhimurium, K. pneumoniae*, and *K. aeruginosa* cultures demonstrated a significant increase in inhibition zone from the lowest to the highest $(Ph_4P)_2[Pd_2I_6]$ concentrations, while *B. cereus* and *E. coli* recorded no notable difference.

The positive control Gentamicin employed in this study exhibited an inhibition range between 21.0-24.8 mm. Previous studies have described palladium nanoparticles as useful antimicrobial agent where more inhibitory toward gram-positive bacteria (*Staphylococcus aureus)* than toward *E. coli* [25]. Palladium (II) complexes were also reported to exhibit remarkable antibacterial activity against *S. aureus* and *E.coli* [20].

Gram-negative bacteria possess lipopolysaccharide (LPS), thin peptidoglycans, and porins proteins with more lipids in their cell walls, which make them less permeable than gram-positive bacteria [26]. Nonetheless, the recovered Pd (II) complexes in this study demonstrated a more significant inhibitory toward gram-negative bacteria. The findings suggested that the complexes could compromise the membrane permeability of the gram-negative bacteria employed. A

significant inhibition improvement in at least one gram-positive bacteria, *B. subtilis*, was also recorded. A previous study supported the current results, in which Pd dichloride ligands ($PdCl_2$BLs) documented the best response against *E. coli, Pseudomonas aeruginosa, S. aureus*, and *B. subtilis* [27].

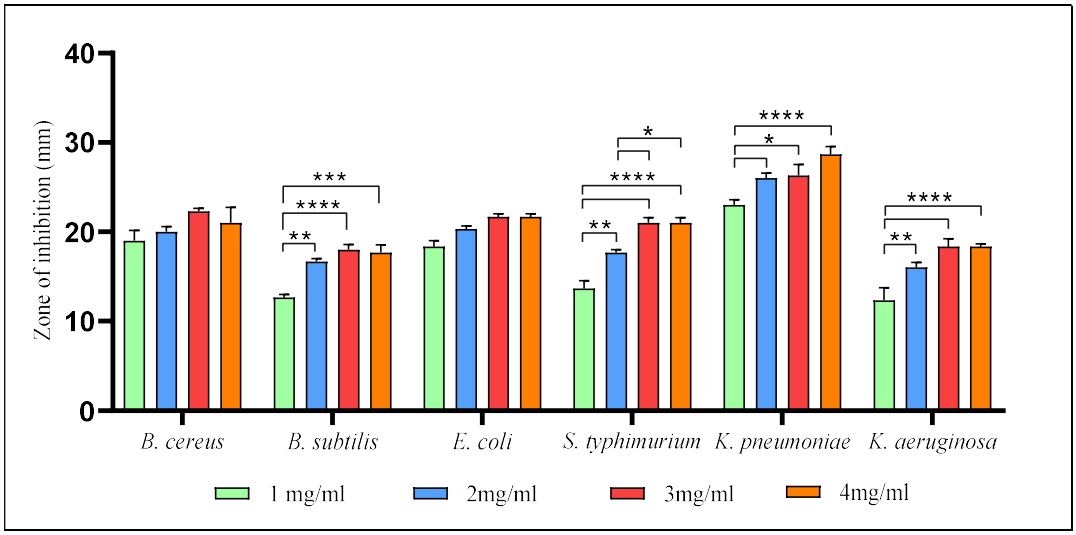

Figure 9. The inhibition zones of the recovered $(Ph_4P)_2[Pd_2I_6]$ against selected bacterial strains. The levels displayed are the mean of three tested cultures ± SEM. The asterisks indicate statistically significant differences analyzed with two-way ANOVA followed by Tukey's multiple comparison post-test

Determination of MIC and MBC

Table 3 summarises the MIC values obtained in the present study. Both *Klebsiella* species were inhibited at 0.625 mg/ml, while *E. coli* and *S. typhimurium* were at 0.156 and 0.313 mg/mL, respectively. The recovered $(Ph_4P)_2[Pd_2I_6]$ also hindered *B. cereus* growth at 0.156 mg/mL. The highest MIC value was recorded by *B. subtilis* at 1.25 mg/mL.

The study findings highlighted the potential of the $(Ph_4P)_2[Pd_2I_6]$ procured to inhibit the growth of bacteria. All MBC plates employed in the present study demonstrated bacterial growth, indicating no bactericidal activity when exposed to the $(Ph_4P)_2[Pd_2I_6]$ complex (see Table 4). Nevertheless, uncertainties remain about the killing properties of the recovered $(Ph_4P)_2[Pd_2I_6]$. Accordingly, further studies are necessary to assess the bactericidal potential of $(Ph_4P)_2[Pd_2I_6]$.

Conclusion

The present study emphasized the utilization of commercially available iodine and tetrabutylammonium iodide to recover Pd metals from TWC waste. The recovered $(Ph_4P)_2[Pd_2I_6]$ complexes were employed directly as a homogeneous catalyst in the C-H functionalization of benzo[*h*]quinoline and 8-methylquinoline. An excellent product yield of 90% was obtained in benzo[*h*]quinoline methoxylation at 100°C. A milder and safer approach adopted at a low-temperature setup (50°C) produced a similar product yield. Conversely, installing the ethoxy- and isopropoxy functional groups into the benzo[*h*]quinoline at 50°C proved challenging. A lower to moderate product yield was recorded due to the solvent stearic effect. Similarly, a reasonable procurement (65%) of 8-(methoxymethyl) quinoline was documented.

In conclusion, the novel method of employing Pd complex as a homogeneous catalyst in C-H functionalization would increase the value of the metal, especially when recovered from TWC waste. Furthermore, the burden on natural reserves as a primary source would also be reduced. This study has also

identified the bacteriostatic potential of the $(Ph_4P)_2[Pd_2I_6]$ complexes. The data provide critical preliminary insights into the role of the metal as an antibacterial agent.

Table 3. The MIC of the recovered $(Ph_4P)_2[Pd_2I_6]$ against selected bacterial strains

Bacteria	**$(Ph_4P)_2[Pd_2I_6]$ concentration (mg/mL)**								
	10	5	2.5	1.25	0.625	0.313	0.156	0.078	Positive control

Abstract

A new effective biopolymer alginate chitosan amine-functionalized silica coated magnetic composite (alg/Cs-NH_2-SiO_2/Fe_3O_4) adsorbent was synthesized and applied for the first time to remove Pb(II), Cu(II) and Cd(II) from aqueous solution by utilizing inductive coupled plasma-optical emission spectroscopy (ICP-OES). The properties of the composite were characterized using Fourier-transform infrared spectroscopy (FTIR), Field emission scanning electron microscopy/energy-dispersive X-ray spectroscopy (FESEM/EDX), and vibrating sample magnetometry (VSM). Evaluation of alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorption performance at optimum conditions revealed that the adsorbent had a maximum adsorption capacity of 41.79, 39.21, and 39.56 mg/g for Pb(II), Cu(II) and Cd(II), respectively. The adsorbent behavior was studied using Langmuir, Freundlich, Temkin, and Dubinin-Rudushkevich's isotherm models. The Langmuir isotherm and the pseudo-second-order were better fitted with the coefficient of determination (R^2) value of 0.99, indicating homogeneous surface and chemisorption processes. The thermodynamic factors indicated endothermic and spontaneous processes at 60 °C. Even after the 5th cycle adsorption-desorption experiments, the adsorbent still retained its adsorption ability above 70% metal ions removal, indicating that the adsorbent was reasonable for metal ions removal in water. Pb(II) was detected in a river near an industrial area (Taman Mewah, Kulai, Johor), which was eventually removed by the adsorbent at 86% efficiency.

Keywords: biopolymer, magnetic adsorbent, heavy metals

Abstrak

Penjerap biopolimer alginat kitosan amina bersalut silika bersalut (alg/Cs-NH_2-SiO_2/Fe_3O_4) yang berkesan telah disintesis dan digunakan buat kali pertama untuk menyingkirkan ion Pb(II), Cu(II) danCd(II) daripada air dengan menggunakan spektroskopi pelepasan atomik-plasma gandingan aruhan (ICP-OES). Ciri-ciri komposit dicirikan menggunakan spektroskopi inframerah-

transformasi Fourier (FTIR), mikroskop elektron pengimbasan pancaran medan (FESEM), spektroskopi sinar-X penyebaran tenaga (EDX), dan magnetometri getaran sample (VSM). Penilaian prestasi penjerapan alg/Cs-NH_2-SiO_2/Fe_3O4 pada keadaan optimum menunjukkan bahawa penjerap mempunyai kapasiti penjerapan maksimum 41.79, 39.21, dan 39.56 mg/g masing-masing untuk Pb(II), Cu(II) dan Cd(II). Prestasi penjerap dikaji menggunakan model isoterma Langmuir, Freundlich, Temkin, dan Dubinin-Rudushkevichs. Isoterma Langmuir dan pseudo-tertib kedua adalah lebih bertepatan dengan nilai pekali penentuan (R2) 0.99, menunjukkan permukaan homogen dan proses penjerapan secara kimia. Faktor termodinamik menunjukkan proses endotermik dan spontan pada 60 °C. Walaupun selepas lima kali eksperimen penjerapan-penyahjerapan , penjerap masih mengekalkan keupayaan penjerapannya dengan % penyingkiran ion logam melebihi 70% menunjukkan penjerap berupaya mengeluarkan ion logam daripada air. Pb(II) telah dikesan di sungai berhampiran kawasan perindustrian (Taman Mewah, Kulai, Johor), akhirnya disingkirkan pada kecekapan 86%.

Introduction

Clean water resources are undoubtedly a basic human need. However, population growth, industrialization and urbanization, domestic and industrial waste generation, and other anthropogenic sources of toxic pollutants have made many water resources detrimental to humans and the environment. Industries that produce large volumes of effluents include textile, breweries, mineral processing, poultry processors, paper and fiber plants, meat packers, fruit and vegetable packing operations, fertilizer plants, refiningand petrochemical operations, and many more. Wastewaters from these industries generally contain heavy metals,dyes, pesticides and, etc [1]. On top of that, they are soluble in water (i.e. dyes and pesticides), non-biodegradable with a tendency to bioaccumulate (i.e. heavy metals), and are easily transported into the food chain [2]. Having high atomic density >5 g/cm^3, heavy metals could be toxic and poisonous even at trace levels [3]. The rapid increases in contamination by heavy metals from industrial and urban wastewaters are undoubtedly worrying [4, 5, 6].

Techniques such as ion exchange, precipitation, coagulation, and floatation, have been utilized to extract and/or remove various heavy metals from water. However due to the issue of sludge/waste disposal [7], alternative methods arise. The adsorption method has been recognized as one of the promising methods since it only requires a small amount of adsorbent, thus promoting simplicity and efficiency to remove heavy metals from water [8]. It utilizes a mass transfer process through which metal ions are transported from solution onto the surface of a solid material (adsorbent) and become attached via chemical or physical interactions. Various adsorbents have been established and reported based on agricultural wastes, clay, zeolite, activated carbon, biopolymer, and others [9]. A new class of materials; organic-inorganic hybrid materials are attracting interest in creating a high-performing polymeric that shows good possibilities for removal of metal ions through modifications. These modified hybrid materials exhibit better properties than the original components [10]. Additionally, the natural materials of the hybrid, for instance, the agro-wastes products, clay, and biopolymers are environmentally friendly and are widely available to serve as alternative low-cost adsorbents to the commercially activated carbon. The need for a safe and better economical method for heavy metal removal from polluted water has challenged researcher's interest in the production of better low-cost alternatives [11]. Some low-cost agricultural by-products such as sugarcane bagasse and the neem backed, rice husks, sawdust, coconut husks, oil palm shells, etc have been described in the literature for metals removal [12]. To step up the performance of adsorbents from agricultural products, some modifications are needed to enhance their adsorption capacities as adsorbents[13, 14]. This included the utilization of magnetic aspect for nanomaterial adsorbents.

Adsorbents from magnetic nanomaterials (MNPs) usually possess a large surface area, and short diffusion route, without the tediousness of filtration and centrifuging. Easy separation of the adsorbents from water/wastewater using an external magnet makes MNPs reusable. However, the MNPs may suffer agglomeration, oxidation in the air during synthesis, not target-discriminatory towards analytes, and are incompatible

with compounds inside complicated matrices. Hence, they can be enhanced by a suitable coating modification to overcome these limitations [15]. The MNPs can be coated from being oxidized or can be dispersed under low pH conditions by surface coating with silica (SiO_2). SiO_2 is stable under the acid condition and inert to redox reactions as compared to the organic coating substances, and hence serves as an ideal shell composite to safeguard the inner magnetic core. Consequently, the SiO_2 coated layer has numerous hydroxyl groups on its surface which offer the easy possibility of the functionalization of the MNPs without damaging or changing the core of the materials. SiO_2-coating of the core-shell MNPs (Fe_3O_4@SiO_2) has been explored for many applications [15]. Features include stability, reactivity, solubility, melting points, and electronic structure relatively different from their original material to give a homogeneous size and shape as well as regulate its stability in aqueous solutions. APTES has been modified on the surface of silica-coated magnetite to form Fe_3O_4@SiO_2-NH_2 used for Zn(II) removal from contaminated effluent [16]. Mercaptamine had been used in silica coated MNPs to obtain the functionalized composite for Hg and Pb(II) removal [17]. Furthermore, As(III) removal had been achieved using encapsulated magnetite adsorbent in which the covalent bond was modified through the alginate to obtain the carboxylic functionalized adsorbent [18]. To explore the effect of the carboxylic alginate modified method, functionalization of the carboxylic group had also been done to enhance adsorption towards Pb(II) removal [19]. The application of alginate-chitosan-based amine-functionalized silica coated magnetite alg/Cs-NH_2-SiO_2/Fe_3O_4 as adsorbent for the removal of Pb(II), Cu(II), and Cd(II), in aqueous environments is still not explored and is an interesting area in adsorbent synthesis research.

This study was designed to develop a new eco-friendly adsorbent, i.e., the alginate-chitosan-based amine-functionalized silica coated magnetic (alg/Cs-NH_2-SiO_2/Fe_3O_4) adsorbents for the removal of Pb(II), Cu(II) and Cd(II) in water and wastewater. The characterization was conducted on the adsorbent, i.e., FTIR, FESEM/EDX, and VSM to ascertain the synthesis process. The optimization of the adsorption parameters such as sample pH, dosage, initial adsorbate concentration, contact time, and temperature was conducted via the batch adsorptions method. Ultimately, the adsorption, kinetic isotherm, thermodynamic, and reusability studies were done to evaluate the fundamental and economic aspects of the adsorbent. A real sample from an industrial wastewater site was applied to test the ultimate effectiveness of the adsorbent in the real application.

Materials and Methods

Chemicals, reagents, and instrumentations

Iron(III) chloride hexahydrate ($FeCl_3.6H_2O$, 99%), ethanol (99%) iron(II) chloride tetrahydrate ($FeCl_2.4H_2O$, 99%), and sodium hydroxide (NaOH), the stock solution of salts copper, lead, cadmium, alginate (alg), and chitosan (Cs) were bought from Merck (Germany). 3-aminopropyltriethoxysilane (APTES), tetraethyl orthosilicate (TEOS), concentrated NH_4OH (28%), HNO_3(65%), and HCL (37%) were purchased from Fluka Chemical. HCl (0.1M) and/or NaOH (0.1M) were used to adjust the pHs of the solutions. Analytical grade chemicals were used without further purifications. All glassware was soaked in 5% HNO_3 acid for 24 h and rinsed in deionized water to prevent metal contaminations. Several instruments were used and applied for the synthesis of magnetic alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbents. These include Avio ^{TM} parker 200 Inductive Couple Plasma-Optical Emission Spectrometry (ICP-OES) was used for the metal ions analysis. ATM 400 FTIR spectrometer from PerkinElmer (Waltham, MA, USA) was also utilized for the characterization of the synthesized adsorbents. FTIR estimations utilizing the KBr pellet procedure and transmission mode of all spectra were recorded from 400 to 4000cm^{-1}. A JSM-6701 F electron magnifying instrument from JEOL (Tokyo, Japan) was utilized for the field emission sample electron microscopy (FESEM) analysis, and the energy dispersive X-Ray examination (EDX). Vibrating sample magnetometry (VSM 7400) from Lake Shore Cryotronics (Ohio, USA) was used to evaluate the magnetic properties of the materials at a utilized greatest field of 15,000 G at room temperature.

Synthesis procedures

The synthesis of iron oxide (Fe_3O_4NPs) was by simple

co-precipitation procedure [20, 21]. This was done by mixing 8.48 g of $FeCl_3.6H_2O$ and 2.25g of $FeCl_2.4H_2O$ in a three-necked round bottom flask and stirring vigorously under argon gas at a temperature of 80 ℃ in a 100 ml volume of deionized water. Subsequently, 24 ml of ammonia (25%) was dropwise added under a constant mechanical stirring for 5 h to form black magnetic oxide (Fe_3O_4) at room temperature. The as-prepared Fe_3O_4 was washed with distilled water and methanol, separated with an external magnet, and finally oven-dried at 60 ℃ for 24 h. The final product was then kept for further experiments in an airtight container. The preparation of SiO_2/Fe_3O_4NPs was done by re-dispersing [22] 1.0 g of the Fe_3O_4NPs in deionized water (50 ml) under argon for 10 mins. After a continuous stirring of the products, TEOS (1 ml) diluted in ammonium hydroxide (2 ml) was finally added dropwise to the dispersion with more continuous mechanical stirring at room temperature for 14 h. The magnetic Fe_3O_4/SiO_2 mixture was then washed with ethanol and water and finally collected by external magnetic separation, then dried overnight in a furnace at 110 ℃.

The Cs-Fe_3O_4NPs was prepared by dissolving 2.0 g chitosan in 100 ml (2%) concentration of acetic acid to form a homogeneous solution. The content was then transferred to a three-necked flask under vigorous mechanically stirring followed by adding 20 ml of glutaraldehyde (5% wt solution) for 4 h. The Cs-Fe_3O_4 NPs formed were recovered by an external magnetic separation. The particles were allowed to settle for at least 2 min before being washed with water/ethanol about three times before finally dried in a vacuum oven at 50 ℃. The preparation of Cs-NH_2-SiO_2/Fe_3O_4 was made by dispersing 2.0 g of Cs-Fe_3O_4 in deionized water (100 ml) followed by 20 ml of APTES with vigorous mechanical stirring of the mixture at 40 ℃ for 1 h. The mixture was left overnight with vigorous stirring followed by vacuum filtration the next day and finally, oven-dried at 50 ℃ and stored for future use. Then, the preparation of the final alg/Cs-NH_2-SiO_2/Fe_3O_4 was done by dispersing 2.0 g of Cs-NH_2-SiO_2/Fe_3O_4 in deionized water (100 ml) under vigorous mechanical stirring of the mixture at 40 ℃ for 1 h. A solution containing 50 ml 0.1M $CaCl_2$ was then added dropwise by using a needle syringe to the resultant mixture in a beaker for the formation of the beads. The beads were then soaked 0.1 M $CaCl_2$ solution overnight and then washed thoroughly with distilled water, oven-dried overnight at a temperature of 50 ℃, and finally stored for further use. The proposed schematic synthesis route is presented in Figure 1.

Batch sorption experiments for metal ions adsorption

Adsorption experiments of Pb(II), Cd(II), and Cu(II) onto the newly synthesized alg/Cs-NH_2-SiO_2/Fe_3O_4 were carried out using the batch sorption method. The influence of solution pH, adsorbent dosage, contact time, temperature, and initial concentration of adsorbate was studied. 100 mL conical flasks holding 50 mL solutions of different metal ions with initial concentrations varying from 20 -100 mg/L, and fixed adsorbent dosage of 20 mg was used for the equilibrium experiments. The solution pH was set at pH 6, then shaked at an equilibrium contact time of 30 min, and temperature at 25 ℃, to establish equilibrium after which, an external magnet was used to separate the adsorbents from their respective solutions. The solutions were analyzed using an ICP-OES instrument for the residual heavy metal ions concentrations, and all experiments were conducted in triplicate. The percentage removal (%R) and the adsorption capacity (q_e) according to equations 1 and 2, respectively [24].

$$\%R = \frac{[(C_i - C_f)]}{C_i} x\ 100 \quad (1)$$

$$q_e = \frac{[(C_i - C_f)]\,V}{m} \quad (2)$$

Where, V = volume of solution (mL), qe = the adsorption capacity in (mg/g), m= quantity of adsorbent (mg), Ci = initial concentration of metal ions (mg/L), and Cf = final concentration of metal ions (mg/L).

Regeneration studies and wastewater samples treatment

The adsorption-desorption experiment for five consecutive rounds of regeneration study was conducted

until a substantial change in the performance of alg/Cs-NH_2-SiO_2/Fe_3O_4 was detected. Consequently, the adsorbed metal ions were desorbed in 5 mL HCL (0.1M), after each 5 min shaking to retrieve the adsorbent from the mixture with an external magnet, then washed with deionized water until neutral, and finally, oven-dried at 60 ºC for 24 h. ICP-OES instrument was used to investigate the residual concentration of heavy metal pollutants in the mixtures [25]. The efficiency of the alg/Cs-NH_2SiO_2/Fe_3O_4 adsorbent towards Pb(II), Cd(II), and Cu(II) from real wastewater effluents was investigated using effluents from industrial locations along the Skudai river at Taman Mewah, Kulai, Johor, Malaysia. The floating solids were eliminated through filtration. HNO_3 was utilized to digest the test samples to further eliminate matrix interferences. The metal ions residual concentrations in the samples were determined after the adsorption experiment using the synthesized adsorbent.

Results and Discussion

Synthesis route for alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbent

The alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbent was synthesized from Fe_3O_4, as a percussor coated with SiO_2, functionalized using APTES (-NH_2), blend combined with Cs, and the bound by alg to form a biopolymer composite adsorbent. The schematic synthesis route of alg/Cs-NH_2-SiO_2/Fe_3O_4 was through five steps namely, Fe_3O_4 was successfully synthesized by mixing $FeCl_3.6H_2O$ and $FeCl_2.4H_2O$). SiO_2/Fe_3O_4 was prepared from Fe_3O_4 and TEOS in diluted ammonium hydroxide. NH_2-SiO_2/Fe_3O_4 was prepared through SiO_2/Fe_3O_4 and APTES. Cs-NH_2-SiO_2/Fe_3O_4 was prepared chitosan in 100 ml (2%) concentration of acetic acid via cross-linking by glutaraldehyde. Finally, the adsorbent alg/Cs-NH_2-SiO_2/Fe_3O_4 was successfully prepared through Cs-NH_2-SiO_2/Fe_3O_4 by forming a composite with the addition of alginate. (Figure 1).

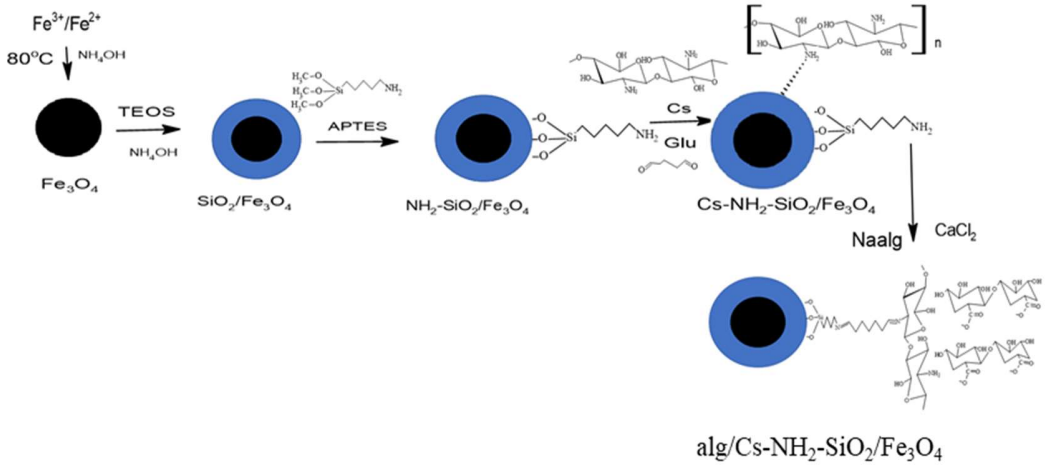

Figure 1. Schematic synthesis route of alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbent

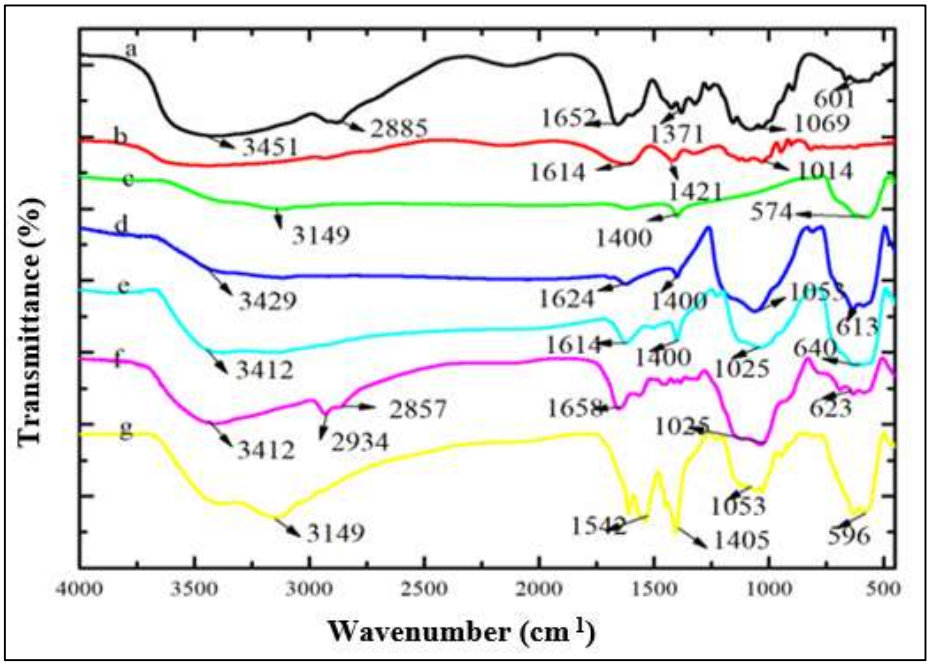
Characterization of the synthesized alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbent

To determine the functional groups in the newly synthesized adsorbent, FTIR analysis was conducted. The FTIR spectra of the raw Cs and alg were compared to the newly synthesized material as indicated in Figure 2(a-b). The peaks for raw Cs at 3451 cm^{-1}, 2925-2885 cm^{-1}, 1652 cm^{-1}, and 1371 cm^{-1} were ascribed to the overlapping between -NH_2 and -OH stretching vibration and the intermolecular hydrogen bonding of the polysaccharide, C-H stretching vibrations of C=O saturated carbons, in acetamide group, and C-O group stretching and C-H bending vibrations. The main spectrum of raw alg (Figure 2(b)) shows 1624 cm^{-1}, 1421 cm^{-1}, and 1014 cm^{-1} which corresponds to C-H vibrational stretch and C=O vibrational stretch. The spectrum of Fe_3O_4 (Figure 2(c)) showed a peak at 574 cm^{-1} for Fe-O bond formation. The spectrum of SiO_2/Fe_3O_4 (Figure 2(d)) showed O-H

vibration, C-H stretching, C-H bending, C-O stretching peaks, Fe-O bond at 3429 cm^{-1}, 1624 cm^{-1}, 1400 cm^{-1}, 1300 cm^{-1}, and 574 cm^{-1}. Additionally, alg/Cs-NH_2-SiO_2/Fe_3O_4 showed the spectra changed with O-H vibration, C-H stretching, C-H bending, C-O stretching peaks, and Fe-O bond formation at 3149 cm^{-1}, 1542 cm^{-1}, 1053 cm^{-1}, and 596 cm^{-1}, respectively. Key findings showed that the spectra at 1658 cm^{-1}, 1025 cm^{-1}, and 623 cm^{-1} disappeared and the formation of new peaks of 1542 cm^{-1}, 1404 cm^{-1}, 1053 cm^{-1}, and 596 cm^{-1}, respectively corresponded to -NH_2,-C=O, Si-O-Si, and Fe-O, respectively, (Figure 2(f-g)), confirming new material. Consequently, the FTIR spectra of alg/Cs-NH_2-SiO_2/Fe_3O_4 presented peaks at 3400 cm^{-1} and 3200 cm^{-1} for O-H stretching and H_2O molecules, respectively, conformed to the findings of others reported in the literature [26].



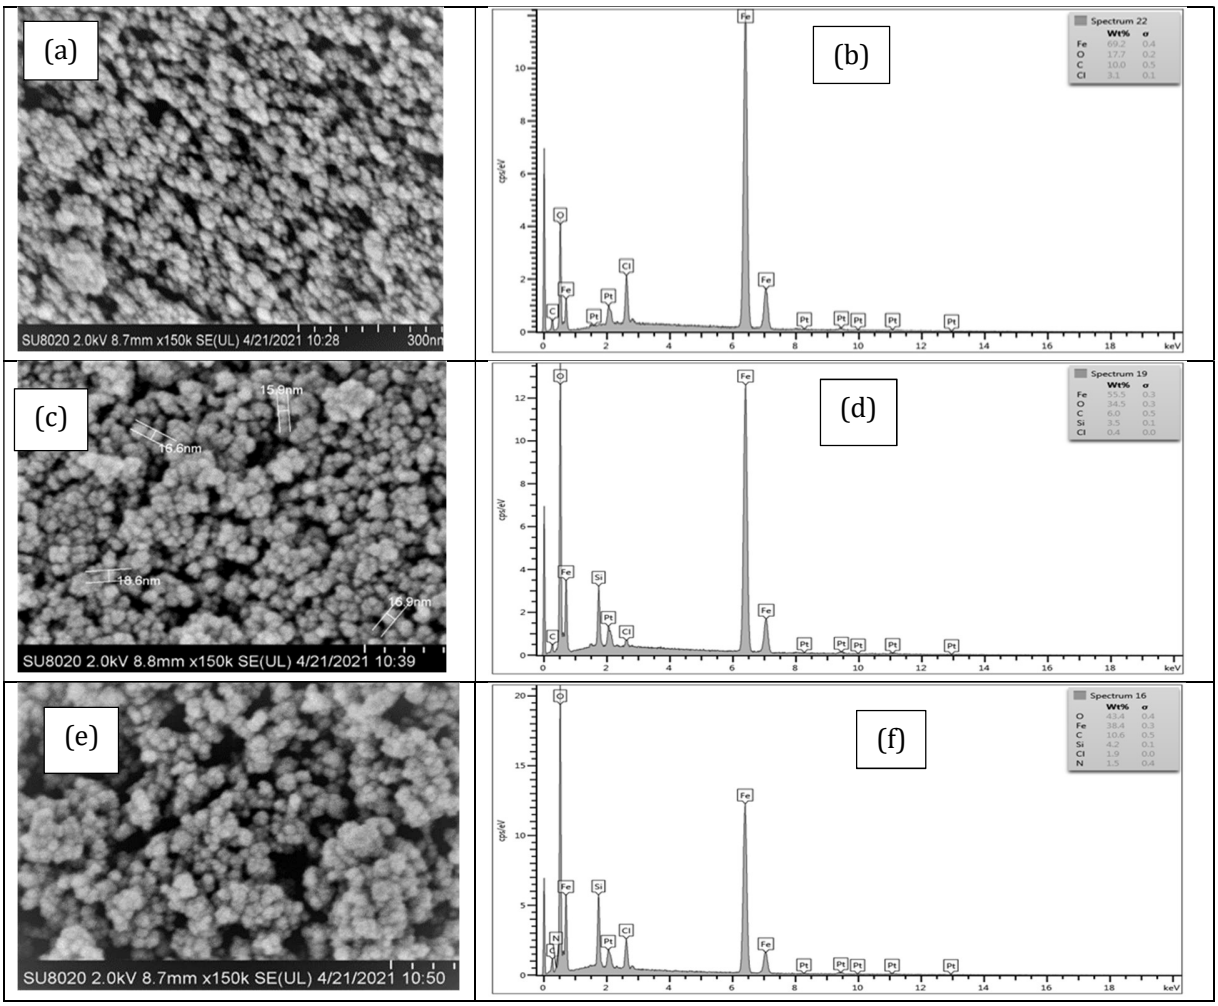


Figure 2. FTIR spectra of (a) chitosan (Cs), (b) alginate (alg) (c) Fe_3O_4, (d) SiO_2/Fe_3O_4, (e) NH_2-SiO_2/Fe_3O_4 (f) Cs-NH_2-SiO_2/Fe_3O_4 (g) alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbent

The FESEM/EDX analysis was conducted to investigate the surface morphology, particle size distributions, and the relative shape of the synthesized materials. The morphologies and the spectra of Fe_3O_4, SiO_2/Fe_3O_4, NH_2-SiO_2/Fe_3O_4, Cs-NH_2-SiO_2/Fe_3O_4, and alg/Cs-NH_2-SiO_2/Fe_3O_4 are shown in Figure 3(a-j). FESEM morphology of Fe_3O_4 (Figure 3a) showed spherical particle distribution with an average grain size range of 11-14 nm nanosized particles. The EDX spectra of Fe_3O_4 (Figure 3(b)) confirmed the element of Fe (69.20%), and O (17.70%). The FESEM morphology of SiO_2/Fe_3O_4 (Figure 3(c)) was much smoother with an increase in the nanosized average diameter of 15 - 16 nm due to the silica coatings on the surface of the magnetite, while the EDX spectra of SiO_2/Fe_3O_4 (Figure 3(d)) confirmed the element of Fe (55.50%), O (34.50%), and Si (3.5%) confirming the coating of SiO_2 on top of the magnetite during the synthesis process. The similar obs ervations were also reported by other researchers [27]. With the addition of APTES to the SiO_2 coated magnetite, the size distribution increased with changes in shape to particle diameter size range of 18-23 nm due to the -NH_2 functionalization of SiO_2/Fe_3O_4. This was well confirmed by the FTIR spectra and the EDX of NH_2-$SiO_2Fe_3O_4$ (Figure 3(f)) containing Fe (38.4%), O (43.4%), Si (4.2%), and N (1.5%) which showed the

functionalization of the SiO_2/Fe_3O_4 with APTES due to the presence of the N element. Furthermore, with the addition of Cs and alg to form alg/Cs-NH_2-SiO_2/Fe_3O_4, the FESEM morphology (Figure 3(i)) showed a more distinctive particle size distribution and shape with a denser and larger particle diameter size range of 23-50 nm and 121-148 nm, respectively. The addition of Cs and alg introduced the element of C (56.2%) (Figure 3(h) and Figure 3(j) owing to the existence of the functional groups of -NH_2 and -OH, respectively. FESEM morphology of alg/Cs-NH_2-SiO_2/Fe_3O_4 (Figure 3(i)) showed the gel formation due to the glutaraldehyde cross-linking resulting in a darker morphology with the largest diameter distribution of 114-148 nm with an oval shape liked morphology quite different from the others in conformity with other reported findings [27]. Undoubtedly, the % elemental composition of Fe, O, and Si continued to decrease with an increase in the diameter of the core-shell of the adsorbent; nevertheless, the magnetism of the final adsorbent was reasonable for removal work (Figure 4).

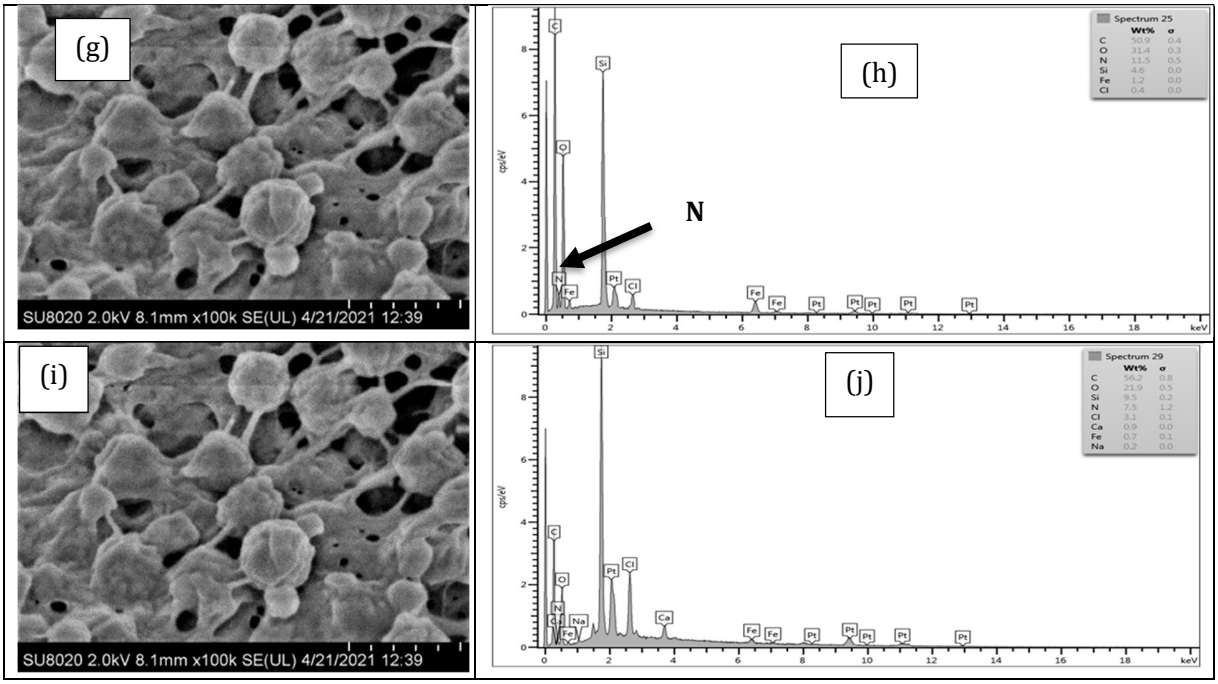

Figure 3. FESEM morphology and EDX spectra of (a-b) Fe_3O_4, (c-d) SiO_2/Fe_3O_4, (e-f)NH_2-SiO_2/Fe_3O_4, (g-h) Cs-NH_2-SiO_2/Fe_3O_4 and (i-j) alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbents Magnification. = 100K or 150K

The magnetization curves of Fe_3O_4, N H_2-SiO_2/Fe_3O_4, and alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbents were investigated via VSM polarization for before and after adsorption in the range of −15000 to 15000KOe. The magnetic hysteresis loops of Fe_3O_4, NH_2-SiO_2/Fe_3O_4, and alg/Cs-NH_2-SiO_2/Fe_3O_4 demonstrated the superparamagnetic characteristic of the materials with saturation magnetization values of 24.48, 20.10 and 14.77 emu/g, respectively (Figure 4(a-c)). The results revealed that the adsorbent alg/Cs-NH_2-SiO_2/Fe_3O_4 displayed sufficient magnetic quality to achieve magnetic separation. Hence, the VSM bends S-shape showed super-paramagnetic properties for nanocomposite well suitable for the assortment of magnetic adsorbents from aqueous solution. The decrease in the saturation magnetization values from Fe_3O_4 to alg/Cs-NH_2-SiO_2/Fe_3O_4 was due to the various modification that had taken place on top of the Fe_3O_4. Although the saturation magnetization value decreased after the immobilization process, the adsorbent responded rapidly to an external magnet and could be separated from the aqueous mixture conveniently within 45 seconds in agreement with the similar finding reported by [28].

Optimization of adsorption using the newly synthesized alg/Cs-NH_2-$SiO_2Fe_3O_4$ adsorbent

The impact of variables such as the sample pH, dosage, initial adsorbate (metals ion) concentration, contact time, and the temperature for the adsorption of selected metal ions using alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbent was analyzed and optimized utilizing the batch adsorption technique (Figure 5a-e).

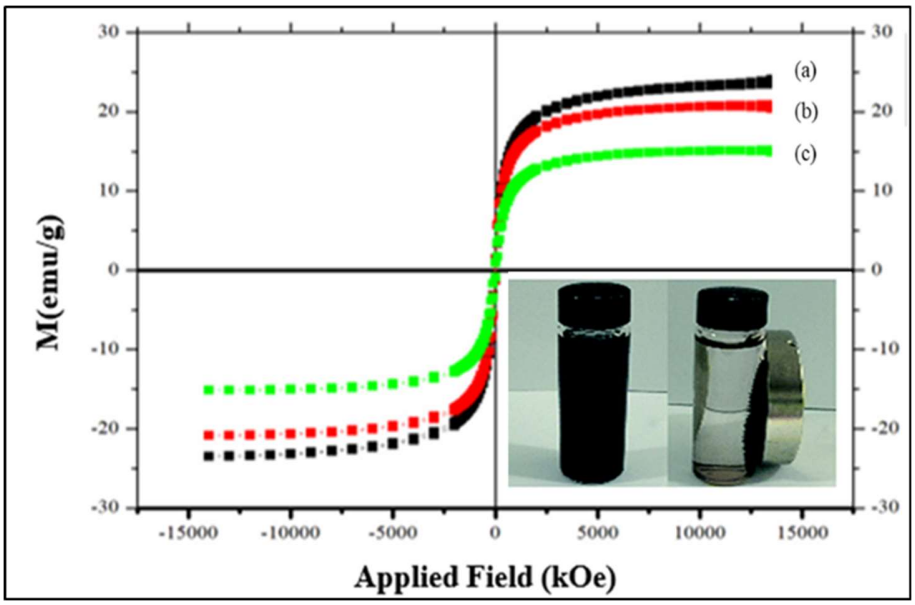

Figure 4. VSM plot for (a) Fe_3O_4 (24.48 emu/g), (b) NH_2-SiO_2/Fe_3O_4 (20.10 emu/g), (c) alg/Cs-NH_2-SiO_2/Fe_3O_4 (14.77 emu/g). The photo showed the separation of adsorbent using an external magnet.

A key to optimizing parameters in the process of metal ions adsorption onto the adsorbent was the pH of the water solution. The effect of pH was conducted by varying the pH from 2-7 and keeping other factors constant (Figure 5a). The findings revealed a maximum pH of 6 with % of metal ions removal for Pb(II), and Cd(II), except pH 7 for Cu(II) with the value of 73.74%, 68.82%, and 66.68% respectively. The adsorbent oxygenated active sites of Cs and alg were $–NH_2$, -OH, and –COOH. At lower pH, protonation occurred at the active sites of the adsorbent, and there was a competition between the protonated (H^+) active sites of the adsorbent and M^{2+} ions which induced electrostatic repulsion between the protonated sites (H^+) and M^{2+}, in turn, reduced quantity of adsorption of the metal. At greater pH values, there were the precipitations of the M^{2+} to form $M(OH)_2$, which resulted in less % metal ions adsorption with a similar pattern to other researchers [29]. Consequently, the value for optimum pH was found to be pH 6. Therefore, pH 6 was most acceptable and used in the next optimization parameter. The influence of contact time on the Pb(II), Cd(II), and Cu(II) adsorption onto alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbent was investigated. Contact time varied from 20-80 mins (Figure 5b).Time was varied while keeping other conditions constant to maximize the efficiency of the removal due to the time factor. The optimum contact time was achieved at 30 mins with % metal ions removal for Pb(II), Cd(II), and Cu(II) of 78.68, 70.66, and 70.88%, respectively. The fast % metal ions removal at the initial increased due to an abundance in the active accessible sites on the adsorbent surface for interaction with the metal ions. The adsorption accessible to active sites gradually reduced, and the interaction forces were weakened, resulting in a decrease in removal %. This observation was similar to the trends reported by some researchers that metal ions removal increased within the first few minutes of contact with the adsorbent surface [30]. Consequently, 30 mins was selected for the next optimization experiment.

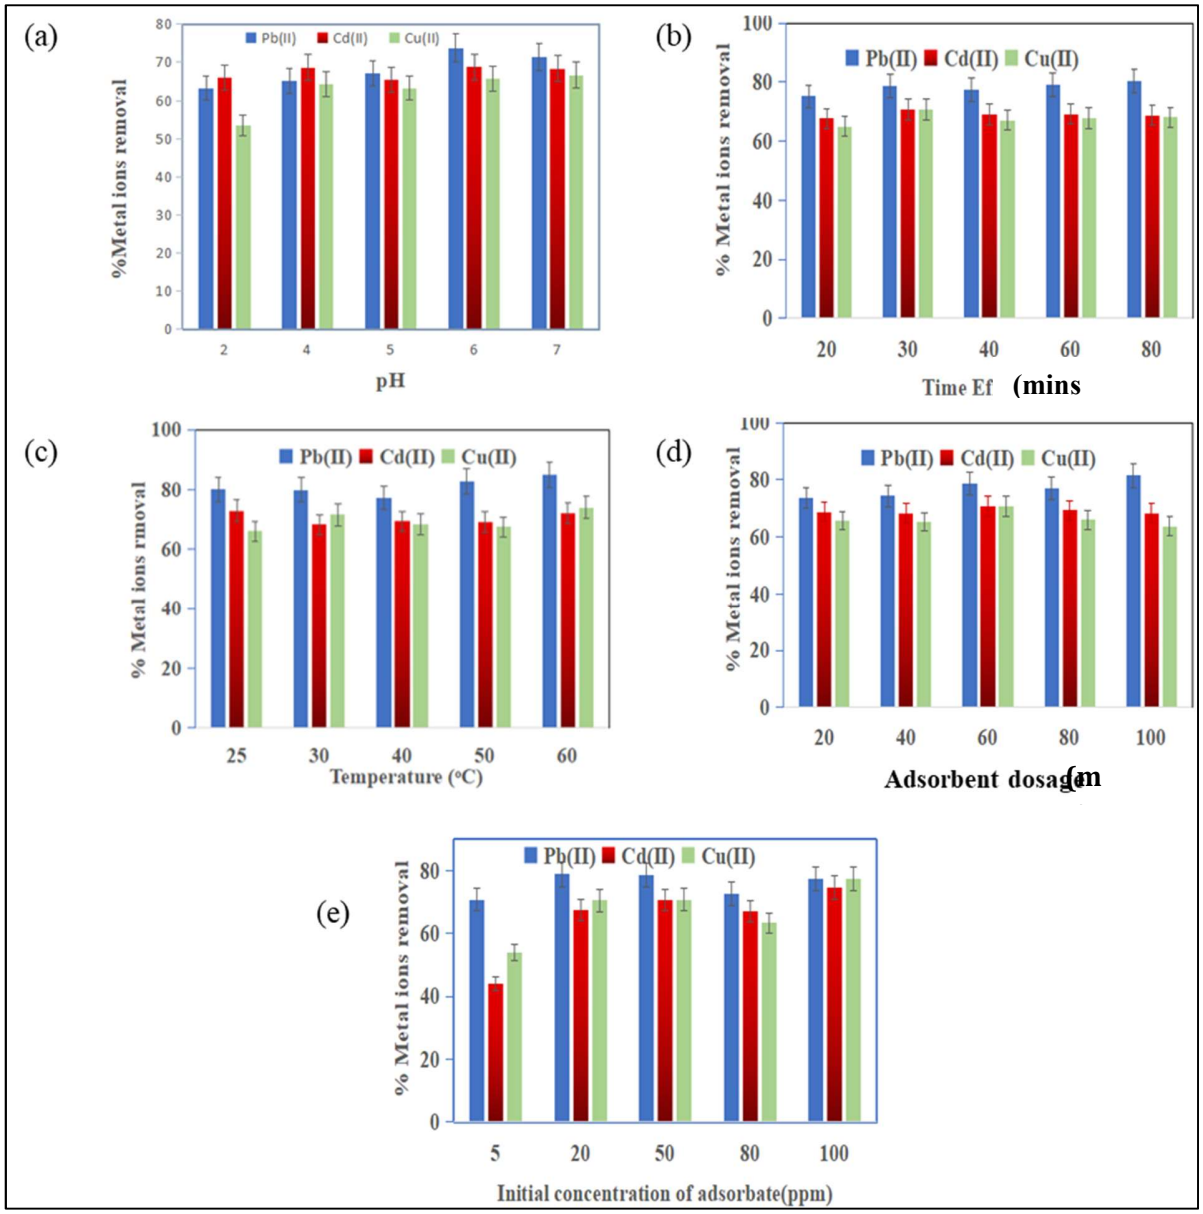

Figure 5. Effect of adsorption parameters (a) pH, (b) time effect , (c) temperature, (d) adsorbent dosage, and (e) initial concentration of adsorbate using alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbent for Pb(II), Cd(II) and Cu(II) removal in water.

The temperature effect on the removal process was a critical optimization parameter because the forces of interactions between adsorbate and adsorbent are either weakened or strengthened with changes in temperature or heat. Additionally, the mobility of metal ions increases with temperature and the affinity of the metal ions at a higher temperature also increased for most magnetic nanocomposites. A series of tests were conducted to study the effect of temperature from 20 - 60 ℃ to find the suitable temperature with the best efficiency of the removal (Figure 5c). The results showed that the optimum was achieved at 60 ℃ with % of the metal ions

of 84.76, 72.10, and 73.96 % for Pb(II), Cd(II), and Cu(II), respectively. The increasing temperature with an increase in the metal ions removal % was attributed to endothermic reactions, [31] as well as the increase in the rate of diffusion of the metal ions at greater temperatures[32]. The temperature at 60 °C was selected for the next parameter optimization. To evaluate the influence of the adsorbent dose on the removal process, the adsorbent amount varied from 20 -100 mg (Figure 5d). It was found that the optimum dosage was achieved at 60 mg, with metal ions removal % of 70.66, 78.68, and 70.88% Pb(II), Cd(II), and Cu(II), respectively. The amount of adsorbent dose was found to increase with the increase in available active sites and vice versa [33]. Consequently, 60 mg was the most appropriate dosage and was therefore adopted as the optimum dosage value for the next experiment. The effect of the initial adsorbate concentration was a crucial optimization parameter to increase the adsorbate active sides for the removal process. Concentrations from 5-100 ppm were investigated (Figure 5e). The results showed that the adsorption equilibrium was reached when the initial adsorbate concentration used was 50 ppm; the heavy metals ion % was 78.68, 70.66, and 70.88 % for Pb (II), Cd(II), and Cu(II), respectively. This agrees with the reports of others that the adsorption of metal ions increased with increasing concentrations due to the increasing availability of metal ions competing for the adsorbents active sites i.e. the more the adsorbate concentration the more the amount of the metal ions to be removed by the active sites of the adsorbent and vice versa[34]. Hence, 50 ppm was selected to be used in the next optimization temperature parameter.

Isotherm study

The equilibrium adsorption experiments of Pb(II), Cd(II), and Cu(II) onto the synthesized adsorbents alg/Cs-NH_2-SiO_2/Fe_3O_4 were studied using Freundlich, Langmuir, Temkin, and Dubinin-Radushkevich (D-R-K) isotherms models as a time function of initial concentrations at optimum conditions. Freundlich isotherm presumes multilayer and heterogeneous adsorption sites and it assumed physisorption observed adsorption mechanism [35, 36,37]. The Freundlich straight plot of the equation is given by the equation 3.

$$logq_e = logk_F + \frac{1}{n} logC_e \quad (3)$$

Where q_e and Ce are the quantity of adsorbate adsorbed per mass of the adsorbent (mg/g), and the equilibrium adsorption capacity of the metal ions pollutants (mg/L), respectively, K_F and n are the Freundlich constant suggestive of adsorbent adsorption capability (mg/g), and the heterogeneity factor, correspondingly. The isotherm findings provided the proper understanding of the kind and mechanism of the interaction behavior between the adsorbent and the adsorbate thus, additional explained the mechanism. That is the affinity of adsorbent, surface properties, and the types of the most appropriate adsorption process. The straight plots of *log* q_e against *log* C_e for Pb(II), Cd(II), and Cu(II), respectively, K_F and n for the separate metal ions were computed from intercept *(log* q_e*)* and slope *(1/n)* of the straight away lines (Table 1). The coefficient of regression (R^2) quantities were not close to unity and the KF quantities were not in harmony with the q_e experimental values. Accordingly, the Freundlich model could not sufficiently describe the adsorption processes. The extent of non-linearity between the solution concentration and adsorption was indicated by n values as shown; if $n=1$ indicated the adsorption is linear, if $n < 1$, indicated the adsorption process is through chemisorption, and if $n>1$, was for physical adsorption. Thus, $0 < n > 1$ is hereby appropriate[37]. Langmuir isotherm was established on the assumptions of monolayer and even distribution of adsorption sites on the adsorbent. Consequently, a saturation value may be achieved beyond which no extra adsorption will occur. Additionally, it was assumed that adsorption occurs through chemisorption at any given homogeneous site without interactions between the adsorbed molecules [37]. The linear Langmuir form is given by equation 4.

$$\frac{C_e}{q_e} = \frac{C_e}{q_m} + \frac{1}{q_m k_L} \quad (4)$$

Where q_m and q_e are the optimum adsorption capacity (mg/g), and the experimental adsorption capacity (mg/g), respectively, kL is the linear Langmuir constant (L/mg) and Ce is the concentration (mg/L) of residual solution. The linear plot of Ce/q_e against C_e gives a straight plot

line with an R^2 value for all the metal ions for Pb(II), Cd(II), and Cu(II) in that order. Here, values of qm and kL are computed from the linear slope ($1/qm$) and the intercept ($1/qmkL$). The findings of the adsorption procedures which fitted the Langmuir model based on the established R^2 values were close to 0.999 for Pb(II), Cd(II), except for Cu(II) < 0.999 as demonstrated in Table 2. Additionally, the experimental qe values for Pb(II) and Cd(II) were 41.8 and 39.2 mg/g, respectively, and they agreed with the calculated qm values of 39.4 and 36.6 mg/g, in that order, validating the Langmuir model's suitability to describe the adsorption processes [37,38]. The exception was Cu(II), where the experimental and calculated qe values were 39.6 and 15.6 mg/g. A separation factor constant (R_L) was introduced furthermore, to evaluate the degree of suitability of the adsorbent towards adsorbate and is described by equation 5.

$$R_L = \frac{1}{1+K_L C_o} \quad (5)$$

where K_L(L/mg) and C_o(mg/L) represent the Langmuir constant and the initial adsorbate concentration, respectively. The magnitude of R_L represents the feasibility of adsorption (Table 2). The dimension of R_L was additionally used, for the adsorption studies, if $R_L > 1$, the value indicated the adsorption is unfavorable, $R_L = 1$, indicated the adsorption is linear, and $R_L < 1$, indicated adsorption is favorable. Consequently, where $0 < R_L < 1$ confirmed R_L to be good and applicable for this study [37]. Additionally, the Temkin and the D-R-K isotherms data could not adequately explain the adsorption process of Pb(II), Cd(II), and Cu(II) onto the synthesized adsorbents alg/Cs-NH_2-SiO_2/Fe_3O_4 because of both R^2 < 0.99 (Table 1).

Table 1. Adsorption isotherm model parameters for Pb(II), Cd(II), and Cu(II) adsorption onto alg/Cs-NH_2-SiO_2/Fe_3O_4

Model	Isotherm Constant	Pb(II)	Cd(II)	Cu(II)
Freundlich	n	0.655	0.749	0.741
	k_F (mg/g)	32.0	36.5	32.0

	β (mol^2/J^2)	1.21x10^7	2.58x10^7	8.36x10^6
	R^2	0.36	0.48	0.76

Kinetics study

The adsorption kinetics provides crucial information about the effective design of the time-dependent batch adsorption system [38]. To examine the adsorption kinetics of the synthesized adsorbent, the pseudo-first-order and pseudo-second-order were studied. By using a predetermined concentration of 50.0 mg/L for each of the metal ions concentrations range and a predetermined adsorbent (60.0 mg) dose, the kinetics experiments were done.

The kinetics of adsorption for Pb(II), Cd(II), and Cu(II) onto alg/Cs-NH_2-SiO_2/Fe_3O_4 was examined using Pseudo-first-order linear equation 6.

$$log(q_e - q_t) = log(q_e) - \frac{tK_1}{2.303} \quad (6)$$

Where q_e and q_t are the capacity of adsorption and the quantity of metal ions removal at equilibrium (mg/g), and the quantity of metal ions removal (mg/g) at time t (min), respectively. K_1 is the pseudo-first-order rate constant (min^{-1}) [38]. The straight plots line of *log(qe-qt)* against *t* of pseudo-first-order rate equation for Pb (II), Cd (II), and Cu (II), respectively, along with the quantities of R^2 and k_1 for the corresponding metal ions, q_e and k_1 were calculated from the slope ($-k_1/2.303$) and $ln(q_e)$ as intercepts was summarized (Table 3). Consequently, the R^2 values were < 0.999 implying that the model could not be used to adequately explained through the adsorption process.

The straight-away kinetics equation for pseudo-second-order of Pb(II), Cd(II), and Cu(II), uptake onto alg/Cs-NH_2-SiO_2/Fe_3O_4 was depicted in equation 7.

$$\frac{t}{qt} = \frac{1}{k_2 q_e^2} + \left(\frac{1}{qe}\right) t \quad (7)$$

The straight-line plot relationship of *t/qt* versus *t* straight plot for pseudo-second-order rate equation for Pb(II), Cd(II), and Cu(II), separately. Where q_e and q_t are the adsorption capacity of metal ions adsorbed at equilibrium (mg/g), and the adsorption capacity of metal ions removal (mg/g) at time *t* (min), respectively. Furthermore, k_2 is pseudo-second-order rate constant (g/mg min)[38]. The R^2 estimations for the metal ions were closer to unity, suggesting theappropriateness of the model to explain the adsorption process. Where k_2 and q_e are computed from intercept ($1/k_2 q_e^2$) and slope ($1/q_e$) correspondingly, (Table 2). Consequently, the breakthroughs discovery confirmed that the removal process was the chemisorption-regulated process in agreement with other works reported [38].

Table 2. Kinetic data parameters for Pb(II), Cd(II), and Cu(II) adsorption onto alg/Cs-NH_2-SiO_2/Fe_3O_4

Model	Parameter	Pb(II)	Cd(II)	Cu(II)
Pseudo-first- order	q_e (mg/g)	40.8	35.6	35.8
	k_L (min^{-1})	0.004	0.314	0.402
	R^2	0.39	0.24	0.59
Pseudo-second order	q_e (mg/g)	38.6	36.4	33.6
	k_2 (min^{-1})	-0.95	0.03	-0.06
	R^2	0.99	0.99	0.99

Thermodynamic study

The thermodynamic factors describe the role of temperature control on the Pb(II), Cd(II), and Cu(II) adsorption process towards the produced alg/Cs-NH_2SiO_2/Fe_3O_4, thus, establishing the practicability and workable energy requirement for the adsorption process. The thermodynamics explained the effect of the factors such as the entropy changes (ΔS), enthalpy changes (ΔH), and Gibbs free energy (ΔG), which endorse the type of the adsorption, either one of randomness or non-randomness, endothermic, or exothermic, as well as spontaneous or non-spontaneous. These factors were established using Van't Hoff equation and Gibbs free energy [39], by an operating temperature range of 313-333K at optimum conditions according to equations 8, 9, and 10.

$$lnK_C = \frac{\Delta H}{RT} + \frac{\Delta S}{R} \quad (8)$$

$$\Delta G = -RTlnK_C \quad (9)$$

$$K_C = \frac{q_e}{C_e} \quad (10)$$

Where q_e and C_e are adsorption capability in mg/g and residual analyte (mg/L) concentration after adsorption, respectively. *T* represents the temperature *(K),* and *R* stands for the general gas constant (8.3145J/mol.K = 8.314x10^{-3} kJ/mol.K), K_C is the equilibrium constant. To assess the thermodynamic parameters of the target adsorbates on the as-synthesized adsorbent, the

adsorption isotherms at various temperatures (313, 323, 333K) were conducted. The straight plot of lnK_C versus *1/T* gives a straightaway line plot with an R^2, as represented. The negative quantity of slope suggested the adsorption method is endothermic type. The quantities of ΔH, as well as ΔS, were achieved from the slope ($\Delta H/R$ = - *slope*) and intercept ($\Delta S/R$ = intercept) of the straight linear plot, correspondingly [40]. The values of ΔG (kJ/mol), ΔH (kJ/ mol), and ΔS (J/mol.k), for removal of the heavy metal's ion onto alg/Cs-NH_2-$SiO_2Fe_3O_4$ (Table 3). The positive value of ΔH for the adsorption process of metal ions suggests the endothermic nature of the adsorption process with the order Pb(II) > Cd(II) > Cu(II) at 313K. This also supported the adsorption process with temperature increasement. The positive quantities of ΔH confirmed that the interaction was endothermic and the positive quantities of ΔS provide randomness attraction [40]. The positive value of ΔS was observed for the adsorption process of the metal ions indicating an increase in randomness at the solid/solution interface during the adsorption process with the order Cd(II) > Pb(II) > Cu(II) at 313K. Negative amounts of ΔS demonstrate s the rise in the randomness of the solid/solution boundary through the adsorption process, while the negative amounts of ΔG endorse that the adsorption process is spontaneous. The negative value of ΔG indicated the spontaneity of the adsorption process with the order Pb(II) > Cd(II) > Cu(II) at 313K. Generally, the change in standard free energy is in the range of -20 to 0KJ/mol and for chemisorption varies between -80 to -400Kj/mol. The results corrosions to spontaneous physical adsorption of the metal ions which indicated the system does not gain energy. In addition, ΔH of 4.0 - 8.0 kJ/mol and 8.0 - 40.0 kJ/mol are related to Van der Waals connections and hydrogen bonding, respectively. Accordingly, ΔH for chemisorption started at 40.0 kJ/mol[35]. Consequently, adsorption is a chemisorption-regulated process (Table 3).

Table 3. Thermodynamic factors for Pb (II), Cd (II), and Cu (II) adsorption onto alg/Cs-NH_2-SiO_2/Fe_3O_4 with temperature variations

Analyte	$T(K)$	R^2	ΔG (kJ/mol)	ΔH (kJ/mol)	ΔS (kJ/mol.K)

Regeneration and real samples analyses

The regeneration of an adsorbent was a crucial parameter that makes it more cost-effective in the practical application to remove metal ions from water with a good recovery. In this study, the newly synthesized adsorbent was evaluated for five consecutive cycles using 5.0 ml (0.1M) HCL**.** The results of the Pb(II), Cd(II), and Cu(II)% removal by alg/Cs-NH_2-SiO_2/Fe_3O_4, adsorbent could efficiently be reused for up to 5 cycles, retaining about 70% of its potential. Consequently, the adsorbent was deemed favorable material for use in metal removal from real wastewater. Pb(II) was detected in a holding pond near an industrial area (Taman Mewah, Kulai, Johor), eventually removed by the adsorbent at 86% where by, Cd(II) and Cu(II) were not detected. The adsorbent (alg/Cs-NH_2-

SiO_2/Fe_3O_4) adsorption capacity towards Pb(II), Cd (II), and Cu(II) was compared with other adsorbents in the literature (Table 4). This adsorbent compared fairly with its contemporaries (Table 4), the *qmax* for PAN-Na-Y adsorbent has 35.39, 40.69, and 35.07 mg/g as well as Mt-Chitosan has 49.33, 28.23, and 20.60 mg/g, respectively, for the removal of Pb(II), Cd (II) and Cu(II)[37,38]. The different Pb(II), Cd (II), and Cu(II) maximum adsorption capacities depended not only on the structure and morphology of the adsorbent, and the presence of functional groups but also on adsorption variables, such as pH, adsorbent dose, metal ions concentration, and contact time. The complexity was further caused by the non-uniformity of the maximum adsorption variable used and the various procedures the adsorption capacities were measured. Finally, in the choice selecting the appropriate adsorbent, availability, reusability, and cost-effectiveness were taken into account, which this adsorbent depicted. Therefore, it is noteworthy to mention that the adsorbent alg/Cs-NH_2-SiO_2/Fe_3O_4 has a promising potential for future use for Pb(II), Cd(II), and Cu(II), removal from effluent solution (Table 4).

Table 4. Comparative study of adsorption capacity of alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbent with similar adsorbents for the removal of Pb(II), Cd(II), and Cu(II) ions from aqueous solutions

Conclusion

In this paper, the novel effective adsorbent alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorbent was successfully synthesized from Fe_3O_4, as a percussor coated with SiO_2, functionalized using APTES (-NH_2), and the blend combined with chitosan bound by alginate as a binder to form the biopolymer composite adsorbent. The adsorbent was characterized for the surface morphology, using FTIR, FESEM/EDX, and VSM methods which demonstrated a successful synthesis. The adsorbent was investigated with the batch method. The evaluation of alg/Cs-NH_2-SiO_2/Fe_3O_4 adsorption performance at optimized conditions of pH, time effect, adsorbent dosage, initial adsorbate concentration, and temperature. The findings revealed that the adsorbent has a maximum adsorption capacity of 41.79, 39.21, and 39.56 mg/g for Pb(II), Cu(II), and Cd(II), respectively. In addition, the adsorbent behavior was studied for the isotherm models using Langmuir, Freundlich, Temkin, and Dubinin-Rudushkevich's isotherm model**s**. Moreover, the results demonstrated that the isotherm and kinetic studies were better fitted to Langmuir isotherm and the pseudo-second order with the coefficient of determination (R^2) close to 0.999, indicating homogeneous surface and chemisorption. The adsorption-desorption experiment for five consecutive rounds of regeneration study was

conducted until a substantial change inthe performance of alg/Cs-NH_2-SiO_2/Fe_3O_4 was detected. Consequently, the findings revealed that the adsorbent still retained its adsorption ability achieved above 70%, after the 5th recycled, which indicated the efficiency of the adsorbent. In addition, the thermodynamic factors were investigated, and the results indicated endothermic and spontaneous processes. The industrial wastewater river area of Taman Mewah, Kulai, Johor, Malaysia for the application for the real sample, and the findings revealed that only Pb(II) was detected at 86% efficiency of removal. The adsorbent (alg/Cs-NH_2-SiO_2/Fe_3O_4) adsorption capacity towards Pb(II), Cd (II), and Cu(II) were compared with other adsorbents in literature and was ranked good among its contemporaries. Therefore, it is noteworthy to mention that the adsorbent alg/Cs-NH_2-SiO_2/Fe_3O_4 has a promising potential for future use for Pb(II), Cd(II), and Cu(II), removal from effluent solution.

Abstract

This study reported an approach of producing biopolymer material from epoxidation of vegetable oils such as palm oil and rice bran oil. The epoxidation of vegetable oils converts from carbon double bonds into oxirane group and achieves by using the conventional method of *in situ* generated formic acid for 6 hours followed by further treatment with citric acid. The presence of oxirane group was proven by Spectroscopy (FTIR) analysis, and shown at the wavenumber of 773 cm^{-1}. Through direct titration, oxirane oxygen content (OOC) for epoxidized palm oil (EPO) and epoxidized rice bran oil (ERBO) were both determined as 2.89% and 3.05% respectively. Surface morphological studies were carried out for both EPO and ERBO bioplastic films by using Scanning Electron Microscopy (SEM). Further analysis with Energy Dispersive X-ray (EDX) spectroscopy showed 68.93% and 78.80% of carbon mass percentages for EPO and ERBO films, respectively. Whilst oxygen mass percentages were exhibited in EPO and ERBO as 31.07% and 21.20%. EPO film is degraded to approximate 50% at 223 °C whereas ERBO at 225 °C from thermogravimetric analysis (TGA). This green initiative of creating bioplastic film is desired to be a substitution for current plastic product which is mostly non-degradable. In long term prospect, it is also hoped to answer to the global plastic issues such as land dumping site and ocean plastic pollution that brings adverse effect to the marine organisms.

Keywords: bioplastic, Malaysian crops, edible oil, plastic pollution

Abstrak

Kajian ini melaporkan pendekatan untuk menghasilkan bahan biopolimer daripada proses pengepoksidaan minyak sayuran seperti minyak kelapa sawit dan minyak dedak padi. Pengepoksidaan minyak sayuran menukarkan daripada ikatan berganda karbon kepada kumpulan oksirana dan dicapai dengan menggunakan kaedah konvensional asid formik secara *in situ* selama 6 jam diikuti dengan rawatan lanjut dengan asid sitrik. Kehadiran kumpulan oxirane telah dibuktikan oleh Spektroskopi (FTIR) analisis, dan ditunjukkan pada nombor gelombang 773 cm^{-1}. Melalui pentitratan terus, kandungan oksigen oksiran (OOC) untuk minyak kelapa sawit terepoksida (EPO) dan minyak dedak padi terepoksida (ERBO) kedua-duanya ditentukan sebagai 2.89% dan 3.05%. Kajian

morfologi permukaan telah dijalankan untuk kedua-dua filem bioplastik EPO dan ERBO dengan menggunakan Mikroskopi Pengimbas Elektron (SEM). Analisis lanjut menggunakan spektroskopi X-ray Penyebaran Tenaga (EDX) masing-masing menunjukkan 68.93% dan 78.80% peratusan jisim karbon untuk filem EPO dan ERBO. Sementara itu, peratusan jisim oksigen dipamerkan dalam EPO dan ERBO sebagai 31.07% dan 21.20%. Filem EPO terdegradasi dianggarkan 50% pada 223 °C manakala ERBO pada 225 °C daripada analisis termogravimetrik (TGA). Inisiatif untuk mencipta filem bioplastik ini diingini untuk menjadi pengganti kepada produk plastik semasa yang kebanyakannya tidak terdegradasi. Dalam prospek jangka panjang, ia juga diharap dapat menjawab isu plastik global seperti tapak pelupusan tanah dan pencemaran plastik lautan yang membawa kesan buruk kepada organisma marin.

Kata kunci: bioplastik, tanaman Malaysia, minyak makan, pencemaran plastik

Introduction

The production of plastic globally was recorded more that 280 million tonnes in 2012, and increase to more than 335 million tones 4 years later [1]. These numbers are expected to grow exponentially over the next 20 years. Part of these plastics can be recycled; however, it was reported that only 21% is recovered over 91% plastic waste, where no less than 8 million tons of plastic as of now winds up in the sea consistently [2]. In Malaysia, the generation of plastic wastes has consistently increased 5% of every 5-years since 1995, where it was reported to produced 0.94 million tonnes in the year of 2018 [3], and projected to exceed 1 million tonnes in 2022. In environment, mismanaged plastic that underwent weathering or degradation process can broke down into smaller pieces to form secondary microplastics, which leads to many questions on the environmental, ecological and human health risks posed by them [4-5]. Therefore, the production of bio-based polymers (bioplastics) has gain interest from the world, as part of mitigation of this issue. With the price of petroleum is continually increase and the problem arise from environmental issues become the factors to utilize biodegradable products, for instance from vegetable oil. Bioplastic is considered to be a great alternative of petroleum free plastic in the industry. To maximize the value of bioplastic, its production should be done by using more environmentally friendly or greener method and resource. It could be seen that fast-growing trend on bioplastic is replacement for the petroleum in polymer industry as it is helpful in reducing a huge tons of carbon dioxide and the usage of petroleum [6].

The term of “bio” in bioplastic is defined as biological based derived plastic or polymer product such as vegetable oil, cellulose, and starch products that undergo chemical reaction to change into associated form, which later can degrade easily or able to be decomposed by microorganisms, therefore it is more sustainable and eco-friendlier [7]. For instance, vegetable oil-derived bioplastic is a type of vegetable oil-based cross-linking polymer plastics that has many repeating units. While fatty acid profiles of commodities such as soy bean and canola oils are major lipid of interest in the world in producing lipid biopolymer, local commodities Malaysia such as palm oil and rice bran oil were given consideration in this proposed study. Malaysia has ranked the top world largest exporter for palm oil production and second largest for palm oil production just a place right after Indonesia [8]. This oil can be obtained from harvesting the cluster or a bunch of palm oil fruit (*Elaeis guineensis*) at about forty to fifty kilograms. Meanwhile, rice bran oil is edible oil that is extracted from the brown husk outer layer of the rice. It has the smoke point at about 232 °C and often suitable for stir frying and deep frying in cooking. A brown husk of rice bran oil can be extracted up to 75% of the oil that is commonly wasted if there is no further research on it. Rice bran oil is obtained from the brown outer coating using hexane extraction and to get 8 to 16% of oil through the process of germ grinding, dehulling and polishing of rice [9]. Refined rice bran oil is often existed in light yellow liquid and highly stable due to the presence of tocopherols (vitamin E) of 320 mg/kg, oryzanols about 2% [9].

These oils are being utilized to produce bioplastic through feasible way of epoxidation process. Epoxidation is one of several reactions that can be carried out to utilize the fatty chain of edible oil in a reasonable cost. Various functional groups can be inserted into the double bond which acts as the reactive

site in the vegetable oils. It was widely proven that oils with high properties of saturated fatty acid and triacylglycerol's are more suitable for the application of fuel biodiesel, while polyunsaturated acids are permitted to participate in conversion of carbon-carbon double bond alkene into epoxy compound is known as epoxidation process [10] that later can be transformed to lipid biopolymer or bioplastics. Nevertheless, epoxidation of vegetable oil has become the popular research to be done by most of the scientist as it is worth at certain values. This is a solution to substitute non-renewable resources of petroleum to act as one of the plasticizers, known as epoxide. There are four major types of methods to produce epoxidation using fatty acids such as epoxidation with percarboxylic acid or acid catalyzed or enzymatic, organic or inorganic with alkaline and nitrile hydrogen peroxide, halohydrins by using hypohalous acids and salt reagent and molecular oxygen [11]. Some of the epoxides with high oxirane oxygen contents and functional epoxy group presence in the chemical structure of epoxidized vegetable oil, it is required a hardening agent to produce bio-based polymer [12]. High viscosity of vegetable oils is commonly implemented in the applications as lubricant and additives in polymer science such as resins and coatings. Our preliminary findings show that the epoxidation reaction, this can be followed by the cross-linking polymerization could be carried out on the reactive sites. Since both oils have differences in the type of fatty acids and their degree of unsaturation, this can impose conditions on their final use for the development of new products such as bio-based polymer and resins.

Materials and Methods

Materials

The following chemicals were purchased from R&M Chemicals (Malaysia): hydrogen peroxide (H_2O_2; 35%), anhydrous sodium sulphate, crystal violet indicator, HPLC grade acetonitrile, sodium chloride and glacial acetic acid. Formic acid (HCOOH; 98%), sodium bicarbonate, hydrogen bromide solution 33 wt.% in acetic acid, 2-propanol gradient grade for liquid chromatography (LiChrosolv) and acetonitrile hypergrade for LC-MS (LiChrosolv) were all purchased from Merck (KGaA, Germany). Citric acid-1-hydrate was purchased from HmbG Chemicals (Germany). Sodium hydroxide in pellets (analytical grade) was purchased from Fisher Scientific (Malaysia). Smith filter paper 101 Qualitative 90 mm was used for filtration purpose. The chemicals used in the study were of analytical grade unless stated otherwise. Palm oil and rice bran oil were purchased from the local market.

Epoxidation of palm oil (PO) and rice bran oil (RBO)

The heating process was begun from 55 °C and monitored carefully. Hydrogen peroxide (H_2O_2; 35%) of 34 mL was dropped wisely due to its exothermic effect that may cause explosion and continuously stirred with the fastest speed. The reactions were taken about six hours to complete. The epoxidized oils were washed with n-hexane, 5% wt. sodium hydroxide (NaOH) and 5% wt. sodium chloride (NaCl). Anhydrous sodium sulphate (Na_2SO_4) of 2 g was added and filtered with Buchner funnel.

Bio-polymerization using citric acid as curing agent

Concentrated citric acid was prepared by mixing 4 parts according to the weight of CA.H_2O ($C_6H_8O_7H_2O$) and one part of distilled water and heated up to 90 °C. Poured the completely dissolved solution into the glass beaker which contained 2 g of epoxidized palm oil or rice bran oil at 90 °C. Solution was stirred to form a layer of emulsion between aqueous citric acid and epoxidized oils. The viscosity would increase as the gelation formed at the same time. The solution was constantly stirred for 10 minutes at 90 °C until it gradually turned translucent and poured into the aluminium mould. The readily samples were both put into the oven (Universal Oven UF110 Memmert). Bio-polymerisation was started for 6 hours at 90 °C and 12 hours at 110 °C. Post curing at 120 °C for an hour and low drying mode at 35 °C to remove moisture for 2 hours.

Chemical analysis of oil and epoxidized oil: Liquid chromatography-mass spectrometry for fatty acid determination

An oil aliquot of 3 g (starting material) was obtained and diluted with 10 mL of ethyl acetate. It was followed by washing with 15 mL of brine (saturated sodium chloride) solution. The mixture was left for a while and later separated into two layers. Upper layer was

collected and washed with 15 mL of 1 M sodium bicarbonate ($NaHCO_3$) solution. Aqueous layer was removed and dried the upper layer with anhydrous sodium sulphate. Nitrogen evaporator (Organomation, N-EVAP 111) was used to concentrate the oils. The oils were weighted and diluted to 0.1 mg/mL in dichloromethane before LC MS/MS analysis for the analysis of fatty acid composition.

Liquid Chromatography Ion-trap Time-of-flight Mass Spectrometer (HPLC-MS-TOF, Shimadzu, Japan) is a unique combination of tandem mass spectrometer and ion trap (IT) with a time of flight (TOF) where ion trap allows MS^n capacity. A Supelco C_{18} column (250 mm x 4.6 mm i.d., particle size 5 µm) (Sigma Aldrich, ON, Canada) was used with the following linear gradient at a flow rate of 200 µL/min with an injection volume of 1 µL: Solvent A is isopropanol (IPA); Solvent B is Acetonitrile (ACN); t = 0, 20% A, hold 0.1 min; t = 25 mins 90% A. Data were acquired using ESI in the positive ion mode, with the following instrumental parameters : declustering potential (DP) at 45 V focus potential (FP) at 150 V; declustering potential 2 (DP2) at 10 V; gas (GAS 1) at 20; nebulizing gas (GAS 2) at 60; and an ion spray voltage of 5200 V [13].

Determination of oxirane oxygen content

Epoxidized oils was tested using AOCS Cd 9-57 for oxirane oxygen value. The direct titration of oils (0.5 g prepared in 10 mL glacial acetic acid) with 0.1 N 33% hydrogen bromide solution (in acetic acid) and was assisted with the use of 0.025% crystal violet indicator solution [14].

Fourier transform infrared spectroscopy (FTIR)

An amount of one-gram of each sample was used for FTIR analysis. The spectra were recorded 4 cm^{-1} resolution on IR spectrophotometer (Perkin Elmer, model FTIR Spectrum 100, Waltham, MA, USA). Data of absorbance against wavelength was generated by FTIR software (Perkin Elmer, OMNIC series suite, MA, USA). Epoxidized palm oils and epoxidized rice bran oils were recorded in transmission mode from 400 cm^{-1} to 4000 cm^{-1}.

Physicochemical analysis of of biopolymer product: Scanning electron microscopy analysis

Thin films were coated with gold using Auto Fine Coater (JFC – 1600, JEOL, Japan). The surface morphology of the bioplastic films was studied using Scanning Electron Microscopy (SEM model JSM - 6360LA, JEOL, Japan) at an accelerating voltage of 30 kV [15]. EDX analysis was done to determine the percentage of carbon and oxygen presence in the thin films.

Thermogravimetric analysis

Thermal degradation of the bioplastic films was both analysed by using thermogravimetric analyser (TGA851/LF 1100, Mettler Toledo). All samples were tested used a mass of approximately 70 mg under a nitrogen flow of 50 mL/min and heating rate of 10 °C /min within temperature range of 20 °C to 900 °C [16].

Results and Discussion

Fatty acid determination and epoxidation of edible oils

The main composition of the starting oils was determined to confirm the fatty acid profile for both starting oils and is illustrated in the Table 1. The commercial cooking oil of palm oil (olein) is made up of major of about 41.5% of C18:1 or oleic acid, followed by 40.2% of C16:0 (palmitic acid), 11.8% of C18:2 (linoleic acid), 5.3% of C18:0 (stearic acid) and 1.2% of other fatty acid constituent (e.g. lauric, myristic, palmitoleic and linolenic acids). This agreed with previous research on other commercial palm oil which usually consisting of 42-45% of palmitic acid, 40-42% of oleic acid and 9-11% of linoleic acid and very small amount of stearic and linolenic acid [17-18]. Meanwhile, rice bran oil is made up of the major composition of unsaturated fatty acids such as oleic acid (C18:1, 45.6%) and linoleic acid (C18:2, 28.3%) followed by saturated fatty acid of C16:0 (palmitic acid) at 22.1%. Previously, Purwanto (2010) and Punia et al. stated that this oil has fatty acid composition of palmitic acid (10-20%), stearic acid (1-5%), 39-43% oleic acid and 28-35% linoleic acid, depending on the method used in the oil extraction process [19-20]. The unsaturation profile of both oils was found to be suitable for further modification by epoxidation reaction.

Table 1: Major fatty acid constituent of edible oils used in the study

Fatty Acid	Composition (%)	
	Palm Olein	Rice Bran Oil
C16:0 (palmitic acid)	40.2	22.1
C18:0 (steric acid)	5.30	1.83
C18:1 (oleic acid)	41.5	45.6
C18:2 (linoleic acid)	11.8	28.3
others	1.20	2.17

Epoxidation with peracid formed *in situ* with hydrogen peroxide is a conventional method that widely used in the large-scale industry. As such, the better selection of formic acid is used in the experiment to enhance the break the unsaturated carbon double bonds into the epoxy group than acetic acid at around 60 °C [19]. There are some negative impacts of high concentration of formic acid towards the selectivity for conversion of oxirane oxygen thus reduced the final yield of epoxy group [21]. Commercialized palm oil (PO) and rice bran oil (RBO) were both underwent performic acid in situ epoxidation at 55 °C and the results shown was low epoxidation rates due to low reaction temperature, similar to the findings by Danov et al [22]. Hydrogen peroxide of 35% is dropped slowly due to its unstable reactivity and avoided adding in once the temperature exceeded higher than 85 °C. During the epoxidation process, RBO was heated to slightly viscous and turned from yellow to slight burnt brown colour in the middle of heating process. This due to the presence of phospholipid in the RBO and the antioxidant effect had caused the oil to brown darkening for several minutes during heating process. Fast stirring was continuously carried out in order to homogenize the viscous vegetable oil and but it could probably decrease the rate of epoxidation and deteriorate the formation of epoxy group [22]. Excessive epoxy ring opening reactions also would appear if the occurrence of side reactions at reaction temperature higher than 70 °C [23]. Stable oxirane rings were achieved at lower temperature and epoxidation under higher temperature was not recommended due to the exothermic effect of hydrogen peroxide that may lead to an explosion [24]. In situ generated formic acid with hydrogen peroxide was a reversible process to occur hydrolysis as it attributed by oxygen carrier from hydrogen peroxide to form peroxyformic acid. The repeatability of this method was done for several times on both PO and RBO to get the most accurate results.

A significant indication to the end of epoxidation process is the formation of light viscous liquid for both EPO and ERBO which takes about six to eight hours. This is faster than previously reported where the reaction for epoxidation process of vegetable oils could be accomplished up to 48 hours, depending on the reaction conditions and parameters [23]. Epoxidized vegetable oil (EVO) by acid generated in situ had achieved the reaction mechanism in two stages. The first step is hydrogen peroxide reacted with concentrated formic acid to form performic acid and water which is also known as hydrolysis process [24]. In the presence of water, performic acid catalysed the ring opening of unsaturated bonds of fatty acid and leading to the cleavage of oxirane rings in stage two [25]. However, a reversible process of formic acid regeneration is more likely to occur due to the unstable oxirane rings and again promote the epoxide group to undergo hydrolysis process [26].

FTIR analysis

Based on the analysis of Fourier Transform Infrared Spectroscopy (Table 1), the palm olein is converted to epoxidized palm oil. It can be seen at the C=O overtone from 3476 cm^{-1} in Figure 1(a) is changed to 3524 cm^{-1} broad stretching of OH in Figure 1(b) which resulted in ring opening of epoxy group [11, 27]. The absence of 3006 cm^{-1} at Figure 1(b) indicates the formation of epoxidation of palm oil and C=C was broken at the reaction. A missing peak of double bonds in the same figure represents that almost 100% conversion into C-O-C, epoxide group [28].

Palm oil has C=C bonds at the wavenumber of 3006 cm^{-1} at Figure 2, but the existence of epoxidation process had diminished this peak to 2927cm^{-1} CH stretching at Figure 3. In FTIR spectrum, epoxidized palm oil is shown a sharp and broader at the wavenumber of 1735 cm^{-1} C=C alkene bonding than the peak of C=O bonds at 1747 cm^{-1} in Figure 2. Stretch vibration of C-O-C ester group is noticeable at 1176 cm^{-1} [15] . Previously, it was reported that C-H rocking for epoxide band also occurred at 725 cm^{-1} in the epoxidized palm oil as proven by the wavenumber of 725 cm^{-1}. It is believed that the sensitivity of FTIR instrument lack of precision due to the disturbance of carbon dioxide because a peak of 844 cm^{-1} is not existed in the EPO, albeit small peak was observed at 831 cm^{-1}. All the functional groups of palm oil and epoxidized palm oil are tabulated in Table 2.

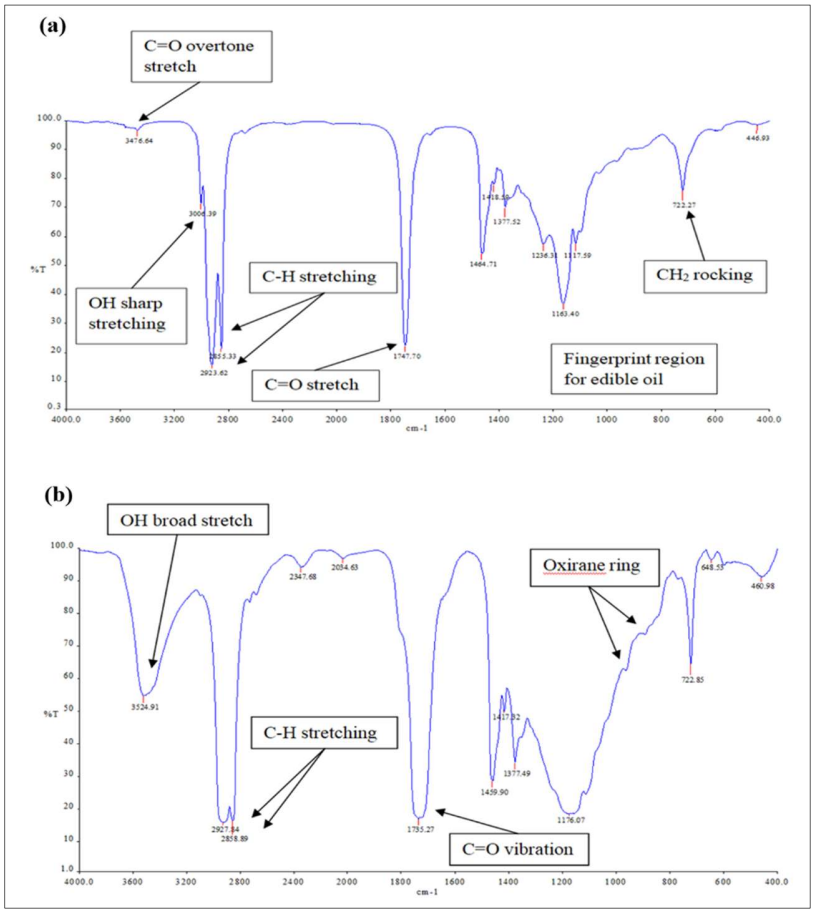

Figure 1. The FTIR spectra for (a) PO and (b) EPO

Separately, there is also an overtone of C=O at wavenumber of 3565 cm^{-1} in the RBO and a broad OH bond stretching at 3500 cm^{-1} , similarly as PO. From the IR spectrum of rice bran oil (Table 2; figure not included), it has a sharp C=O stretch at the wavenumber 1746 cm^{-1} whereas in epoxidized rice bran oil (ERBO) this peak has shifted to a lower wavelength range of 1728 cm^{-1}, similar to the infrared spectrum reported in [25]. Additionally, there is an existence of oxirane oxygen content (OOC) at the wavenumber of 773 cm^{-1} for ERBO when compares to RBO. This showed the

complete conversion of C=C double bonds into C-O bonds.

Based on the infrared frequency table, the spectrum falls under the range of wavenumber from 750 cm^{-1} to 825 cm^{-1} is a monosubstituted epoxides as a proof to RBO being epoxidized. There was a disappearance of C=C at the wavenumber of 3008 cm^{-1} of rice bran oil which is extremely approximate to the 3007 cm^{-1} reported by the author Gupta et al., [29] . From the results of rice bran oil and epoxidized rice bran oil, it could be seen that the patterns and wavenumber are almost totally matched to the experimental graph in the waste rice bran oil and epoxidized waste rice bran oil [29]. Ring opening of ERBO is indicated at 3500 cm^{-1} which has minor variation to the stated wavenumber of 3440 cm^{-1} from the same study.

Table 2. The IR frequency tables for both palm oil and rice bran oil before and after epoxidation are tabulated

		PO	RBO
	Functional Group	**Wavenumber (cm^{-1})**	**Wavenumber (cm^{-1})**
Before epoxidation	C=O (overtone)	3476	3565
	C=C (sharp stretch)	3006	3008
	C-H (stretch)	2923, 2855	2925, 2854
	C=O (stretch)	1747	1746
	CH_2 (rocking)	722	722
After epoxidation	OH (broad)	3524	3500
	C-H (stretch)	2927, 2858 c	2926, 2855
	C=O (vibration)	1735	1728
	C-O-C (vibration)	1176	1175
	C-O-C (oxirane)	831	825

Oxirane oxygen content

EPO and ERBO were later tested for the epoxy weight percentage analysis by using a direct titration method with 0.1 N hydrogen bromide (HBr) solution in 33% of acetic acid. This method was successfully measured the oxirane oxygen content (OOC) and show the epoxidation state of the reaction. An equilibrium point was achieved when the crystal violet solution had changed to blue green which represented the existence of OOC [30]. The oxirane oxygen for the EPO in the first, second and third tests (triplicate) were obtained at 2.96%, 2.80% and 2.90% respectively. Hence an average result of oxirane values was calculated for EPO as 2.89%, and this is closely approximate to the range of 2.7 to 2.9 % by author Tajulruddin et al. [31]. For ERBO that has been synthesized, the oxirane oxygen were recorded at 2.98%, 2.90% and 3.28% for triplicate analysis. The RBO was synthesized originally from waste rice husk so the ERBO has an average OOC of 3.05% which is very approximate to the 3.2% reported by Gupta et al., [29]. Hence, there was an inverse relationship between the conversions of OOC to the increasing reaction time of epoxidation. However, this would not much be affecting the final yield of the product since the difference in the percentage conversion is small. The percentage of the OOC value obtained from the current study was tabulated as below in Table 3.

Table 3. Oxirane oxygen content (OOC) of both EPO and ERBO

Sample	**1**	**2**	**3**	**Average**
EPO	2.96%	2.80%	2.90%	2.89%
ERBO	2.98%	2.90%	3.28%	3.05%

Curing of films with citric acid

A recent trend of biodegradable polymerization is usually focussed on the organic weak citric acid that made up of three carboxylic acids, COOH groups. Epoxidized oils that has good heat stabilizer are very beneficial in the production of plastics. EPO and ERBO were blended separately with 2 g of citric acid and 0.5 mL of distilled water and agitated to mix well. To promote the cross-linking of epoxidized oil and citric acid to form bio polymeric film, it was heated at 90 °C to enhance the effect. Epoxide is cyclic ethers with three membered-ring that is produced from peracids with alkenes. Vegetable oils for instance PO and RBO that are composed of oleic acid (C18:1), linoleic acid (C18:2), linolenic acid (C18:3) (Table 1) which allowed for conversion of bonds by peracids into epoxides. Asymmetric epoxides would undergo solvolysis by methanol and the ring opened by SN_2 mechanism where nucleophilic attacked at the less-substituted carbon region. In contrary, solvolysis also could be existed in acidic methanol and this reaction mechanism would be attacked at the more substituted site of carbon [32]. In the present study, citric acid acted as a curing agent and catalyst to epoxidized oils in which consisted of epoxy and triglycerides to produce polymeric films from renewable materials using vegetable oils. The reaction between epoxidized oil and citric acid was appeared in a translucent viscous gel that is known as biodegradable, non-toxic and greener biopolymer [33].

In this study, bio-polymerization process was started by mixing the epoxide oil with the curing agent at the first 6 hours (90 °C) reaction, followed by another 12 hours (110 °C) for hardening of the films in the oven. Previously, Kolanthai et al. [34] reported that the higher citric acid concentration will lead to fragility of the polymer film that might break into smaller pieces. Hence, a modified method was implemented during post-curing process. The original post-curing method by author Altuna et al. [35] was conducted at 150 °C under a monitoring period, but in the present study the temperature for post-curing was set at 120 °C for one hour to avoid the excessive burning of the samples. The biopolymer films were further dried under low oven drying mode at 35 °C for another 2 hours to remove the wettability or water content from the films. Oven dried of films were relatively carried out under a controlled environment of temperature, humidity and air circulation, thus helped to boost the water evaporation compared to the silica gel in desiccators method.

SEM-EDX analysis of bioplastic film

Scanning electron microscopy (SEM) that coupled with the function of energy dispersive X-ray (EDX) was used as a preliminary method to determine quantitative compositional data of the biopolymer film by observing the mass percentage of carbon and oxygen elements (Table 4). EPO shows that 74.72% of carbon atomic and 25.28% of oxygen atomic in the composition of its bioplastic film. While bioplastics from ERBO consists of 83.20% of carbon atomic, thus can be used to predict that the ERBO has longer chain than EPO. This is because the epoxidation will break the double bonds and increases the number of carbon single bonds as monomers repeating unit cross linked with each other in the polymerization process.

Table 4. EDX data analysis for EPO and ERBO bioplastic films produced

Sample	Element	(keV)	Mass%	Atomic%
EPO	C	0.277	68.93	74.72
	O	0.525	37.07	25.28
ERBO	C	0.277	78.80	83.20
	O	0.525	21.20	16.80

Epoxidized palm oil is suitable to cure with citric acid, as Figure 2a shows that EPO bioplastic film has a smooth and illuminating surface at 30 times of magnifications. There is a correlation to the increasing amount of citric acid blend towards the compatibility of bioplastic, similar to the previous reported findings by Ouipanich et al. [36]. Figure 2b shows the uneven surface thickness of the specimen but high miscibility due to strong hydrogen bonding interactions with epoxy, hydroxyl and carbonyl group making a smooth surface

[27]. It shows uniform vertical stripes and grid pattern under 1000 magnifications at an accelerating voltage of 10 kV. Epoxidized palm oil film is in long cross-linking shape and homogenously distributed under the boost of high temperature curing in Figure 2c. The overall of the film is concluded as very brittle due to the uneven surface thickness and fracture.

Meanwhile, epoxidized rice bran oil (ERBO) bioplastic film illustrates a clear and shiny image. It can be seen that the pattern is looked like cracked fracture dry land in Figure 3a. The crackle is short and distributed homogeneously on the entire surface of the specimen. As the numbers of crack front increasing on bioplastic film, the higher the flexibility and the ductility of the film [11]. It shows horizontal stripes at 30 times of magnification. Figure 3b is open-pores image that shows on the surface of the film and they are cross linking like bee hives, similar to the finding elsewhere [37]. The presence of voids on Figure 3b under magnification of 350 times is due to the degree of dispersion of citric acid in the polymerization of epoxidized rice bran oil. Hence, it can be explained by the increasing of natural glycerol content in vegetable oil will decrease the tendency to form void and increase the phase separation [38]. Meanwhile, in Figure 3c, a round spot is virtually observed, with the round holes shaped of the pores is noticeable at 1000 magnification of 10 kV accelerating voltage.

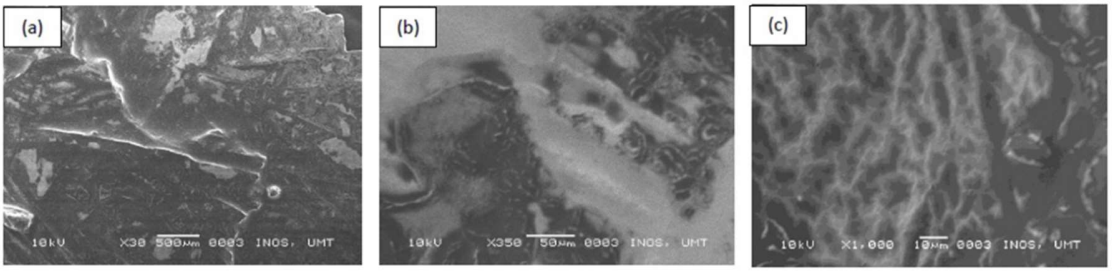

Figure 2. SEM micrograph for different magnifications of EPO bioplastic film at 10kV of (a) 30X, (b) 350X, (c) 1000X magnifications

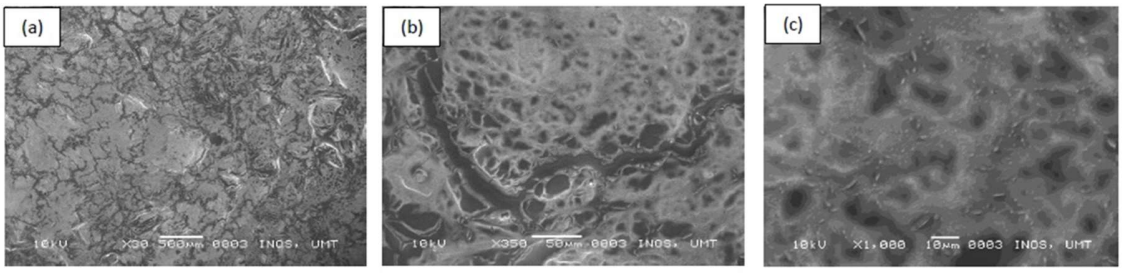

Figure 3. SEM micrograph for different magnifications of ERBO bioplastic film at 10kV of (a) 30X, (b) 350X, (c) 1000X magnifications

Thermogravimetric analysis (TGA)

Thermogravimetric is the analysis that provided information on the weight loss with the increasing of temperature in order to obtain the degradation level of biopolymeric films under an inert nitrogen environment. To observe the thermal behaviour of biopolymer films, the initial decomposition temperature, 50% degradation level and maximum decomposition rate are recorded in TGA and DTG curves. In general, the results show that the films could started degrading at higher temperature (>180 °C), thus proven that formation of biopolymers was successful. Figure 4 shows thermogravimetric

analysis of biopolymer made from EPO and ERBO is illustrated as three stages according to the percentage of degradation. While, table 5 shows the thermal degradation of biopolymer films at different temperatures.

Table 5. Thermal degradation of epoxidized oil biofilms at different temperatures

Sample	T_i(°C)	Wt.%	T_{50}(°C)	Wt.%	T_{max}(°C)	Wt.%
EPO film	29.10	70.56	223.35	36.71	895.46	8.32
ERBO film	30.28	70.54	224.90	35.29	897.65	7.30

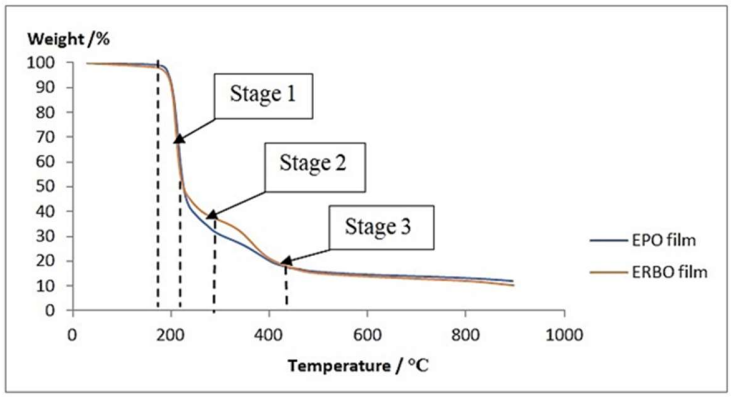

Figure 4. The thermogravimetric analysis of epoxidized palm oil (EPO) and epoxidized rice bran oil (ERBO) biopolymer films on weight percentage

From thermogravimetric analysis (TGA), the starting temperature (T_i) for biopolymer made from EPO film is 70.56 mg at 29.10 °C in Figure 5a. It is started to degrade at 182 °C and left 36.71 mg or 52% of the product at 223 °C. At 895 °C, it only contains a residue of 8.32 mg for EPO film. There is some weight loss at the initial stage of EPO biopolymer film due to the evaporation of water at the temperature between 37 °C to 176 °C, similar to the previously reported [16]. According to the first differential thermogravimetric curve (DTG), it illustrates in Figure 5b that the maximum degradation of EPO at 38% weight remained for biopolymer film at 252 °C [37].

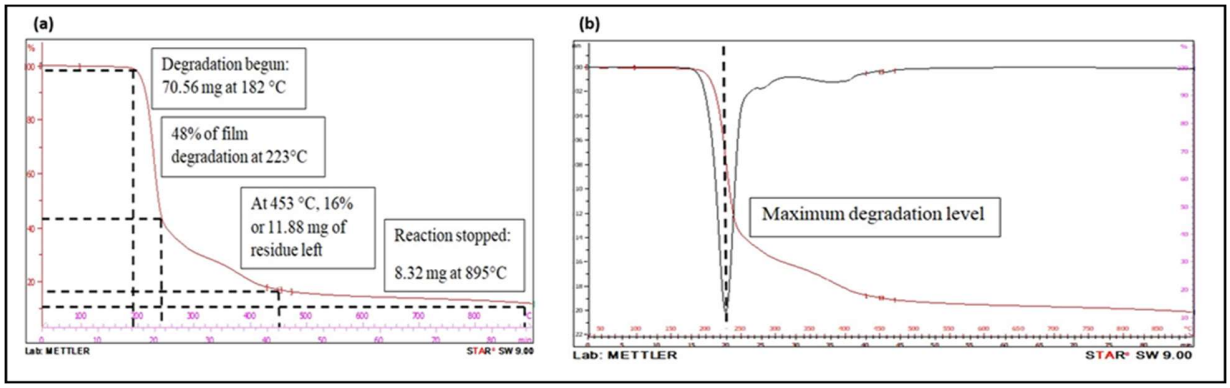

Figure 5. (a) Weight percentage of EPO from TGA curve, and (b) DTG thermograms from TGA curve of EPO

While in ERBO, it is first beginning with 70.54 mg at 30 °C in Figure 6. Then, it is started to decompose at 106 °C and remain 35.29 mg or 50% at 225 °C. At the end process of 897 °C, there is a 7.30 mg or 10% of ERBO film residue. Whilst, the differential thermogram (DTG) shows that the 257 °C is the maximum degradation level of ERBO in Figure 6 which still has 41% of the original product remained as biopolymer film. It is suggested that thermal decomposition of ERBO is well cross-linked with citric acid in order to have longer polymerization chain length, hence it is observed to degrade at slightly higher temperature compare to EPO film. This is found to be similar to the finding by an earlier study, where they reported that the contribution of network structures in enhancing the thermal stability of the biopolymer material [39].

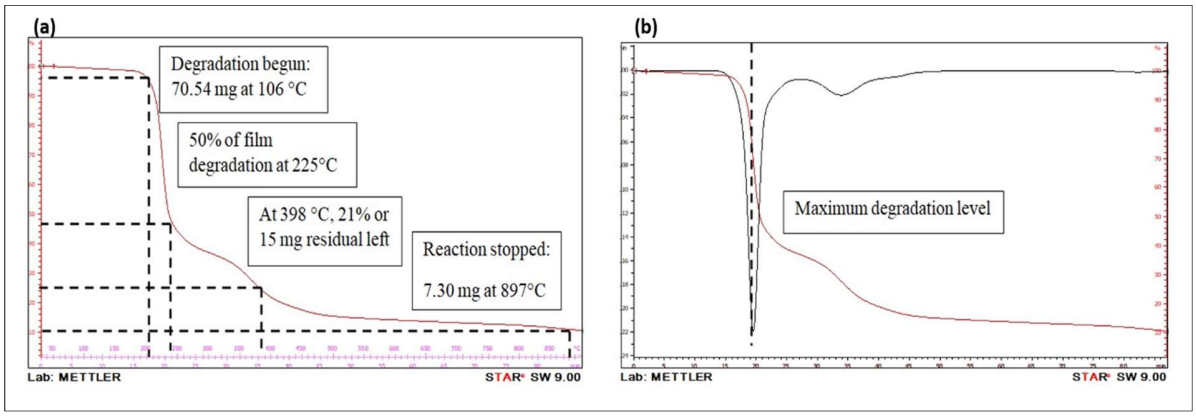

Figure 6. (a) Weight percentage of ERBO from TGA curve, and (b) DTG thermograms from TGA curve of ERBO

Conclusion

In this present study, the epoxidation process of palm oil (PO) and rice bran oil (RBO) were succesfuly converted the double bonds into epoxides that subjected for further polymerization. Oxirane oxygen content of EPO is 2.89% which is less than 3.05% of ERBO, showing that the latter has longer chain polymerization. The improvement of post-curing process shown that the cross-linking could be achieved at lower temperature while still promoting excellent polymer sturcture. From SEM analysis, bioplastic films made of EPO have smoother surface than ERBO, whilst thermogravimetric analysis (TGA) shows the degradation of both films only noticable after 180 °C, and still recorded mass residual of 10.35% (ERBO film) and 11.79% (EPO film) after 890 °C, owing to their excellent thermal stability characteristic. This shows that the PO and RBO can be used as starting material for epoxidation reaction and biopolymer transformation, and can be further explored for their degradation profile, tensile and mechanical stress as well as life-cycle assesment, thus can be used an alternative material in plastic pollution mitigation.

Abstract

Dichloro-*N*'-(3-chlorobenzylidene) benzohydrazide nickel(II) complex was successfully synthesised using 4-chloro-*N*'-(4-chlorobenzylidene) benzohydrazide ligand with nickel(II) chloride. The synthesised ligand and complex were characterised by various instruments including FTIR, ^{1}HNMR, ^{13}CNMR, and UV-Vis spectroscopy. The preliminary complexation study between Ni^{2+}cation and ligand showed that 1:1 stoichiometric formation corresponded to the metal-ligand ratio. The catalytic performance of the complex was tested using a Suzuki reaction between phenylboronic acid and four different aryl bromides (1-bromo-4-nitrobenzene, 4-bromoanisole, 4-bromoacetophenone, and bromobenzene) at different solvents and bases. The per cent (%) conversion rate of reactant to the product was determined using GC-FID. The best catalytic performance was found in the reaction between phenylboronic acid and 1-bromo-4-nitrobenzene using 0.5% mmol catalyst loading, methanol as a solvent, and K_2CO_3 as a base at temperature of 65°C within 2 h reaction time, giving a conversion rate of 81.86%.

Keywords: hydrazone ligand, nickel (II)-hydrazone complex, Suzuki reaction

Abstrak

Kompleks dikloro-N'-(3-klorobenzilidena) benzohidrazida nikel(II) telah berjaya disintesis menggunakan ligan 4-kloro-*N*'-(4-klorobenzilidena) benzohidrazida dengan nikel(II) klorida. Ligan dan komplex yang disintesis dicirikan oleh pelbagai alat terdiri daripada FTIR, ^{1}HNMR, ^{13}CNMR, dan spektroskopi UV-Vis. Kajian awal pembentukan kompleks antara kation Ni^{2+} dan ligan menunjukkan stoikiometri pembentukan ialah 1:1 sepadan dengan nisbah logam-ligan. Prestasi pemangkinan komplek telah diuji menggunakan tindak balas Suzuki antara asid fenilboronik dan empat aril bromida yang berbeza (1-bromo-4-nitrobenzena, 4-bromoanisol, 4-bromoacetofinon, dan bromobenzena) pada parameter yang berbeza seperti jenis pelarut dan bes. Peratus (%) kadar

penukaran bahan tindak balas kepada produk ditentukan menggunakan GC-FID. Prestasi pemangkinan terbaik didapati dalam tindak balas antara asid fenilboronik dan 1-bromo-4-nitrobenzena dengan menggunakan pemuatan mangkin 0.5% mmol, metanol sebagai pelarut, K_2CO_3 sebagai bes pada suhu 65°C dalam masa tindak balas 2 jam memberi kadar penukaran sebanyak 81.86%.

Kata kunci: ligan hidrazon, kompleks nikel (II)-hidrazon, tindak balas Suzuki

Introduction

Suzuki reaction is one of the most used techniques for producing C-C bonds. It involves coupling an organoboron reagent with an organic halide or pseudo-halide in the presence of a palladium or nickel catalyst and a base [1]. Nickel catalyst have various advantages over palladium catalyst that are more commonly used, including the capacity to activate aliphatic electrophiles and the ability to avoid β-hydrogen elimination by alkyl-metal intermediates that help in avoiding lowering the yield [2]. In addition, nickel systems are frequently more reactive in oxidative addition or insertion reactions due to the smaller atomic radius, lower electronegativity, and greater negative redox potentials of low-valent nickel species [3]. Due to the economic aspect the selection of nickel-based catalysts is ideal for industrial-scale use more than noble metal-based catalysts due to their lower cost and high activity [4]. Many of industries use the Suzuki reaction, such as polymers, pharmaceutically active chemicals, herbicides, novel materials, liquid crystals, and chemical synthesis [5].

Improving the catalytic activity of nickel-based catalyst towards the specified reaction is important and influenced by its structure. Thus, a suitable ligand design is an essential step in the development of a catalyst that lead to higher reaction rates, improved lifetime, and stability. The ability of ligands to donate electrons is crucial in coordination chemistry because it is one of the most important factors influencing the properties and reactivities of complexes [6]. Hydrazone is a ligand that has different binding modes and lone pair electrons with the structure $R_1R_2C{=}NNH_2$. In such instances one donating element (iminic nitrogen, N), and its subgroups (acyl and aroylhydrazones) can function as bidentate (N, O) or tridentate (N, O, X=O, N, S) ligands [7, 8]. The exploration of ligands containing hydrazone is interesting because the diversity of it is seen in the coordination, a preference for higher coordination number stereochemistry, the capacity to operate as neutral or deprotonated ligands, and the ability to assume various conformations [9]. Due to its flexibility and versatility, the coordination chemistry of hydrazone-based ligands has proven to be highly relevant due to their strong complexation potential towards a wide range of metals ions and the possibility of catalytic application [5, 10].

Exploration of the capability of hydrazone as a ligand with nickel(II) catalyst, particularly is currently limited. The goal of this research is to design a novel nickel(II)-hydrazone complexes that can be used as Suzuki reaction catalysts. The optimum reaction conditions of a newly synthesised catalyst were studied and identified using several parameters.

Materials and Methods

Chemicals and instruments

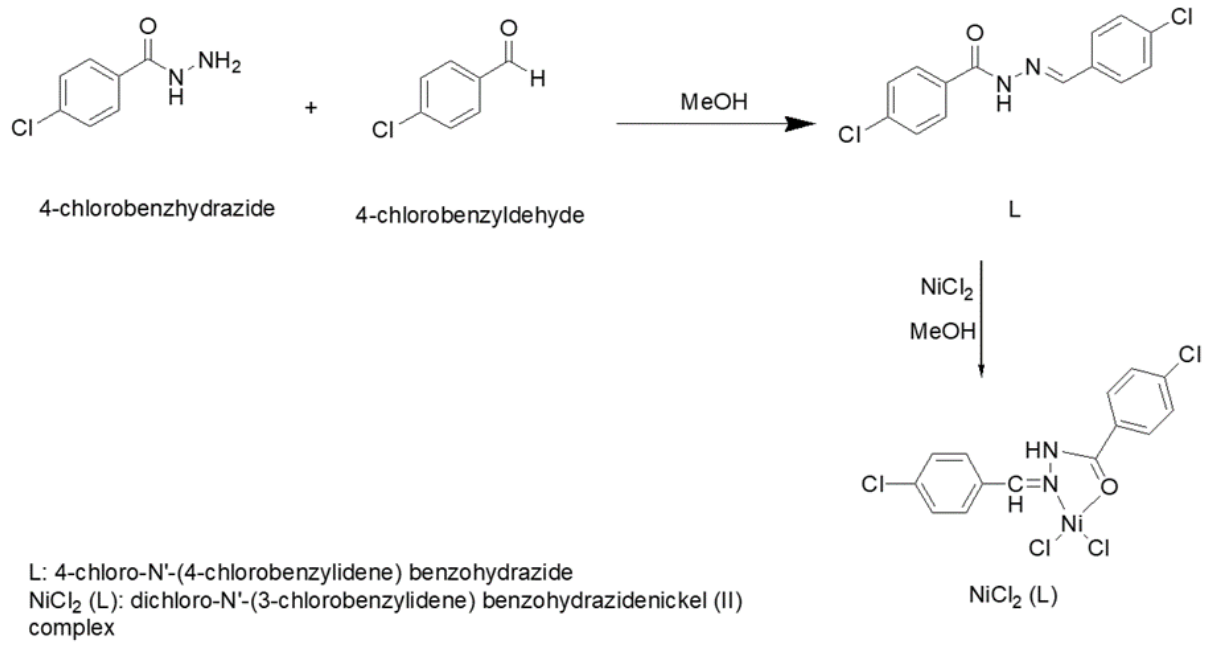
All the chemicals and solvents obtained from commercial suppliers were used as received. The chemicals used were 4-chlorobenzyldehyde (Sigma), 4-chlorobenzhydrazide (Sigma), dimethyl sulfoxide (DMSO) (Merck), methanol (Merck), sodium acetate (NaOAc)(Merck), sodium carbonate (Na_2CO_3) (Sigma), potassium carbonate (K_2CO_3) (Merck), dimethylacetamide (DMA) (Merck), phenylboronic acid (Sigma), nickel(II) chloride (Merck), 1-bromo-4-nitrobenzene (Merck), 1-bromobenzene (Merck), 1-bromoacetophenone (Merck), 4-bromoanisole (Merck) and nitrogen gas. All solid products produced at the end of every synthesis were collected by high vacuum filtration or slow evaporation at room temperature.

The product was characterised using Fourier Transform Infrared (FTIR) spectroscopy, Nuclear Magnetic Resonance (NMR) and UV-Visible (UV-Vis) Spectroscopy. Meanwhile the catalytic performance was determined by using Gas Chromatography Flame Ionisation Detector (GC-FID). The FTIR spectrometer use is a Perkin Elmer Spectrum 400 where the FTIR spectra were determined as reduced total reflectance (ATR) in the range of 4000-200 cm^{-1}. The ^1H and

^{13}CNMR spectroscopy were analysed using a Bruker Advance 400 spectrometer model at 400 MHz with tetramethylsilane (TMS) as an internal standard. The UV-Visible spectroscopy use is a T80+ UV-Vis spectrometer in of 500-240 nm range. The % of conversion rate and turnover number (TON) were calculated using the below equation that use the data from GC-FID. The analysis used HP-5 capillary column (15 m x 0.25 mm x 0.25 mm) with Flame Ionization Detector. The samples were injected at 50°C, with a maximum temperature of 250°C. The temperature was raised at a rate of 15°C per minute and 1.9162 mL/min was utilised as the flow rate [7].

$$\% \text{ Conversion rate} = \frac{(A_{initial})- (A_{final})}{(A_{initial})} \times 100 \quad (1)$$

Where; $A_{initial}$ = peak area of reactant before reaction, and A_{final} = peak area of reactant after reaction



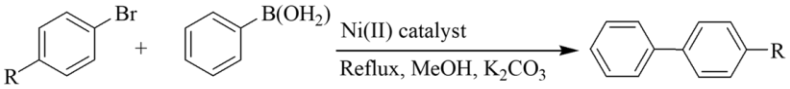
$$\text{Turnover number (TON)} = \frac{\text{Percentage of conversion rate}}{\text{Amount of catalyst loading}} \quad (2)$$

Synthesis of compounds

The outline for the preparation of nickel (II)-hydrazone complex is given in Scheme 1.

Synthesis of hydrazone ligand (L)

Hydrazone ligand prepared in the presence of nitrogen gas, an equimolar of 4-chlorobenzhydrazide (0.5 g, 2.98 mmol) and 4-chlorobenzyldehyde (0.5 g, 3.79 mmol) refluxed in 10 mL of methanol for 2 hours. The reaction mixture was then allowed to cool to room temperature before filtering using vacuum filtration to obtain a solid product. The solid was washed several times before being recrystallized from methanol forming white crystals.



Scheme 1. Synthesis steps of nickel (II)-hydrazone complexes

Synthesis of nickel(II)-hydrazone complex ($NiCl_2(L)$)
After combining stoichiometric amounts of ligand (0.1 mmol) and nickel chloride (0.1 mmol) dissolved in methanol (15 mL), the reaction mixture was refluxed for 2 h. Filtering off the precipitates was then performed before washing the mixture with methanol and drying it in a vacuum desiccator over anhydrous $CaCl_2$.

Preliminary complexation study
A preliminary complexation study was conducted to determine the stoichiometry ratio between ligand and metal using the UV-Vis spectroscopy titration method. Solutions of hydrazone ligand and Ni^{2+} cation were prepared in DMF with concentration of 2.3×10^{-6} mmol and 1×10^{-4} mmol, respectively. The source of Ni^{2+} cation was nickel chloride. The quartz cuvette was filled with 3 mL of ligand solutions and titrated with Ni^{2+} cation solution. At each titration the solution mixture was left about 5 min before run at the UV-Vis in the 270-300 nm range [11,7].

Catalytic testing
The investigation into the catalytic activity of the complex (0.5% mmol) in the Suzuki reaction was tested by the reaction of phenylboronic acid (0.182 g, 1 mmol) with 1-bromo-4-nitrobenzene (0.20 g, 1 mmol) in 5 mL methanol under 65°C with the presence of K_2CO_3 as a base (0.276 g, 2 mmol). All chemicals were mixed in a three-neck round bottom flask and refluxed for 2 h in the presence of nitrogen gas. The mixture was then poured into a separatory funnel, followed by the addition of water (30 ml) and dichloromethane (3 x 10 ml). After allowing the mixture to settle for 30 minutes, the organic layer was collected and discarded into a beaker, and then dried over $MgSO_4$. The mixture was subsequently filtered using vacuum filtration to obtain the product. The product was evaporated using a rotary evaporator and dried in an oven. Meanwhile, the catalytic performance was analyzed using GC-FID spectroscopy. The steps were repeated with using 4-bromoacetophenone, bromobenzene and 4-bromoanisole as an aryl bromide as substituted of 1-bromo-4-nitrobenzene. Different types of solvents and bases were also tested. The reaction is shown in Scheme 2, where R is referred to as $-NO_2$, $-OCH_3$, $-COCH_3$, and H.

Scheme 2. Catalytic reaction of 1-bromo-4-nitrobenzene with phenylboronic acid

Results and Discussion

Characterization of synthesized compounds
This study successfully synthesised 4-chloro-*N*'-(4-chlorobenzylidene) benzhydrazide ligand and dichloro-*N*'-(3-chlorobenzylidene) benzohydrazide nickel(II) complex. The physical properties of the synthesised ligand and complex are listed in Table 1. According to the observations, the colour of the ligand changed because of the complexation process, from white to pale green. Meanwhile, the melting points of the complex was greater than the respective ligand due to the interaction of nickel(II) with the ligand's structures. These metal-ligand bonding in the structure of the complexes required more energy to break, which caused an increase in the melting point [7].

Table 1. Physical properties of synthesized compounds

Sample	Colour	Melting Point (°C)	Yield (%)
Ligand	White, powder	168-169	82.41
Complex	Pale green, powder	220-221	41.87

The formation of ligand and complex were confirmed using FTIR, ^{1}HNMR, ^{13}CNMR, and UV-Vis spectroscopies. The significant FTIR absorption bands a re summarised in Table 2. The successfully synthesised ligand is indicated by the presence of a strong absorption band at the range of the carbonyl group but at an unusually low value (1650 cm^{-1}), signified by the C=O amide. New medium absorption bands of C=N imine at 1600 cm^{-1} is also an important signal to confirm the formation. The C=N bond was formed by the reaction between the C=O aldehyde of 4-chlorobenzaldehyde and primary amine (-NH_2) of 4-chlorobenzhydrazide via the removal of H_2O molecules. However, the presence of a resonance effect in the structure led to the absorption band of C=N observed at a lower frequency when compared to the normal range, which is around 1650 cm^{-1}. Other absorption peaks were observed at 3218 cm^{-1} and 1090 cm^{-1}, which were attributed to the N-H and C-H stretching, respectively [7, 12]. The coordination of nickel(II) to the ligand in the FTIR spectrum could be observed by the shift of C=O and C=N stretching absorption bands to the low frequency at 1620 cm^{-1} and 1567 cm^{-1}, respectively. This observation indicated that the C=O oxygen and the C=N nitrogen were probably involved in coordinating to the central nickel (II) ion via contributing the lone pair [13].

Table 2. Significant FTIR absorption bands of synthesized compounds

Assignment	**Wavenumber (cm^{-1})**	
	Ligand	**Complex**
N-H	3218	3214
C=O amide	1650	1620
C=N imine	1600	1567
C-N	1090	1095
C-Cl	819	819

The spectra of ^{1}HNMR and ^{13}CNMR (Figure 1) were recorded for synthesised ligand, and the significant attributes are tabulated in Tables 3 and 4. A singlet appeared at 8.44 ppm and was assigned to the proton of azomethine (CH=N) proton. Another important peak at 12.00 ppm was assigned to the proton of N-H adjacent to C=O, which was observed as an enolic form [13]. The structures of the ligand were further supported by ^{13}CNMR data. The carbonyl carbon signal appeared at 162 ppm (C=O), whereas signals that appeared at 147 ppm were assigned to the carbon of the azomethine group (CH=N). The other five signals at 129-137 ppm were due to the substituted benzene ring carbon. Unfortunately, the reading of signals for the complex was unreadable due to the paramagnetic effect of nickel in the compound [14].

Attributions	Chemical Shift, δ (ppm) Ligand
-CH aromatic	7.51 [2H]
	7.60 [2H]
	7.75 [2H]
	7.94 [2H]
-CH	8.44 [1H]
-NH	11.98 [1H]

Table 4. Significant attributes of [13]CNMR data of ligand

Attributions	Chemical Shift, δ (ppm) Ligand
C=O	162
HC=N	147
CH	129-137

Figure 2 shows the UV-Vis spectra of the ligand and complex. The ligand showed absorption bands at 257 nm and 298 nm. These wavelengths were assigned to the $\pi - \pi^*$ transition in the structure of the ligands. The spectrum of the complex also showed two absorption bands at 258 nm and 312 nm, signifying a similar pattern of the ligand in the region. These absorption bands were also presented in the spectrum of the nickel(II) complex, although they underwent red shift. The coordination of the ligand to the nickel(II) ion was supported by this shift in the spectra of the produced complex [15]. The region for nickel metal is 480 nm but it could not be observed in this study because nickel contained unpaired electrons exhibited d-d transition and paramagnetic causing weak absorption [16].

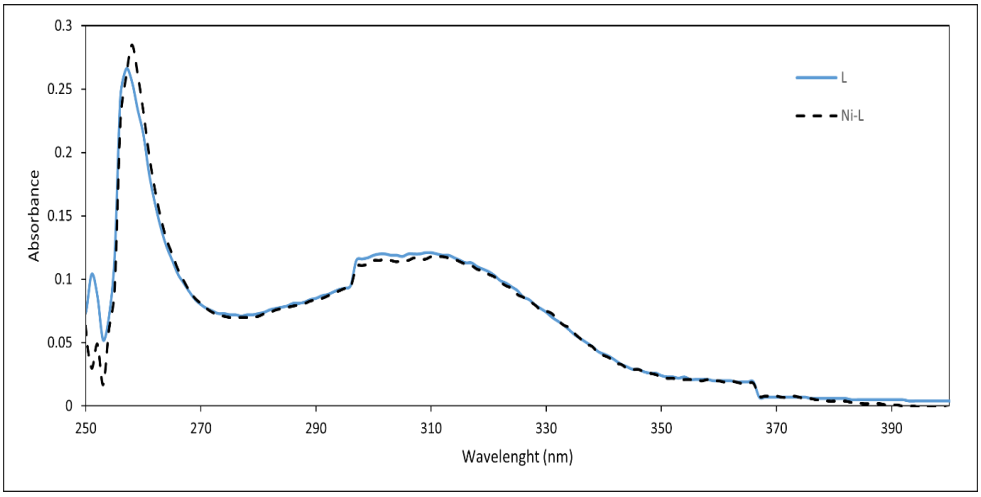

Figure 2. UV-Vis spectrum for ligand and complex

Preliminary complexation study

The preliminary complexation study using the titration method between ligand and nickel(II) was analysed via UV-Vis spectrum in the range of 270 nm to 300 nm. As seen in Figure 3, the absorption spectra of the ligand steadily increased as the mole fraction of Ni^{2+} ion increased. A graph of absorbance versus molar ratios of $[Ni^{2+}]/[L]$ was plotted. It showed that the stoichiometry was 1:1, consequently supporting the structure of the nickel complex [17].

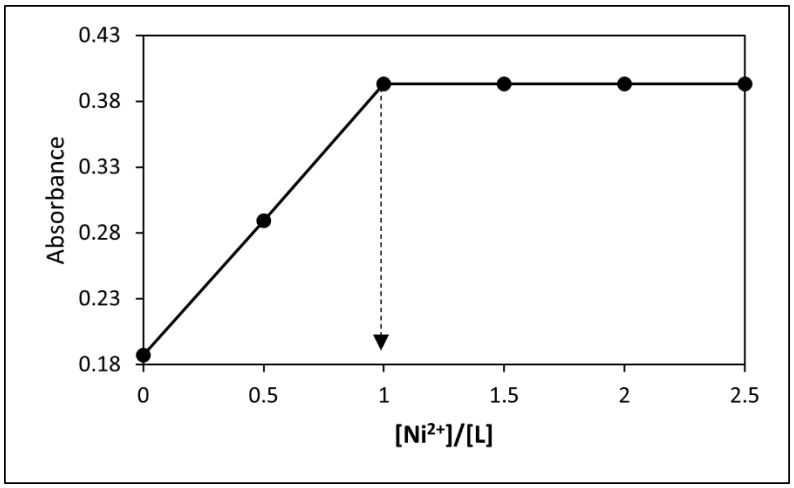

Figure 3. Graph plotted based on absorbance versus $[Ni^{2+}]/[L]$

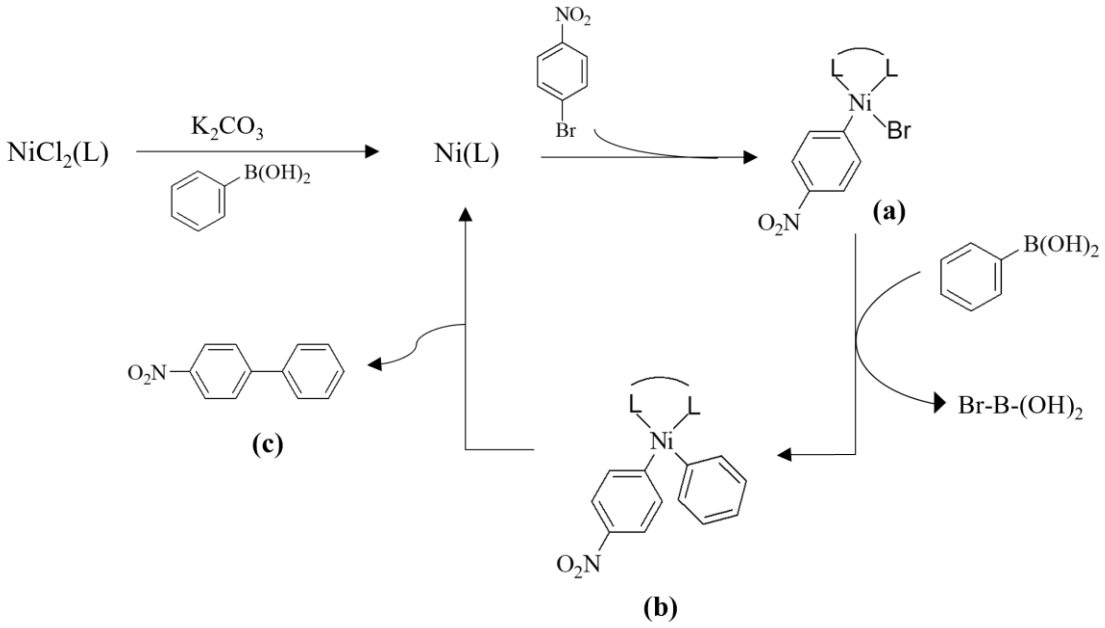
Catalytic testing

By using 0.5% mmol of catalyst loading, the catalytic activity of Ni-L complex was investigated in a reflux system with different aryl bromides, types of solvent, and bases within a 2 h reaction time. Catalytic performance was measured using data from GC-FID spectra. The conversion rate (%) and turnover number (TON) of arylbromides were computed by using equations 1 and 2 and presented in Table 5.

Table 5. The catalytic performance of Ni-L catalyst in Suzuki Reaction

Entry	R	Solvent	Base	Conversion Rate (%)	Turnover Number (TON)
1	NO_2	MeOH	K_2CO_3	81.86	163.72
2	OCH_3	MeOH	K_2CO_3	0	0
3	$COCH_3$	MeOH	K_2CO_3	69.86	139.72
4	H	MeOH	K_2CO_3	0	0
5	NO_2	MeOH	Na_2CO_3	29.76	59.52
6	NO_2	MeOH	NaOAc	41.7	83.40
7	NO_2	DMA	K_2CO_3	37.06	74.12



Reaction condition; Catalyst loading= 0.5 mmol%, Reaction time= 2h

In the presence of K_2CO_3 base, the complex catalytic performance of a Suzuki reaction was tested in the reaction of different types of arylbromide where R is –NO_2, -H, -OCH_3 and –$COCH_3$ (Entry 1-4) with phenylboronic acid. Based on the result in Table 5, the complex showed good catalytic activities in the reaction of 1-bromo-4-nitrobenzene (Entry 1), giving the highest conversion rate of 81.86%. The presence of NO_2 as a substituent aryl bromide caused resonance and inductive effects on electronic charge stabilisation. Meanwhile, arylbromide that contains electron donating group (EDG), such as –OCH_3, showed less reactive reaction (Entry 2). This finding is because slower rate of transmetallation occurs in EDG compared to electron-withdrawing groups (EWG) [16].

Considering the results obtained, 1-bromo-4-nitrobenzene showed relatively better catalytic activity than the other arylbromides. Therefore, 1-bromo-4-nitrobenzene was selected as the model for the study of different bases (Entries 1, 5 and 6). Three types of bases were selected, namely K_2CO_3, Na_2CO_3, and NaOAc. Meanwhile, the catalyst loading and reaction time remained constant. The reaction that used K_2CO_3 produced the highest conversion rate of 81.86% (Entry 1) as compared to other bases Na_2CO_3 and NaOAc, which showed only 29.76% (Entry 5) and 41.73% (Entry 6), respectively. K_2CO_3 is the strongest inorganic base and has a high capability of neutralising protons generated in the oxidative addition mechanism [7, 12]. On other hand, the lowest conversion rate was observed in Entry 5 by using Na_2CO_3 as a base. It has a slower rate of dissolution into a polar protic solvent that causes low yield [18].

The reaction was repeated in a different solvent, i.e., DMA (Entry 7). A similar reaction condition was used as the reaction conducted in Entry 1. The results of the catalytic reaction that used methanol as a solvent showed a higher conversion rate of 81.86% (Entry 1) compared to DMA, which only released 37.06% (Entry 7). This result concluded that the most suitable solvent for this reaction was methanol due to the solubility of starting material and K_2CO_3 in a protic solvent, which promoted rapid reaction and at the same time, pointed to hydrogen bonding as an important contribution to better coupling reactions [19].

A plausible reaction mechanism of the reaction between 1-bromo-4-nitrobenzene and phenylboronic acid is portrayed in Scheme 3. The reaction was started with the reduction of the catalyst, complex $NiCl_2$(L) to the catalytic active species Ni(L) with the presence of K_2CO_3 and phenylboronic acid, where L was the bidentate hydrazone ligand as shown in Scheme 1. The active species was Ni(0)-catalysed coupling reaction in three steps; (I) oxidative addition of 1-bromo-4-nitrobenzene to generate **(a)**, (II) transmetalation of phenylboronic acid in the formation of the complex **(b)**, and (III) reductive elimination of **(b)** to produce the product 1-nitro-4-phenylbenzene **(c)** and regeneration of active species [20].

Scheme 3. The proposed mechanism of the Suzuki reaction in the presence of a $NiCl_2(L)$ as a catalyst

Conclusion

This study successfully demonstrated the synthesis and characterisation of hydrazone ligand and nickel(II)-hydrazone complex. The synthesised nickel(II) complex can be used as a catalyst for the Suzuki reaction in MeOH as the solvent, K_2CO_3 as a base, and the reaction temperature of 65°C. The proposed complex exhibited the best catalytic performance with the highest conversion rate (%) and TON. The reaction was conducted in the presence of a small amount of catalyst loading (0.5 mmol%) at a 2h reaction time.

Abstract

A simple, portable, visible spectrophotometer was constructed and used for analytical measurements. The spectrophotometer was built using consumer electronics components such as an LED as the light source and a web camera as the detector. Using parameters including linearity, limit of detection, quantification, and precision to analyze the methyl red and dichromate standards, the analytical performance of the webcam spectrophotometer was evaluated. Results showed that, for methyl red, the webcam spectrophotometer gave a linearity range of 2–10 ppm with a limit of detection and limit of quantification of 0.69 and 2.11 ppm, respectively, and precision as a relative standard deviation of approximately 5%. The dichromate standard gave a linearity range of 0.7–1.5 ppm with a limit of detection and limit of quantification of 0.12 and 0.41 ppm, respectively, and precision as a relative standard deviation under 5%. These analytical performances are comparable but not better than those of the two commercial spectrophotometers used as comparators. The application of a webcam spectrophotometer to quantify the rhodamine B content in a traditional food sample, *pacar cina* jelly, also gave an equivalent analytical performance, and the rhodamine B analyte quantification capability was not significantly different from that of commercial spectrophotometers.

Spektrofotometer nampak dan mudah alih telah dibina dan digunakan untuk pengukuran analitik. Spektrofotometer dibina menggunakan komponen elektronik pengguna seperti LED sebagai sumber cahaya dan kamera web sebagai pengesan. Menggunakan parameter termasuk kelinearan, had pengesanan, kuantifikasi dan ketepatan untuk menganalisis piawaian metil merah dan dikromat, prestasi analisis spektrofotometer kamera web telah dinilai. Keputusan menunjukkan bahawa, untuk metil merah, spektrofotometer kamera web memberikan julat lineariti 2-10 ppm dengan had pengesanan dan had kuantifikasi masing-

masing 0.69 dan 2.11 ppm, dan ketepatan sebagai sisihan piawai relatif kira-kira 5%. Piawaian dikromat memberikan julat lineariti 0.7–1.5 ppm dengan had pengesanan dan had kuantifikasi masing-masing 0.12 dan 0.41 ppm, dan ketepatan sebagai sisihan piawai relatif di bawah 5%. Prestasi analisis ini adalah setanding tetapi tidak lebih baik daripada dua spektrofotometer komersial yang digunakan sebagai pembanding. Penggunaan spektrofotometer kamera web untuk mengukur kandungan rhodamine B dalam sampel makanan tradisional, jeli *pacar cina*, juga memberikan prestasi analisis yang setara, dan keupayaan pengkuantifikasian rhodamine B tidak jauh berbeza daripada spektrofotometer komersial.

Kata kunci: spektrofotometri nampak, spektrofotometer kamera web, prestasi analisis, analisis kuantitatif

Introduction

Spectrophotometry is a qualified technical analysis method that is commonly used to provide qualitative and quantitative solutions to problems in food, agriculture, pharmacy, biology, and clinical chemistry. Spectrophotometry techniques typically used in the food sector include fluorescence, Fourier transform infrared (FTIR) spectroscopy, near infrared (NIR) spectroscopy, and ultraviolet–visible (UV–Vis) spectrophotometry. Specifically, the UV–Vis spectroscopy has been used to analyze different food matrices (such as meat, milk, coffee, wine, vegetables, fruits, drinks, and olive oil) in relation to their composition, authenticity, adulteration, and quality [1].

Concerns about food quality and safety have grown in recent years among the public, apparently due to changes in eating habits, consumer behavior, development, and improvements in food supply chain industrialization. The high quality and safety requirements of food products require high standards for quality control and processing, which in turn require appropriate analytical tools to investigate the food [2]. In line with advances in consumer electronics technology, some studies have attempted to use smartphones as food diagnostic tools, such as for food allergen determination, functional food active compound detection, and foodborne pathogen identification [3]. Other studies have attempted to develop web camera-based spectrophotometers for detecting food oils or food colorings [4]. The idea behind developing this consumer electronics-based instrument is to make it available to a wide range of users, including the possibility of citizen-based food safety control [5].

Generally, a spectrophotometer may be assembled from several components, such as a light source from a white LED, a diffraction grating using a DVD, a detector from a CCD/CMOS webcam, and an image-based data acquisition/processing software or a direct spectrum recorder [6]. As a food diagnostic tool, a low-cost multifunctional webcam spectrophotometer was developed and applied to measure molecular absorption and fluorometry. The results of the determination of the same compound are comparable with other commercial spectrophotometers [7]. Moreover, a spectrophotometer constructed with LED components as the light source and a webcam as the detector was successfully built and was capable of providing a representative spectrum from various fruits such as apples, cherries, and pears [8].

This study attempted to build a portable absorption spectrophotometer that can be used to analyze food and other related materials using consumer electronic components. The reproducibility of performance from device to device can be a major challenge when using consumer electronics in portable systems [9]. Moreover, each portable spectrophotometer must provide results with verified precision and accuracy [10]. As an initial step towards developing a portable spectrophotometer-based food analysis system, this study, in addition to presenting the constructed portable spectrophotometer configuration, also shows a performance test of the spectrophotometer using organic and inorganic standard compounds. Furthermore, a performance comparison with commercial spectrophotometers is performed. In addition, a spectrophotometer for detecting hazardous materials contained in food was successfully developed.

Materials and Methods

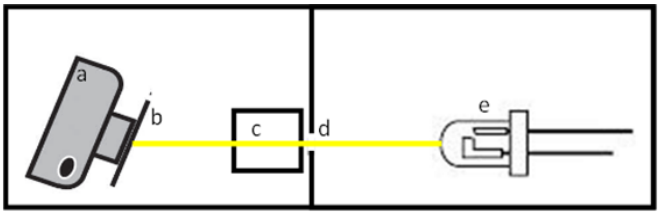
The main materials used in this research were purchased from Merck: methyl red, $K_2Cr_2O_7$, rhodamine B, ethanol (96%), 1,5-Diphenylcarbazide, and other reagents. A sample of *pacar cina* jelly was obtained from a local market in Bogor. The main component of the webcam

spectrophotometer is the web camera used as the detector, which is a Logitech HD c270. The commercial spectrophotometers used for comparison was the Spectronic 20D+ and Genesys 10UV (Thermo Fisher Scientific).

Webcam absorption spectroscopy development

The spectrophotometer was constructed based on the scheme shown in Figure 1(a). A white LED lamp (HPL Epistar) powered by a 9-volt battery was used as the light source. The optical layer of a DVD (GT-Pro) was used as the diffraction grating, and a webcam was used as the detector. Spectrum data acquisition was performed using Spectral Workbench, which was provided by Publiclab.org as a web instrument with a feature to capture the spectrum using a webcam and other features to visualize, manipulate, and store the spectrum from the web browser page [11]. Figure 1(b) shows the spectrophotometer built using all the components. The light source, cuvette holder, grating, and webcam were located in a black box. The grating is attached to the front of the webcam lens. The positions of the components, particularly the webcam and light source, were then determined experimentally. The webcam was placed opposite to the 45° incident light, and the distance was set to minimize the probability of saturation due to excessive light. In this spectrophotometer, the distance between the webcam used as a sensor and the light source was 25 cm (S1), and the distance between the webcam and slit was 7 cm. The slit width was set to 1 mm, and a 1 mL cuvette was placed directly behind the slit.

Calibration and mode of measurement of webcam spectrophotometer



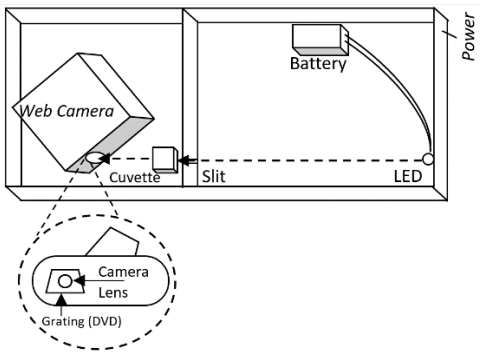
The spectrophotometer produces a sample spectrum with the aid of the tools from Spectral Workbench. Sample measurements began with a spectrophotometer connected to a computer using an I/O cable from the webcam. Using the profile that has been registered in the Spectral Workbench, the 'Capture Spectra' facility in the Spectral Workbench is used to recognize the webcam from the spectrophotometer and capture the spectra from the sample. The sample spectrum was calibrated using a CFL calibration spectrum to obtain a line spectrum with an intensity value at a certain wavelength. When the spectrophotometer was turned on (turning the white LED on), the light passed through the gap into the cuvette and towards the webcam. The grating attached in front of the webcam diffracts white light into the color components that the webcam captures, functioning as the sensor. The color spectrum of the diffraction pattern was visualized in real time on a Spectral Workbench (Figure 2). The Spectral Workbench simultaneously shows the transmission spectrum, with the y-axis representing the percentage of intensity (%I) and the x-axis representing the wavelength. To obtain the correct scale of the wavelength in the spectrum, calibration was first performed using a CFL lamp as the light source. A CFL lamp produces a well-known spectrum characterized by sharp and identifiable peaks. The Spectral Workbench performed the calibration process by adjusting the scale of the wavelength on the spectrum based on the peaks of the specified CFL emission, that is, at 436 and 546 nm.

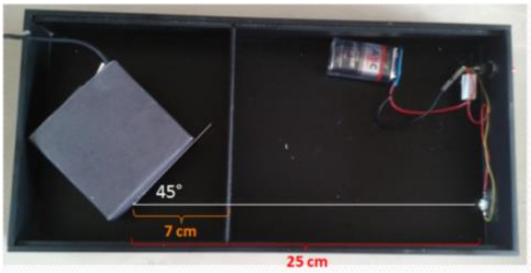
The Spectral Workbench acquired the spectrum of the sample by transforming the color spectrum image into data. The resulting data can be exported in xls format by tabulating the wavelength and approximating the light intensity as the average values of RGB divided by 257 (interpretation of the Spectral Workbench algorithm to a single 8-bit byte pixel) (I') (S2 and S3). A percentage of approximate intensity on the y-axis of the transmission spectrum was calculated using Eq. (1):

$$\%\mathrm{I}' = \frac{\mathrm{I}'}{257} \times 100\% \,. \quad (1)$$

The webcam spectrophotometer was constructed as a single-beam spectrophotometer. To obtain the absorbance (A) of the sample, the approximate intensities of a blank and sample or standard were compared using Eq. (2):

$$\mathrm{A} = log \frac{\%I'_{blank}}{\%I'_{standard}} \,. \quad (2)$$





a: web camera

b: DVD grating

c: cuvette

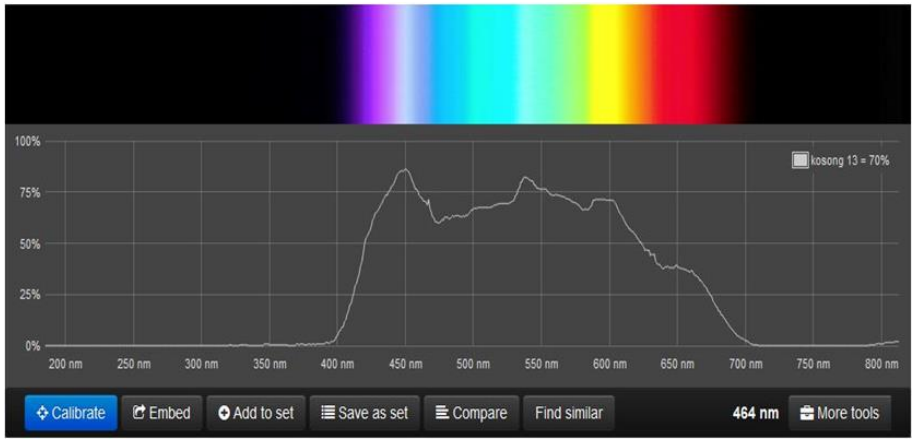

Figure 2. Example of a color spectrum and a spectrum with calibrated scale of wavelength from the webcam-based spectrophotometer

Webcam spectrophotometer performance and performance comparison with commercial spectrophotometers

The analytical performance of the webcam spectrophotometer was evaluated by determining the linearity, limit of detection, limit of quantification, and precision of methyl red and dichromate standard concentrations. The measurement results of the webcam spectrophotometer were then compared with those of the commercial spectrophotometers, Spectronic 20D+ and

Genesys 10UV (Thermo Fisher).

Linearity test

This test was performed by preparing calibration curves for five concentrations of methyl red and dichromate standard solutions. Ten milligrams of methyl red were dissolved in ethanol in a 100-mL volumetric flask. This standard solution was then diluted to yield a series of methyl red standard solutions with concentrations of 2, 4, 6, 8, and 10 ppm in a 25-mL volumetric flask. The concentrations of the methyl red standard solutions were measured directly using a spectrophotometer. Dichromate solutions were prepared using the $K_2Cr_2O_7$ standard at five different concentrations of 0.7, 0.9, 1.1, 1.3, and 1.5 ppm. The dichromate standards were measured after the first reaction with diphenylcarbazide (DPC). Each of the dichromate standard solutions (10 mL) was added to a reaction tube, followed by the addition of 0.4 mL of 0.25% DPC. After shaking the solution, 1 mL of a phosphoric acid-water mixture (1:1) was added. The solution obtained was shaken again, allowed to sit for 15 min, and finally measured with a spectrophotometer. Absorbance was measured in six replicates. Calibration curves were constructed by connecting the concentration (x-axis) and absorbance (y-axis). Linearity can be deduced from the correlation coefficient (r).

Limit of detection (LoD) and limit of quantification (LoQ)

The LoD and LoQ of the webcam spectrophotometer were determined by measuring the blank absorbance in ten replicates, and the standard deviation of the blank absorbance was calculated. The LoD and LoQ values were calculated using Eq. (3):

$$LOD = \frac{3.3 \times SD}{S}, \quad LOQ = \frac{10 \times SD}{S} \qquad (3)$$

where SD is the standard deviation of the blank absorbance, and S is the sensitivity (slope) of the calibration curve.

Precision

Precision was assessed using the relative standard deviation (RSD) of seven standard solutions with the same concentration. Methyl red was used at a concentration of 5 ppm, and dichromate was used at a concentration of 1 ppm.

Analysis of Rhodamine B in traditional food pacar cina jelly

To demonstrate the application of the spectrophotometer in sample analysis, a webcam spectrophotometer was used to determine the level of Rhodamine B in the traditional food, *pacar cina* Jelly. The results were compared to those obtained using commercial spectrophotometers. A 5 g sample of *pacar cina* jelly sample was weighed and immersed in 2% ammonia in 70% ethanol for 24 h to dissolve all the dyes. The colored solution was filtered, evaporated, and concentrated on a hot plate at 65 °C for 4 h. The concentrated solution was added to 30 mL of an aqueous solution and stirred to homogeneity. After adding the homogenous solution to a separatory funnel, 6 mL of 10% NaOH was added and shaken, followed by 30 mL of diethyl ether, which was shaken again until two layers were formed. The water layer was discarded, and the ether layer was washed with 5 mL of 5% NaOH and shaken. The ether layer was extracted three times with 10 mL of 0.1 N HCl. The HCl extracts were then collected in a 50-mL volumetric flask and diluted with 10 mL of 0.1 N HCl to the mark. The samples were then ready for measurement. The concentration of rhodamine B was measured by using a calibration curve of rhodamine B at concentration series of 1, 2, 3, 4, and 5 ppm and 0.1 mL HCl as the blank.

Results and Discussion

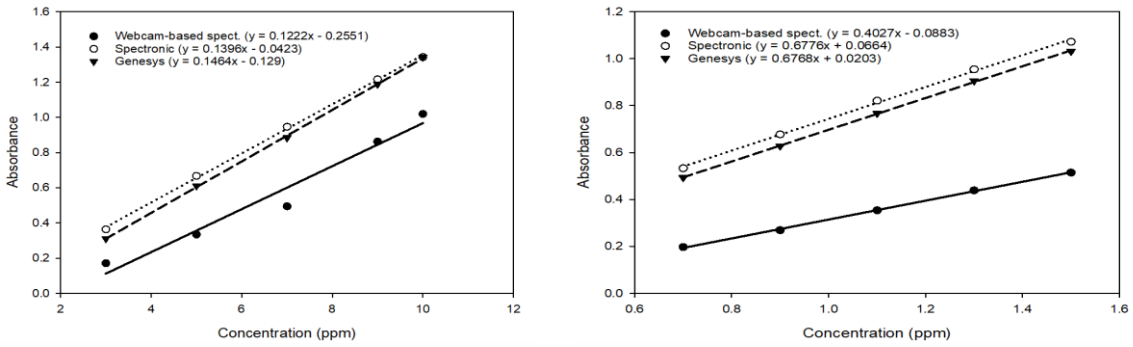
The analytical performance of the webcam spectrophotometer was evaluated based on the linearity, limit of detection, quantification, and precision of methyl red and dichromate standard concentrations. All measurements were performed at wavelengths of 495 and 543 nm, which are the maximum wavelengths for methyl red and dichromate, respectively. Tables 1 and 2 show the analytical performance compared with that of Spectronic 20D+ and Genesys 10UV.

Table 1. Analytical performance of spectrophotometers in determining methyl red standard concentration

Parameter	Spect. Webcam	Spectronic 20D+	Genesys10UV
Linearity(R^2)	0.9638	0.9991	0.9996
LoD (ppm)	0.7	0.1	0.1
LoQ (ppm)	2.1	0.3	0.2
Precision (%RSD)	5.2	1.6	1.7

Table 2. Analytical performance of spectrophotometers in determining dichromate standard concentration

Parameter	Spect. Webcam	Spectronic 20D+	Genesys10UV
Linearity (R^2)	0.9991	0.9983	0.9998
LoD (ppm)	0.1	$2x10^{-3}$	$4x10^{-3}$
LoQ (ppm)	0.4	$8x10^{-3}$	$1x10^{-2}$
Precision (%RSD)	2.6	0.6	0.3



Generally, webcam spectrophotometers have not outperformed commercial spectrophotometers in terms of analytical performance. For the two standards used, the LoD, LoQ, and %RSD values of the webcam spectrophotometer were higher than those of the commercial spectrophotometers. In this study, the LoD and LoQ were calculated according to IUPAC definitions. Considering that the spectrophotometric method is used to measure standards using a simple matrix, the assumption of using blanks to determine LoD and LoQ can be fulfilled [12]. However, the linearities of commercial spectrophotometers were better than those of webcam spectrophotometers.

As shown in Figure 3, when compared to commercial instruments, the use of consumer electronics components (e.g., LED as the light source) as components of the webcam spectrophotometer results in a lower absorbance signal and a webcam as the detector results in lower calibration sensitivity. The webcam system for the detector typically undergoes signal deviation owing to the default image processing system and therefore offers limited quantitative data acquisition capability [13].

A similar phenomenon related to this analytical performance was found in another study by Danchana et al. [14], who developed a webcam-based molecular absorption spectrophotometer to measure iron levels, and in a study by Kotchabhakdi and Grudpan [15], who developed a digital camera-based atomic absorption spectrophotometer to measure metal elements in various types of food, water, and fertilizer samples. Nevertheless, the performance of this spectrophotometer was still reasonable and within the acceptable limit, as seen by the precision value that gave a lower %RSD than 2/3x CV Horwitz [16].

In this study, a webcam spectrophotometer was used to quantify the rhodamine B content in the traditional food *pacar cina* jelly. Rhodamine B is an organic chloride salt commonly used as a dye in plastics, textiles, and printing products. Rhodamine B was once used as a food additive, but its use in food is now prohibited [17]. However, some studies have found that Rhodamine B is still used illegally as a food additive, which could be harmful to consumer health [18].

Rhodamine B quantification by spectrophotometry began with a multi-stage extraction. Five samples of *pacar cina* jelly were purchased from local markets in Bogor. The samples were macerated and partitioned with various solvents to obtain rhodamine B in an HCl solution. The absorbance of the extracts was measured using a webcam spectrophotometer and subsequently compared with that of standard solutions to determine the level of rhodamine B. Measurements were performed using commercial spectrophotometers (Spectronic 20D + and Genesys 10UV). Table 3 shows the results of the rhodamine B content using the three types of spectrophotometers in conjunction with the statistical parameters of the method.

(a) (b)

Figure 3. Calibration curve for methyl red (a) and dichromate (b) standards

The webcam spectrophotometer used to quantify rhodamine B demonstrated the same pattern of analytical performance as the methyl red and dichromate determinations when compared with the two commercial spectrophotometers. The webcam spectrophotometer gave the largest relative standard deviation value compared to the two other spectrophotometers, but still maintained the precision within the acceptable limit of %RSD, which was lower than 2/3x CV Horwitz. The %CV Horwitz = $2^{1-0,5 \log C}$ acceptance limit can also be used as a starting point when the repeatability limits have not been determined through the control chart. Regarding the rhodamine B content in the samples, the three instruments yielded values that were not significantly different. Food producers used rhodamine B at a sufficiently high level, almost three times the 7.06 µg/g found in cassava chips [19]. The low F-value indicates that the model does not substantially differ in the mean of rhodamine B obtained from the three spectrophotometric methods.

Table 3. Rhodamine B content in samples and statistical parameters of method

Parameter	Spect. Webcam	Spectronic 20D+	Genesys10UV
[Rhodamin B] ($\bar{x} \pm sd$ µg/g)	21.65 ± 0.63	21.46 ± 0.34	21.83 ± 0.13
RSD (%)	2.91	1.56	0.61
2/3 CVHorwitz	6.7146	6.7236	6.7063

Note: ANOVA showed no significant difference (average of the three analyses).
($F_{calculation} = 0.9792 < F_{table}$, 0.05;2,12 = 3.8852, p = 0.4036)

Conclusion

A spectrophotometer model ("Webcam Spectrophotometer") has successfully been built utilizing consumer electronics components such as a LED as the light source and a webcam as the detector. The analytical performance was evaluated to determine the methyl red and dichromate standard solution concentrations, and the performance was compared with that of two commercial spectrophotometers. The analytical performance parameters of the webcam spectrophotometer (linearity, detection limit, quantification limit, and precision) were all within acceptable values of performance parameters and were comparable to those of commercial spectrophotometers. Further application of the spectrophotometer model to quantify the rhodamine B content in food samples demonstrated equivalent analytical performance with no significantly different analyte quantification capability compared to the other two commercial spectrophotometers. Based on the above, webcam spectrophotometers can potentially be used as an alternative instrument for food, related food materials, and product quality control.

Abstract

The modern composites industry heavily relies on carbon fibre as a raw material due to its high tensile strength, fatigue resistance, and temperature resistance. Thus, researchers are investigating the use of lignin extracted from biomass as a precursor for carbon fibre to reduce costs and environmental impact. Oil palm biomass is classified as a lignocellulosic compound due to its high cellulose, hemicellulose, and lignin content. Since lignin has a complex structure with numerous linkages between its monomeric components, it can be complicated to isolate it from lignocellulosic components. Deep eutectic solvents (DESs) are a promising new class of environmentally friendly solvents owing to their low toxicity, low production cost, and high biodegradability. Lignin valorisation has received much attention due to immense ability of DES to dissolve and extract lignin without condensation. This review aimed to provide a comprehensive and comparative analysis of the physicochemical and thermal properties of DES for utilisation in lignin extraction from biomass, with a focus on its potential as a precursor for carbon fibre.

Keywords: deep eutectic solvent, carbon fibre, lignin, precursor, oil palm biomass

Abstrak

Industri komposit moden sangat bergantung pada gentian karbon sebagai bahan mentah kerana kekuatan tegangan yang tinggi, rintangan kelesuan dan rintangan suhu. Oleh itu, penyelidik sedang mengkaji penggunaan lignin daripada biojisim sebagai prekursor yang lebih mesra alam dan kos efektif untuk gentian karbon. Biojisim kelapa sawit dikategorikan sebagai lignoselulosa, kerana kandungan selulosa, hemiselulosa dan lignin yang tinggi. Walau bagaimanapun, mengasingkan lignin daripada lignoselulosa memberikan cabaran kerana strukturnya yang rumit dan mempunyai pelbagai sambungan antara komponen monomeriknya. Pelarut Eutektik Dalam (DES) ialah generasi baharu pelarut hijau yang mudah disediakan, tinggi biodegrabiliti, kos pembuatan yang rendah dan ketoksikan yang rendah. Keupayaan DES yang luar biasa untuk melarutkan dan mengekstrak lignin tanpa pemeluwapan telah mencetuskan minat yang ketara dalam valorisasi lignin. Kajian ini bertujuan untuk menganalisis secara sistematik dan perbandingan sifat fizikokimia dan terma DES untuk pengekstrakan lignin daripada biojisim, dengan

penekanan khusus pada penggunaannya sebagai prekursor untuk gentian karbon.

Kata kunci: pelarut eutektik dalam, gentian karbon, lignin, prekursor, biojisim kelapa sawit

Introduction

Advanced materials interest industrial strategists, economists, and policymakers due to their far-reaching potential and impact across various industries. Carbon fibre has a high strength-to-weight ratio and is lightweight, making it a desirable component in various high-tech and extensive applications. Bengtsson et al. [1] reported that a substantial amount (>96%) of carbon fibre is manufactured from the fossil-based polymer polyacrylonitrile (PAN), with the remainder coming from petroleum, coal-tar pitch, and rayon. The need for lightweight composites has led to the increasing popularity of carbon fibres. Hence, developing a more sustainable and cost-effective alternatives is necessary due to their high manufacturing costs and reliance on fossil-based resources.

Owing to its abundance and carbon neutrality, lignocellulosic biomass has the potential to replace fossil fuels as renewable feedstock. Lignin is a naturally occurring renewable raw material with exceptional chemical and physical properties. It is cheap and has the potential to replace feedstocks that are based on fossil fuels. Lignin extracted from palm oil biomass can be processed in several ways to yield various value-added carbon products [2]. However, physical and chemical heterogeneities of lignin render it a poor feedstock.

The hot and humid climate of Malaysia makes it ideal for growing oil palms, one of its most important crops. The palm oil milling industry produces millions of metric tonnes of waste annually. Oil palm fronds, mesocarp fibres, palm kernel shells, empty fruit bunches, and oil palm trunks are all renewable resources that make the palm oil industry a significant biomass producer [3]. Oil palm biomass is produced during milling, burned for energy recovery, or left to biodegrade in the plantation. Inefficient management practices exacerbate the production of harmful greenhouse gases. Oil palm biomass, with its high lignin content, may be able to replace PAN and pitch as carbon fibre precursors.

The environmental benefits of DESs as ‘green solvents’ have garnered widespread interest. DESs are compounds that contain at least one hydrogen bond donor (HBD) and one hydrogen bond acceptor (HBA) and form a transparent liquid eutectic mixture at temperatures ranging from 60°C to 80°C [4]. The hydrogen-bonding network formed between the components and the associated charge delocalisation causes the melting point of DES to be much lower than the melting points of the individual components [5]. Due to their low toxicity, high biodegradability, low production cost, and broad applicability, DESs have been used in various processes, such as metal extraction, bio-catalysis, CO_2 capture, and biodiesel synthesis [6].

As shown in Figure 1, several studies suggested that DESs may dissolve lignin from woody plants by disrupting the β-O-4 linkages between lignin and carbohydrates. Type III DES, which are commonly synthesised by reacting quaternary ammonium or phosphonium salts as HBAs with acids, alcohols, amines, or carbohydrates as HBDs, are the most explored for biomass treatment due to their cheap cost, non-reactivity with water, and biodegradability. However, their effectiveness depends on the specific DESs used and molar ratios. Due to their impact on biomass processing, especially the modes of action on cellulose, hemicellulose, and lignin, a complete understanding of the properties of DESs is crucial. Furthermore, lignin extracted with DES as a carbon fibre precursor has not been studied, and there have been no findings regarding its fundamental properties.

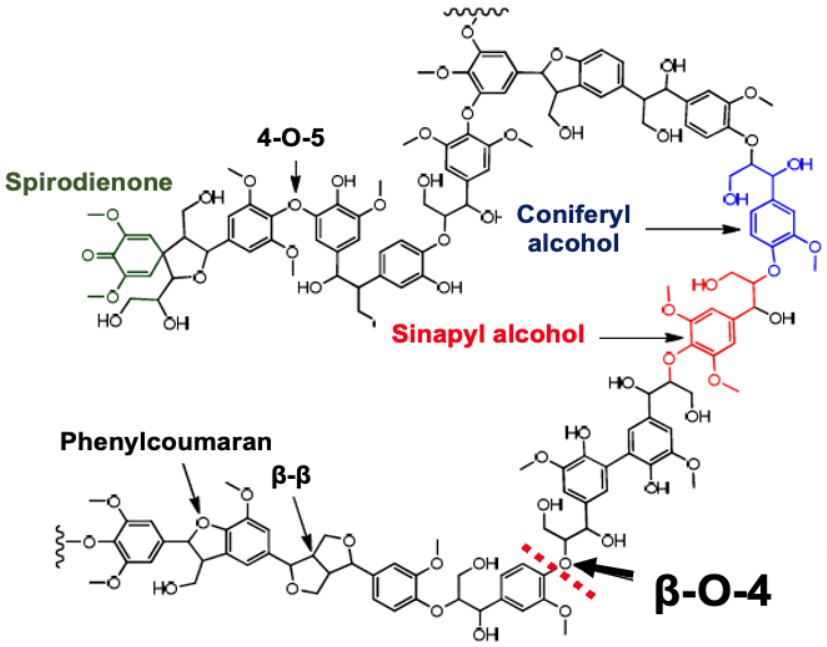

Figure 1. Selective cleavage of β-O-4 in lignin by DES

Deep eutectic solvents and its properties

DESs are eutectic mixtures of solid compounds that melt at lower temperatures than their components [7]. The hydrogen-bonding network between the components and the resulting charge delocalisation lowers the melting point. Abbott et al. [7], who discovered the dissolving power of DES mixtures, documented the first report on DESs. Understanding the HBA and HBD properties based on the functional group and mixing them in the precise molar ratios enables the synthesis of DESs to be accomplished quickly and efficiently. Finally, they have low toxicity and production costs when designed properly, particularly when produced from renewable sources.

DESs are solvents similar to ionic liquids (ILs), which are made up of a cation and an anion. ILs are widely used as solvents, although their hazardous effects on the environment and human health are well known [8]. In contrast to ILs, DES synthesis is a straightforward mixing procedure that can be scaled up to produce environmentally friendly and effective alternative solvents. Ca+X-zY is a common formula for DES, whereby Ca+ is the principal cation (typically ammonium, phosphonium, or sulfonium), and X- is a Lewis base (typically a halide anion). Figure 2 shows the interaction between the X- and z molecules of Y, where Y can be a Lewis acid or a Brønsted acid [9].

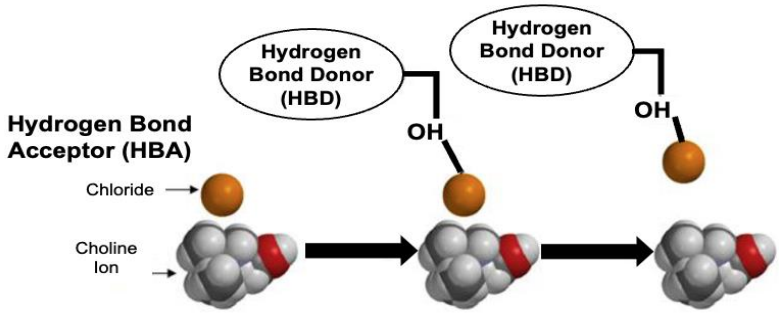

Figure 2. HBA and HBD components of DES

Table 1 shows the four distinct categories of DESs based on the chemicals used to produce them. The high melting temperatures of non-hydrated metal halides restrict the use of Type I DESs in biomass processing. On the other hand, Type II DESs are a much more cost-effective option for industrial processes because hydrated metal halides are cheaper. It is possible to tailor the physical properties of Type II DES to meet the needs of various applications by varying the HBD [8]. Type III DESs. On the other hand, Type III DESs are the most studied and investigated due to their low cost, non-reactivity with water, and biodegradability. Finally, Type IV DESs combine inorganic transition metals with urea to create eutectic mixtures, although metal salts do not typically ionise in non-aqueous media.

Table 1. Classification of DESs [8]

Type	Component	General Formula	Example
I	Metal salt organic salt	$Ca^+ X^-$ zMClx; M = Zn, Sn, Fe, Al, Ga. In	$ZnCl_2$ + ChCl
II	Metal salt hydrate + organic salt	$Ca^+ X^-$ zMClx.yH_2O; M = Cr, Co, Cu, Ni, Fe	$CoCl_2.6H_2O$ + ChCl
III	HBD + organic salt	$Ca^+ X^-$ zRZ; Z = $CONH_2$, COOH, OH	Urea + ChCl
IV	Zinc/aluminium chloride + HBD	MClx + RZ = $MCl_{x-1}{}^+$. RZ+ $MCl^-{}_{x+1}$; M = Al, Zn & Z = $CONH_2$, OH	$ZnCl_2$ + ChCl

DESs are typically formed by reacting quaternary ammonium or phosphonium salts with HBD, such as acids, alcohols, amines, or carbohydrates [10]. Quaternary ammonium salts such as choline chloride (ChCl) are common HBAs, and metal salts, urea, carboxylic acids, and polyols are examples of HBDs, as shown in Figure 3 [11]. Selecting the most appropriate HBA and HBD with the right molar ratio allows for developing DESs tailored for specific applications. For example, Francisco et al. [10] observed that lactic acid:betaine (2:1) resulted a clear liquid of DES while lactic acid:histidine (2:1) showed no evidence of melting. This demonstrates that the specific molar ratio is dependent on the type of HBA and HBD combination.

Farooq et al. [12] reported that modifying the degree of basicity of hydrogen bonds in DESs can increase their efficacy. Based on their findings, the use of acidic carboxylic acids as HBDs with higher HBD:HBA molar ratios is proposed for high extraction efficiency with biomass [12]. Although a high extraction yield is desired, the fundamental properties of the extracted compounds may vary depending on the nature of the raw materials, particularly lignocellulosic compounds, which include various constituents. Information on the physiochemical and thermal properties of DES is required owing to the growing interest in this compound. The freezing point and decomposition temperature of DESs and physicochemical properties (viscosity, density, refractive index, and pH) vary with HBA and HBD combinations and molar ratios. The review on the physicochemical and thermal properties of DES is important because these properties are related to a potential lignin valorisation pathway, particularly as a carbon fibre precursor.

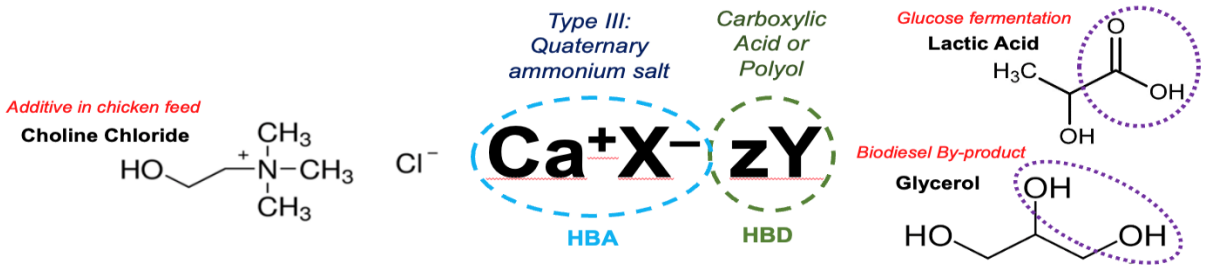

Figure 3. HBAs of quaternary ammonium salts (ChCl) and HBDs of carboxylic acids (lactic acid) and polyols (glycerol)

Viscosity

The viscosity of a fluid indicates the extent to which it resists its movement. The higher viscosity of DESs as compared to organic solvents makes handling, stirring, and filtration more challenging. The type of HBD, molar ratio, and temperature play a role in the viscosity of binary eutectic mixtures owing to hydrogen-bonding, Van der Waals, and electrostatic interactions [13]. Yusof et al. [14] reported that an increased number of hydroxyl groups produced higher viscosity due to the increased adhesive force between molecules provided by the increased number of hydrogen bonds. For example, citric acid, which has three carboxyl groups, forms stronger hydrogen bonds with ChCl owing to its larger molecular size. Therefore, the molecules in the ChCl:citric acid system are less mobile than those in the ChCl:malic acid system. Meanwhile, the hydrogen bond interaction between ChCl and lactic acid is weaker owing to its smaller molecular size [15].

Due to the sparse network between the different groups in DES, decreasing the salt molar ratio can decrease viscosity [16]. For instance, as the molar ratio of ChCl increased, the viscosity of ChCl:glycerol decreased, most likely due to the dissolution of intermolecular hydrogen bonds, resulting in molecular disruption [17]. Therefore, the frictional forces were diminished, and the molecular motion became less restricted. On the other hand, the viscosity of the DES increased as the molar ratio of HBD increased. For example, increasing the molar ratio of HBD causes the viscosity of ChCl:fructose to increase from 28.31 cP to 72.42 cP. This may be due to the increased hydrogen bond strength between the chloride ion and hydrogen atom due to the higher fructose concentration [15]. In addition, the viscosity significantly varies with temperature. Increasing the temperature caused the viscosity of the DES to decrease. Shear impact and thermal expansion can weaken the internal structure of DESs, leading to low viscosity [18]. Francisco et al. [19] stated that higher temperatures could increase the kinetic energy and reduce viscosity by weakening the attractive forces between molecules.

Density

The density influences the diffusion rate of the solvent and its ability to mix with other liquids. Density can be affected by various factors such as temperature, pressure, intermolecular interactions, and molecular weight. The density differences could be attributed to the different arrangements or packing of DES molecules [13]. Designing a DES without establishing a correlation between HBD and density is impossible. The density of DES is affected by the number of hydrogen bonds present in the solution [14, 20].

Fuad et al. [15] reported that DESs containing high-molecular-weight compounds have a greater density in the eutectic mixture than DES containing low-molecular-weight compounds. Since lactic acid had a relatively low-molecular-weight (90.08 g/mol), the ChCl:lactic acid mixture had a low-density of 1134 kg/m^3. On the other hand, ChCl:maltose density is 1431 kg/m^3 high molecular weight (342.3 g/mol) of maltose [15]. The density of a DES is also affected by the organic salt-to-HBD molar ratio. For instance, increasing the molar ratio of ChCl:glycerol from 1:1 to 1:4 resulted in an increase in density from 1160 kg/m^3 to 1210 kg/m^3

[21]. As the salt concentration relative to the HBD increased, the liquid became more structured, and the free volume decreased. When the free volume decreases, the molecular mobility decreases and the viscosity gradually increases [19].

Yadav and Pandey [22] stated that the DES density can be altered by the presence of water, making it less dense. For example, the density decreased from 1219.4 kg/m^3 to 1111.3 kg/m^3 when 50 vol% of water was added to the DES solution [23]. In addition, increasing the temperature reduced the DES density. Shahbaz et al. [24] reported that the rapid motion of DES particles increases the number of voids within the molecule as the temperature increases, making the DES less dense.

pH

The pH of a solution can affects chemical reactions in several ways, making it a crucial physical property. The applications of DESs in catalysis, biological activities, and metal treatment depend on the pH. Donor and acceptor acidity and basicity are responsible for the pH of DESs [25]. Hydrogen bonding and other molecular interactions between these ions and other species in the solvent affect the pH. For example, the ChCl:glycerol solution has a higher pH than the ChCl:malic acid solution (4.9 vs 2.4) [25]. This study demonstrated that DES acidity increased when acidic compounds were added to HBD.

Hayyan et al. [26] investigated numerous molar ratios of ChCl and fructose-based DES. They found that when the HBD content was reduced, the pH decreased as well. In addition, the pH value declined with increasing temperatures. For instance, at a molar ratio of 1:1, the pH of ChCl:fructose declined from 6.1 to 4.4 as the temperature increased from 25°C to 85°C [26]. Hypothetically, the slightly acidic pH of the DES aids lignin extraction. Although the acidity of the DES is important, it is not the most crucial factor for isolating lignin from lignocellulosic biomass. However, the extraction of lignin can be affected by factors such as the swelling of the material, the amount of carbohydrates bound to lignin, and the proportion of syringyl to guaiacyl units in the lignin structure [27].

Refractive index

The refractive index is important for understanding molecular interactions and free volumes, which heavily depend on the optical properties of the medium [28]. Salmaliyan et al. [29] found a positive correlation between the refractive index and density. Therefore, a DES with a higher refractive index is typically denser. Changes in the molar ratio, temperature, and chemical structure affect the refractive index of the DES. Chen et al. [30] observed that the refractive index of ChCl:lactic acid was 1.4590 at a molar ratio of 1:2 but declined to 1.4399 at a molar ratio of 1:4. Hence, it can be concluded that the higher the lactic acid concentration, the lower the refractive index of the DESs. A reduced concentration reduces the number of light-striking molecules, resulting in a lower refractive index ([31].

In contrast, DESs have a refractive index that decreases with temperature. For example, the refractive index of ChCl:ethylene glycol decreased from 1.468 to 1.4610 when the temperature increased from 298.15 K to 328.15 K [30]. At higher temperatures, the refractive index of the DES was reduced due to changes in its physical properties and the motion of its molecules [30]. In addition, the density and refractive indices of ChCl:ethylene glycol and ChCl:glycerol, as well as their aqueous mixes, were investigated at standard atmospheric pressure and temperatures between 298.15 K and 333.30 K [32]. A linear decrease in the density and refractive index with increasing temperature and an increase with increasing DES molar ratios were observed for pure and aqueous solutions. Furthermore, at constant molar ratios, DES with glycerol had a higher refractive index than DES with ethylene glycol.

Freezing temperature

Freezing temperature is also an important factor when assessing the liquidability of DES. All of the reported DESs have freezing points below 150°C, which are lower than their individual freezing points [13]. Donors such as carboxylic acids and sugar-derived polyols lower the freezing point of acceptor salts. The strength of hydrogen bonds is also affected by the composition of the salt owing to the charged shield [13]. In addition, the strength of the intermolecular interactions in the structure significantly affects the freezing point [33].

The freezing point of the DES mixture is typically lower than that of the individual HBAs and HBDs formed. For example, Abbott et al. [7] hypothesised that a ChCl:urea mixture with a molar ratio of 1:2 would have a freezing point of 12°C, which is lower than those of ChCl (303°C) and urea (133°C). DESs with freezing points lower than 50°C are preferable as solvents or liquids in various applications owing to their wide liquid range. Freezing point depression is proportional to the HBA and HBD interaction strength, which depends on their structures and molar ratios. Smith et al. [8] postulated that charge delocalisation due to hydrogen-bonding between the HBD and halide ion is responsible for the sharp decrease in the freezing point of DESs. Moreover, the freezing point of DES is affected by entropy change during liquid formation and the internal energy of DES molecules. Glycerol is one of the few HBDs that can yield a liquid DES at room temperature when combined with ChCl. This is possible due to the low eutectic melting point of −40°C at molar ratios of 1:2–1:4. Carboxylic acids, including levulinic acid, malonic acid, and phenylpropionic acid, have been shown to form liquid DES at room temperature [13].

For ChCl-based DES, the choice of the HBDs is decisive in producing a eutectic combination with a low melting temperature. Polyols such as glycerol or ethylene glycol HBD typically have lower freezing temperatures and may remain liquid below room temperature. This indicates that ChCl-based DESs using polyols as HBDs are viable alternatives to conventional solvents [34]. Qin et al. [35] suggested that the freezing points of DES are significantly affected by the molar ratio of HBA to HBD and that HBD compounds determine the lowest freezing point. It is theorised that freezing point depression is proportional to the molecular weight of the organic acids, with a larger effect for those with lower molecular weights.

Decomposition temperature

The decomposition temperature is the temperature range wherein the DESs are stable in the liquid phase. It is affected by various variables, including temperature, pressure, molar ratio, and heating rate. In addition, the constituent proportions and molar ratios influence DES stability and thermal behaviour [36]. However, analysis of thermal stability is relatively scarce. The robust hydrogen-bond networks of DESs may contribute to their thermal degradation characteristics. Hydrogen bonds hinder molecular escape, complicating DES decomposition. The maximum degradation temperature increased because the DESs required more energy to break bonds. Since the hydrogen bond interactions weaken with increasing temperature, DES separates into HBDs and HBAs. HBDs with lower thermal stability and boiling points then volatilise/decompose first, whereas HBAs volatilise/decompose at higher temperatures [37].

Florindo et al. [38] evaluated the decomposition temperature of various DESs. The decomposition temperature of DES was measured between 126.85°C and 226.85°C. The highest temperature at which ChCl:glutaric acid decomposed was 239.05°C, while the lowest was 124.68°C for ChCl:malic acid. In addition, Chemat et al. [39] found that the decomposition temperature of ChCl:urea+L-arginine increased from 215.38°C to 230.07°C as the molar ratio of L-arginine increased. A higher decomposition temperature resulted in a greater thermal stability. The Intermolecular interactions and coordination nature of the ions in the mixture may account for the enhanced thermal stability of ChCl:urea+L-arginine [39].

Delgado-Mellado et al. [40] found that ChCl:glycerol eutectic mixtures were stable due to the increased thermal stability of glycerol. These findings indicated that the thermal decomposition of ChCl and the vaporisation of glycerol simultaneously occurred in ChCl:glycerol, resulting in a single mass loss step due to the decomposition temperature of ChCl (250°C), which was close to the glycerol boiling point (290°C) [40]. Therefore, the higher decomposition temperature of DES may be attributed to the high thermal stability of glycerol, which ensures that the eutectic mixture never solidifies. As a result, HBD with low volatility and high thermal stability should be used to produce DES with high stability.

Lignin extraction from biomass by using DESs

Several obstacles must be overcome to extract lignin from biomass successfully. Pure lignin is difficult to

extract from lignocellulosic biomass due to the highly linked structures of lignin and carbohydrates [41]. The condensation and oxidation of lignin also occur during isolation, thereby increasing the complexity of the process. In biomass, lignin and carbohydrate compounds form lignin-carbohydrate complexes (LCCs) with strong bonding strengths, which may affect their extraction [42]. There are eight types of lignin-carbohydrate bonds: benzyl ether, benzyl ester, glycosidic or phenyl glycosidic, hemiacetal or acetal linkages, and ferulate or diferulate esters. Tarasov et al. [43] found that LCCs facilitate bond cleavage and increase the accessibility of enzymes to biomass.

A thorough understanding of the LCC structure may help devise the best methods for breaking bonds to separate lignocelluloses efficiently and selectively. In recent years, there has been a surge in research and development of greener solvents for lignin isolation. DES can dissolve lignin from woody plants by rupturing lignin-carbohydrate bonds, thus liberating lignocellulose components [44]. The combination of HBA and HBD facilitates the breakdown of the ether bond between the phenyl propane units, resulting in low-molecular-weight lignin [45]. Evidence suggested that DES can improve the efficiency of biomass enzymatic saccharification despite its low polysaccharide solubility [46]. The rate of lignin extraction is affected by the structure of lignocellulosic biomass, which varies between species. The high solubility of lignin in DESs makes it an ideal solvent for isolating lignin from biomass. Therefore, the use of DESs to extract lignin holds great promise. Achieving biorefinery goals heavily relies on the efficient fractionation of biomass components. Several studies have demonstrated that different DES can be used to extract lignin from biomasses successfully (Table 2).

Understanding the relationship between the various types of functional groups in HBD is crucial to developing a DES capable of extracting lignin with specific properties. Although carboxylic acids and polyols are commonly used as HBAs, ChCl is more commonly used as a HBD. Alvarez-Vasco et al. [45] compared the effectiveness of DESs in extracting lignin from hardwood and softwood species. Four HBDs (glycerol, levulinic acid, lactic acid, and acetic acid) and ChCl were used in this study. DESs extracted 79% of lignin from hardwood poplar but only 58% from softwood Douglas fir (softwood). These results indicated that DESs can successfully extract lignin from plants with a purity of 95%. Chen et al. [44] investigated lignin extraction from poplar wood. A ChCl:lactic acid molar ratio of 1:9 was the optimal molar ratio for dissolving 95% of lignin from poplar wood at 120°C for 6 h, with a lignin purity of 98.1%. Tan et al. [47] reported that the extraction efficiency of DES is significantly affected by the functional groups present in the acid component. The HBD with a carboxylic acid double bond improved lignin extraction due to its short alkyl chain and OH group.

In the past, studies on DES have shown that they have the potential to be the most effective method for high-yield lignin extraction. The amount of lignin extracted depends on many variables, such as reaction time, temperature, and molar ratio. Increasing the reaction temperature is necessary to improve lignin extraction, thus decreasing the viscosity and improving DES diffusion into the lignocellulosic matrix [56]. Increasing the temperature enhances the molecular polarity and ionic properties of the DES. Therefore, it promotes the breakdown of the intermolecular hydrogen bond network to increase the solubility of lignin [10]. A higher acid concentration in the DESs promotes lignin extraction and leads to lower residue recovery [48]. This was corroborated by Tan et al. [47], who found that increasing the molar ratio of HBD to HBA in DES may have a synergistic effect, effectively increasing its ability to extract more lignin. The physicochemical and thermal properties of DESs, such as freezing point, density, surface tension, and viscosity, are also noteworthy because they can affect the isolation of lignin. In addition, the selectivity of HBD and HBA largely depends on their low cost and biocompatibility [57].

Table 2. Previous studies on lignin yield (%) with various reaction conditions

DESs	Molar Ratio	Feedstock	Reaction Temperature (°C)	Reaction Time (hr)	Lignin Yield (%)	References
ChCl: LA	1:2	Poplar	145	6	78.5	[45]
	1:2	Corncob	90	24	64.7	[48]
	1:5	Corncob	90	24	77.9	[48]
	1:10	Corncob	90	24	86.1	[48]
	1:15	Corncob	90	24	93.1	[48]
	1:5	Rice straw	60	12	60	[49]
	1:9	Poplar	120	6	95	[44]
	1:10	Willow	120	12	91.8	[50]
	1:5	Sugarcane bagasse	80	12	50.6	[51]
	1:10	Eucalyptus	110	6	80	[52]
ChCl:Glycerol	1:2	Corncob	150	15	59.0	[53]
	1:2	Switchgrass	110	1	76.6	[37]
ChCl:Ethylene Glycol	1:2	Corncob	90	24	87.6	[48]
ChCl:Oxalic Acid	1:2	Rice straw	120	1	75.9	[54]
	1:1	Corncob	90	24	98.5	[48]
ChCl: Urea	1:2	Corncob	80	15	27.1	[53]
	1:2	Rice straw	130	8	44.7	[55]

Lignin extraction from wheat straw increased from 48.76% after 2 h to 73.75% after 12 h [58]. On the other hand, the amount of lignin extracted increased from 90°C to 145°C but declined when the temperature was increased to 180°C. Lignin is most efficiently extracted from poplar and Douglas fir at 145°C with ChCl:lactic acid [45]. Moreover, lignin extraction was affected by the molar ratio of ChCl to carboxylic acid. The lactic acid:ChCl molar ratio increased the lignin extraction rate from 64.7% to 93.1% [48]. In addition, when the ChCl:lactic acid ratio increased from 1:1 to 1:15, the percentage of lignin extracted increased from 33% to 61%. [47].

The hydrophilic amorphous fractions of cellulose and hemicellulose facilitate extensive interactions between the fibres and solvents. Owing to their relatively high chloride ion concentration and activity, DESs are anticipated to play a crucial role in dissolving lignin. As shown in Figure 4, DES can break down LCC linkages due to the hydrogen-bonding interactions between the HBA anion and the hydroxyl group in the LCCs [9]. Several studies have found that DESs affect cellulose solubility, which is likely the cause of the observed interactions [59-61]. To dissolve cellulose, the hydrogen bonds between cellulose molecules and their intramolecular bonds must be broken. In addition, the inherent charge of the fibre may need to be considered [60]. During lignin extraction, the chemical bonds between cellulose, lignin, and hemicellulose are broken, leading to the formation of cellulose pulp. Thus, lignin degradation products are soluble in DES.

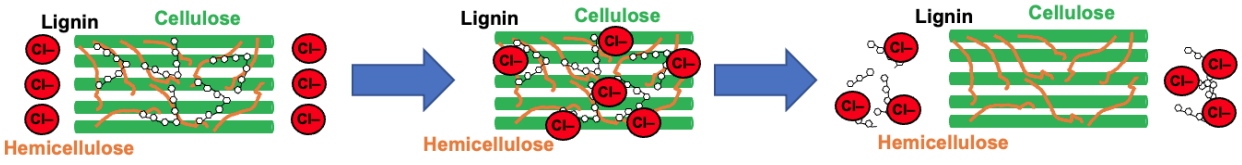

Figure 4. Isolation of lignin from the LCCs

Lignin extraction from oil palm biomass

Lignin from oil palm biomass can be extracted by using DESs. These studies have been performed to remove lignin from cellulose and hemicellulose [62-64]. However, it should be noted that these studies explored the possibility of removing lignin from LCCs. However, since lignin was not the primary focus of these studies, there are few studies on the fundamental properties, structures, or functional groups of the isolated lignin.

New et al. [23] obtained oil palm fronds delignification rate of 16.31% with a ChCl:urea molar ratio of 1:2 at 120°C for 4 h. Tan et al. [65] focused on the delignification of empty fruit bunches by using ChCl as the HBA and various types of HBD, including carboxylic acid and polyol. The study discovered that acids could extract a significant amount of lignin from empty fruit bunch (EFB), with ChCl:lactic acid yielding 88%. However, the near-neutral pH of the eutectic system is thought to be responsible for the 22% lower yield observed in lignin extraction using ChCl:glycerol [65]. Lignin can be extracted more efficiently with DES at an acidic pH than with DES at a neutral pH. Cl- in DES form's hydrogen bonds with hydroxyl groups in lignocellulose, cleaving LCC and releasing the constituent lignin and hemicellulose [66].

Tan et al. [47] examined the effects of different acidic hydroxyl groups, including lactic, malic, citric, formic, and acetic acids, on lignin extraction from EFB under the same conditions (120°C and 8 h). The lignin yield from ChCl:lactic acid was 33.5% at a molar ratio of 1:1, which increased to 61% at a molar ratio of 1:15. Lignin is more readily obtained using ChCl:lactic acid (monocarboxylic acids) than using ChCl:citric acid (dicarboxylic acid) or other HBD types. This was consistent with the findings of Hou et al. [54], who discovered that the delignification efficiency of dicarboxylic acids for rice straw pre-treatment was lower than that of monocarboxylic acids. ChCl:malic acid and ChCl:citric acid was significantly more viscous than ChCl:lactic acid. Lower extraction efficiencies could have resulted from a lack of solvent interactions with lignin due to low molecular mobility [47].

Lignin extraction from empty fruit bunches by using ChCl:lactic acid and ChCl:glycerol is efficient, with a lignin yield of 74.61% [67]. They found that a high HBD molar ratio and prolonged reaction time facilitated the lignin extraction. They concluded that DES could reveal biomass recalcitrance and increase the surface area for more efficient lignin extraction. However, ChCl:lactic acid was more effective than ChCl:glycerol in disrupting aromatic-dominated lignin linkages and cellulose crystallinity associated with β-(1,4)-glycosidic linear bonds. Despite having multiple HBD sites (-OH), the longer hydrocarbon site chain in glycerol molecules resulted in a lower hydrogen-bonding capacity and solubilising ability [67, 68].

The chemical structure and composition of lignin significantly differ depending on its origin, type, and extraction method. Lignin in oil palm biomass must be characterised for this reason. The chemical structure of lignin has been investigated by using various analytical methods. Thus, the most beneficial lignin modification can be identified and evaluated via structural elucidation. Fourier transform infrared spectroscopy (FTIR) was used to determine the chemical composition and functional properties of the extracted lignin. The primary functional groups in lignin include hydroxyl, methoxy, and carbonyl groups [69]. The FTIR spectra of lignin extracted from oil palm biomass using various DES have been reported by Tan et al. [47]. The FTIR analysis showed that all spectra contained guaiacyl lignin units, G (1269 cm^{-1} and 850 cm^{-1}), and syringyl, S (1328 cm^{-1} and 1118 cm^{-1}). The peaks at 1421 cm^{-1}, 1508 cm^{-1}, and 1593 cm^{-1} belong to aromatic skeleton vibrations (C-C). The peak between 850 cm^{-1} and 650 cm^{-1} was characteristic of aromatic C-H bending. Peaks at 3371 cm^{-1} and 1365 cm^{-1} were also identified as phenolic and aliphatic OH in lignin, respectively. Unconjugated C=O was detected at 1700 cm^{-1}. The number of lignin functional groups is affected by the HBD type. The potential of lignin as an aromatic feedstock is related to its aromatic structure and hydroxyl and carbonyl groups. This suggested that DES-extracted lignin, which retains all necessary structures and high intensities, may be particularly suitable for manufacturing aromatic chemicals.

The phenolic hydroxyl group (PhOH) content indicates

the reactivity of lignin for further modification because PhOH is the most reactive functional group in lignin [70]. The solubility and derivatisation potential of lignin are significantly affected by the presence of PhOH groups. The PhOH content in lignin from EFB was found to be the highest when using ChCl:lactic acid, as opposed to ChCl:malic acid, ChCl:formic acid, or ChCl:citric acid [47]. However, the PhOH content declined from 3.72 mmol/g to 3.33 mmol/g when the molar ratio of ChCl:lactic acid was increased to 1:15. Increasing the acidity of the solvent caused lignin condensation, which reduced PhOH content [47].

Lignin as carbon fibre precursor

Carbon fibres have high tensile strength, fatigue resistance, and heat tolerance despite their lightweight. Carbon fibre is an important and promising raw material for fibre-reinforced composites, particularly for high-performance applications. Nonetheless, the precursor materials significantly affected the final carbon fibre properties. Approximately 90% of the raw material for carbon fibres is PAN, making it the most widely used precursor. The remaining 10% were rayon or petroleum pitches. PAN-based carbon fibre-reinforced composites have been singled out by the US Department of Energy as a material with immense potential for use in lightweight vehicles with a 60% weight reduction [71]. While conventional carbon fibre-reinforced composites are inexpensive, PAN-based carbon fibres can be up to ten times more expensive. In addition, the time and energy spent on the thermal treatment necessary to convert PAN into carbon fibre considerably increases the cost of the process.

The high cost of fossil-based PAN precursors accounts for a significant portion of the cost of producing carbon fibre, making it necessary to develop cost-effective precursors, preferably from renewable sources. The prominence of lignin arises from its potential as a cheap carbon fibre precursor and its abundance and sustainability [72]. In addition, lignin is the most appealing renewable precursor for carbonaceous materials due to its aromatic properties and high carbon content (> 60%) [2]. Because lignin has a low decomposition temperature, partially oxidised properties, and high carbon content, it can be melt-spun and stabilised at a higher heating rate [73]. They are non-petroleum-based and, therefore, more environmentally friendly resources.

Compared to alternative materials, the production cost of carbon fibre made from lignin is lower. However, impurities in isolated lignin and complex structures may compromise the mechanical properties and carbon fibre construction. A study was conducted to identify differences between unmodified and modified lignin carbon fibres. Untreated lignin was found to have a tensile strength of 0.38 GPa and a yield of 31%, while treated lignin carbon fibre achieved tensile strengths of 0.710 GPa and yields of 41% [71].

Highly pure lignin with precisely controlled properties is essential for producing high-performance carbon fibres. Highly pure lignin is required to produce carbon fibres with exceptional characteristics and minimal impurities (ash, volatile, and particulate matter). High carbon content, narrow molecular weight distribution, and sufficiently high glass transition temperature all play important roles in the conversion of lignin into carbon fibre through spinning, thermal stabilisation, and carbonisation [2]. Oak Ridge National Laboratory developed a set of specifications to evaluate the potential of lignin as a precursor to carbon fibre [74]. Table 3 presents the specifications.

Table 3. Lignin as carbon fibre precursor

Criteria	Value (wt.%)
Lignin Purity	99
Ash Content	< 0.1
Volatile Matter	< 0.5
Particulate Matter	100% removal of matter >1 μm in diameter
Carbon content	> 60

A lignin purity greater than 99% is required as a carbon fibre precursor. Carbon fibre relies on its high purity to maintain its mechanical properties. Nonetheless, the extraction and use of lignin are complicated by its structural complexity and heterogeneity, primarily linked by aryl ether bonds and C-C bonds. The ability of DES to break β-O-4 aryl ethers and specific lignin-carbohydrate covalent bonds has been reported to increase lignin solubilisation significantly compared to conventional pre-treatment methods [75]. Many studies have successfully used DES to extract high purity lignin from biomass as shown in Table 2. In their study of lignin extraction from poplar using various DESs, Chen et al. [44] found that increasing the reaction temperature from 100°C to 130°C resulted in a higher purity of lignin (98%) due to the breakdown of hemicellulose. Furthermore, lignin purity of 95% from willow was achieved by using ChCl:lactic acid at a molar ratio of 1:10 [76]. These results confirmed the viability of ChCl:lactic acid for efficient isolation and extraction of high purity lignin. Li et al. [50] extracted lignin with high purity (94.46%) using a ChCl:lactic acid eutectic mixture with a molar ratio of 1:10 for 12 h at 120°C.

Ash is the residue remaining after the high-temperature (900°C) combustion. Most ash is composed of minerals found in biomass, such as calcium, magnesium, and potassium. The amount of inorganic matter in the recovered lignin must be kept to a minimum because it affects the mechanical properties of the carbon fibre. Therefore, it should be less than 0.1 wt.%. The stability of a polymer is determined by its volatility. The volatile matter content was determined by comparing the mass of the samples before and after 6 h of heating at 250°C. The volatile matter content of lignin must be less than 5 wt.% for no volatiles to be released during carbonisation. Carbonisation changes porosity [2]. As a result, the high volatile content of lignin could lead to a flaw on the surface of the carbon fibre.

Carbon fibre extracted from lignin was superior due to its low solid particle content. Lignin extraction removes solid particles larger than 1 μm in diameter [77]. Particles, such as sand or clay, are the main cause of impurity precipitation during the extraction process [78]. These impurities must be eliminated because they alter the mechanical properties of the carbon fibre, especially its fibre breakage point, by decreasing its modular and tensile strengths [74].

The extracted lignin should have a carbon content of at least 60 wt.%. The carbon content of commercial lignin is typically 59% to 61% [79]. Since lignin loses mass during carbonisation, the precursor must have a high carbon content and a low amount of non-carbon elements. High-quality carbon fibre requires a carbon content of at least 92 wt.% after the carbonisation of the precursor. A study has shown that ChCl:lactic acid at a molar ratio of 1:10 produced lignin with a high carbon content of 60.08% and negligible nitrogen (0.41%), hydrogen (5.50%), and oxygen (33.50%) content [76].

Furthermore, a uniform structure in carbon fibre is formed after carbonisation only if its molecular weight distribution is narrow [71]. Therefore, it is essential to determine the average molecular weight of lignin and its glass-transition temperature. The average molecular weight is essential for analysing the heterogeneity of long-chain lignin [80]. There is a correlation between the average molecular weight and glass transition temperature, the temperature at which lignin becomes brittle when cooled and soft when heated. However, the melt-spinning process requires a high glass transition temperature to prevent decomposition during the fibre-spinning process. Alvarez-Vasco et al. [45] reported that lignin extracted using ChCl:lactic acid has a low and narrow molecular weight range of 490 g/mol to 2600 g/mol, with an average molecular weight of approximately 890 g/mol. Results showed that DES depolymerises native lignin by selectively cleaving ether linkages without condensation. Lyu et al. [76] investigated the characteristics of lignin extracted from willow using ChCl:lactic acid at a 1:10 molar ratio. They observed that the average molecular weight decreased from 1806.7 to 1042.5 g/mol with a longer reaction time. The rate of lignin macromolecule degradation increases over time owing to the absence of intermolecular lignin bonds [81].

Conclusion

This mini review showed that DESs have the potential to be used as solvents in biomass processing. Organic

acid-based DESs have shown promise for biomass processing due to their ability to extract lignin in a simple, single-stage process while maintaining high purity. Many industrial processes would benefit from the use of DESs owing to their low density, low viscosity, and high thermal stability. Selecting appreciate HBD functional groups and molar ratio is important as it affects the physicochemical and thermal properties of the compounds through intermolecular interactions. On the other hand, the composites and polymer industries have recognised the value of carbon fibre, prompting researchers to explore lignin from biomass for its potential as a low cost, more environmentally friendly and economically viable precursor. More studies are needed to investigate the application of DES with varied functional groups of HBA to HBD for lignin extraction from oil palm biomass, with a particular focus on the effect of varying molar ratios and other operating conditions such as temperature and reaction time. Furthermore, to assess its feasibility as a carbon fibre precursor, the fundamental properties of lignin-derived oil palm biomass must be established, which are critical in establishing whether the isolated lignin is viable as a carbon fibre precursor.

Abstract

The feasibility of classifying soybean frogeye leaf spot (FLS) has been investigated with the advance of hyperspectral technology. Hyperspectral reflectance data of healthy and FLS disease soybeans were used. The first step was to smooth out the data by using a filtering technique namely Savitzky-Golay to eliminate the noise of the spectrum. In order to select the most significant wavelengths, genetic algorithm (GA) was used as a forward feature selection technique. This analysis involved the implementation of machine learning (ML) algorithms, including decision trees, random forests, and stacking, to classify soybean FLS severity levels. Preprocessing ML steps including converting class numbers to strings, identifying and removing missing values, partitioning and normalizing data were implemented prior to the development of the model. Overall accuracy and the receiver operating characteristic curve measure were used to assess the performance of this analysis. All of these steps were carried out through KNIME analytical platform. Based on the results of the analysis, GA-stacking and random forest algorithms achieved the best overall accuracy of 85.9% and 84.3%, respectively. In terms of reproducibility, data flow control, data exploration, analysis and visualization, KNIME Analytics Platform provided great convenience in connecting tools graphically and ensuring the same results on different operating systems. The rapid implementation of workflow in KNIME Analytics Platform provided the opportunity to process hyperspectral reflectance data to classify crop diseases.

Keywords: hyperspectral reflectance, forward feature selection, genetic algorithms, machine learning, KNIME analytics platform

Abstrak

Kebolehlaksanaan mengklasifikasikan bintik daun frogeye kacang soya (FLS) telah disiasat dengan kemajuan teknologi hiperspektral. Data reflektan hiperspektral kacang soya yang sihat dan penyakit FLS telah digunakan. Langkah pertama ialah melicinkan data dengan menggunakan teknik penapisan iaitu Savitzky-Golay untuk menghapuskan hingar spektrum. Untuk memilih panjang gelombang yang paling ketara, algoritma genetik (GA) digunakan sebagai teknik pemilihan ciri ke hadapan. Analisis ini melibatkan pelaksanaan algoritma pembelajaran mesin (ML), termasuk pohon keputusan, hutan rawak, dan pemadatan, untuk mengklasifikasikan tahap keparahan FLS kacang kedelai. Langkah-langkah pra pemprosesan ML termasuk menukar nombor

kelas kepada rentetan, mengenal pasti dan mengeluarkan nilai yang hilang, mempartisi dan menormalisasi data telah dilaksanakan sebelum pembangunan model. Ketepatan keseluruhan dan ukuran lengkung ciri operasi penerima digunakan untuk menilai prestasi analisis ini. Kesemua langkah ini telah dijalankan melalui platform analisis KNIME. Berdasarkan keputusan analisis, algoritma GA-stacking dan random forest masing-masing mencapai ketepatan keseluruhan terbaik iaitu 85.9% dan 84.3%. Dari segi kebolehulangan, kawalan aliran data, penerokaan data, analisis dan visualisasi, Platform Analisis KNIME memberikan kemudahan besar dalam menyambungkan alatan secara grafik dan memastikan hasil yang sama pada sistem pengendalian yang berbeza. Pelaksanaan pantas aliran kerja dalam Platform Analisis KNIME memberi peluang untuk memproses data reflektan hiperspektral dalam klasifikasi penyakit tanaman.

Kata kunci: reflektan hiperspektral, pemilihan ciri ke hadapan, algoritma genetik, pembelajaran mesin, platform analisis KNIME

Introduction

As a legume, soybean is an essential source of proteins and fatty acids, the major feed sources of proteins, and the second primary producer of editable oils. The total production for soybean around the world was 367.76 million tons in 2021 and it is estimated that there will be a decrease of 17.04 million tons or 4.63% in the soybean production across the globe [1]. Apparently, the use as a primary source in pig feed increases the consumption of soybean worldwide. However, several diseases have severely harmed the quality and the seed of soybean. For example, frogeye leaf spot (FLS) is a soybean foliar disease caused by the fungus *Cercospora sojina* Hara (CSH) leads to yield losses, seed damage, and economic losses. FLS infections may result in yield losses of up to 60% [2, 3]. FLS is a polycyclic illness which its infection, symptom development, and reproduction may occur several times within the span of a single season [4]. It is crucial to assess and to detect the expanse of disease so that its economic losses can be estimated and proper management can be implemented.

The present method for determining the severity of foliar disease is mostly dependent on visual assessment. Experts physically evaluate the size of lesion area, the leaf color patterns, the distribution and the shape of leaves, the number of stems and branches, and also the density of soybean [5]. However, the visual assessment method is bias and can be altered by the experimental observations of experts. Another assessment method is molecular procedures such as enzyme-linked immunosorbent assay (ELISA) and polymerase chain reaction (PCR), which are very sensitive and capable of detecting disease. The drawback of this approach is time-consuming and destructive [6]. Thus, non-destructive highly efficient methods such as remote sensing tool remains warranted to assess the severity of soybean diseases.

Hyperspectral reflectance has attracted much focus in identifying and estimating the severity level of soybean disease. The hyperspectral technique consists of a narrow bandwidth and more than ten different channels that are capable of identifying subtle changes in an object of interest. Hyperspectral technique is frequently used to determine biophysical properties of certain crops, such as chlorophyll content, moisture content, trace element content, crop cell structure and nutrient contents [7-9]. Several studies have demonstrated the effectiveness and the potential of hyperspectral reflectance in identifying disease severity, such as rice false smut disease [10], citrus disease [11], oil palm *Ganoderma* disease [12], and soybean stem rot disease [13].

Rapid development of an automation system for classifying disease of the infected crops is an emerging area in precision agriculture. Machine learning (ML) method has been adopted to develop classification models using hyperspectral reflectance data for crop disease detection such as support vector machine, random forest (RF) and artificial neural network [14]. [15] has successfully developed random forest algorithms to classify wheat and rye leaves rust based on pure spectra. The result showed that the RF model based on the selected spectral wavelength achieved promising accuracy with the accuracy of 96.6%. In addition, hyperspectral data contain extra, redundant and highly correlated information across a large number of wavelengths, which can increase the complexity of analysis. Therefore, data dimensionality reduction, which cut down and optimize the whole wavelength, is

required. Several methods have been used effectively to reduce the dimensionality of hyperspectral data, including generic algorithms [16], principal component analysis (PCA) [17], and successive projection algorithm 18], and others [19-21]. To detect Huanglongbing disease in citrus, [11] used PCA to reduce the number of spectral features, and the selected PC scores were used in the classification algorithms such as quadratic discriminant analysis (QDA) and k-nearest neighbor (KNN). The results showed that the selected features achieved an overall average classification accuracy of 86% and 93% using KNN-based and QDA-based algorithms, respectively. In another similar study, [22] applied feature selection technique based on successive projection algorithm (SPA) to detect vineyard disease. The result demonstrated that SPA technique performed better than common VIs with the overall classification accuracy of about more than 96% for both DA and SVM. Nevertheless, implementing data dimensionality reduction in analyzing hyperspectral reflectance data can sometimes be computationally demanding.

The KNIME analytics platform is an open-source software that aims to solve these problems by creating a platform that can easily be extended with new tool integrations, which features a strongly typed data system, and permits creators to record in detail each step of the workflow [23]. One of the KNIME's benefits is its multimode of nodes for performing a sequence of ML process with its offerings of various advanced ML algorithms. In this study, the hyperspectral analysis was conducted to classify the FLS disease on codeless platform. This is the first study to use such platform to perform the hyperspectral processing including the feature selection and the classification approaches in KNIME analytics platform. Therefore, the main objectives of this study are to estimate FLS disease class using hyperspectral reflectance, to evaluate the performance of proposed feature selection by comparing with full dataset and to determine the feasibility of classifying FLS through the proposed ML method.

Materials and Methods

Data acquisition

Leaf hyperspectral reflectance data were collected using a FieldSpec® HandHeld 2 spectrometer (Analytical Spectral Devices, Inc., Colorado, USA). The hyperspectral region ranged from 325 to 1075 nm, with a resolution of 3 nm. The number of hyperspectral channels is 512. Each diseased or healthy leaf was considered as one sample. A total of 440 samples, comprising 340 diseased and 100 healthy leaves, were collected and evaluated. Four severity classes such 0%–1% (class 1), 1%–3% (class 2), 3%–6% (class 3), 6%–20% (class 4), and lastly the healthy leaves were regarded as class 0. The data was obtained from [24], which has been appropriately cited.

Preprocessing

The wavelengths were cut to remove the excitation wavelength and keep the useful wavelength that represent the reflectance of the disease. Only useful wavelength interval from 450 nm to 1000nm was remained. Then, the preprocessing technique such as Savitzky-Golay filter was used. The purpose of Savitzky-Golay filter is to smooth the original data while also eliminating noise from the spectrum [25]. The length of the filtering window and the order of the polynomial interpolation were set to 11 and 3, respectively. In addition, the first and second derivatives orders were generated over the course of the investigation. The preprocessing workflow was implemented using the installed KNIME interactive R statistics integration to use the R package and to execute them in KNIME analytic platform, as shown in Figure 1.

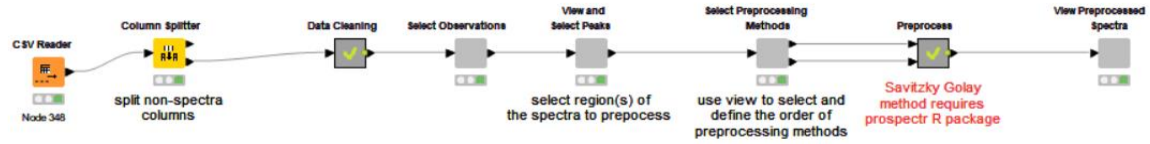

Figure 1. The workflow of preprocessing

Processing

Forward feature selection method such as genetic algorithm was applied to select the useful wavelengths and to eliminate the redundant wavelengths. The genetic algorithm is a chaotic approach for optimizing functions that is based on evolution and genetics. In genetic algorithm, an optimal set is determined based on evolution. The first step in selecting the features is to generate a population based on the subsets of possible features. The subsets from this population are then evaluated using a predictive model to obtain the weights of each individual on the populations. By that, N individuals are chosen, where N is the size of the population, given that previously calculated weights, and two new individuals are generated from each pair of individuals. In this way, each generation have the same number of individuals as the previous one which can bring it forwards when the algorithms run in many iterations. The next step is reproduction, which entails this numbers will be used to randomly split the parents' genes into pieces of varying sizes. The first new person will have the first piece from parent A and the second chunk from parent B. The second new person will be made out of the first and the second halves of parent B. Lastly, mutation mitigates the risk of the search falling into a local optimum and getting stuck. At each generation, in addition to the crossover, a random mutation is added. The reproduction and the mutation processes are then repeated once the new population has been produced, with the weights of each individual being recalculated. A workflow illustrating the forward feature selection process is shown in Figure 2. Using the KNIME workflow, raw data was recorded using the 'CSV Reader' node, and then combined with the 'Number to String' node to represent the disease severity classes into a string, and finally a metanode that comprised of several nodes was created to execute genetic algorithms via a sequence of forward feature selections.

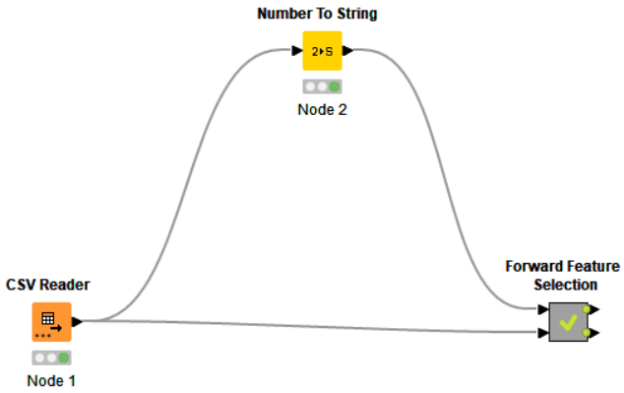

Figure 2. The workflow of feature selection

Modelling methods

Several ML algorithms were used to classify the severity level of FLS disease in soybean. Decision tree, random forest and stacking were used as the ML algorithms in this study. Each of the ML algorithms were implemented in the KNIME workflow. In general, raw data was recorded using a CSV Reader node, then the preprocessing ML steps such as converting the class numbers to strings, and identifying and removing missing values were carried out, followed by data partitioning (X-partitioner and X-aggregator) and normalization (normalizer and apply normalizer). Next, ML algorithms namely random forest, decision tree, and stacking were implemented and evaluated using a scorer and receiver operating characteristic (ROC) curve. The mechanisms of each ML algorithms are stated as followed.

Random forest: Random forests combine multiple trees and assemble decision trees through 'bagging' to create a final model. In this method, bootstrapping is used to select 'k' samples from the original dataset at random. The output is finalized by aggregating the predictions of each decision trees. These samples are used to build decision trees and create output depending on its predictions. The model parameters are adjusted accordingly through trial and error. The split criterion is assigned as information gain. The tree depth and the minimum node size were tuned accordingly and set to 5 and 2, respectively. The workflow of random forest is shown in Figure 3.

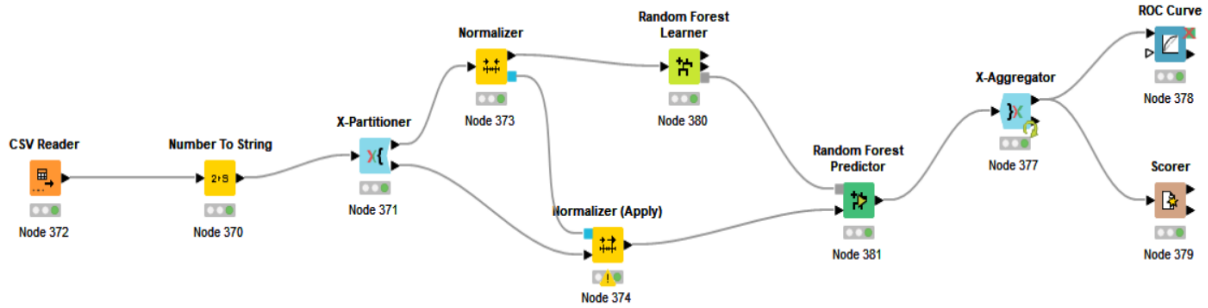

Figure 3. The workflow of random forest algorithm

Stacking: In stacking, heterogeneous base learners consisting different ML models are applied and trained in parallel. Then, heterogeneous base-learners are combined in aggregating the output of each single base-leaners by training a meta-learner to create a prediction based on different base learner's predictions. The purpose of the meta-learner is to determine how to combine the input predictions made by the base-learners with the output made by the training dataset to achieve better predictions [26]. Stacking algorithm was implemented by utilizing KNIME Weka Data Mining Integration, which provide Knime plugins that include the Weka data mining framework's functionality [27]. In this study, Naïve Bayes, J48 and Kstar algorithms were selected as base learners, and logistic regression was used as meta-learner. The workflow of stacking algorithm is shown in Figure 4.

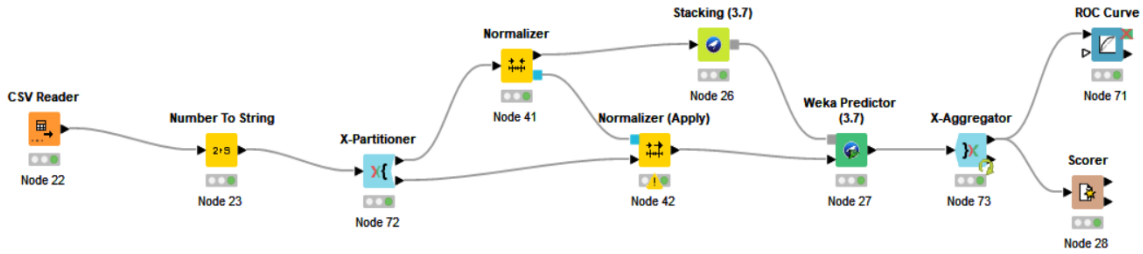

Figure 4. The workflow of stacking algorithm

Decision trees: A decision tree is a tree-representation classifier in which each leaf node corresponds to a class label and each inside node represents a feature. Branches represent conjunctions of features that lead to those class labels. Pruning is applied as it is the important part in decision trees, used to decrease the size of the decision tree. Several parameters were set such as quality measures (Gini index), minimum number records per node (8) and pruning method (Minimum Description Length). The workflow of decision tree is shown in Figure 5.

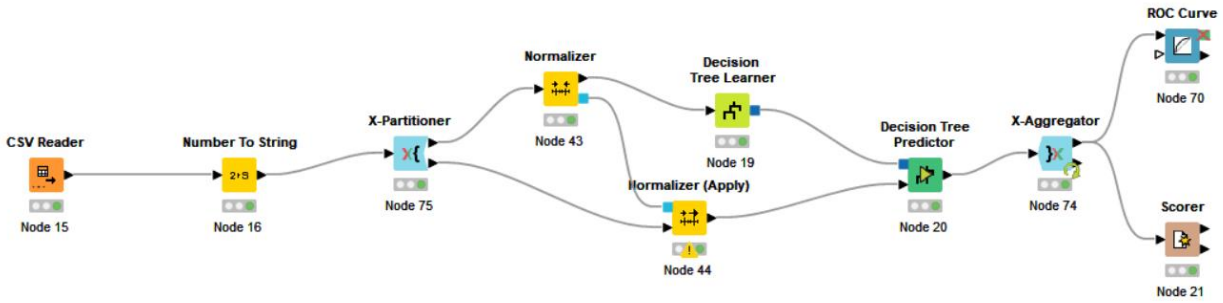

Figure 5. The workflow of decision tree algorithm

Performance evaluation

Cross-validation was used as a resampling strategy in the evaluation process to assess the ML models. The number of groups into which a particular data sample to be divided is denoted by K-fold, which is used to separate each observation from the original dataset into an equal probability of occurring in the training and the test sets. In this investigation, K was set to 10, training the (K-1) folds and testing the model with the Kth fold remaining. The procedure is repeated K times until the final average score is determined. Cross-validation is applied for the evaluation metrics in the accuracy assessment. In order to analyze the efficacy of the ML algorithms, accuracy assessment is important in the classification of FLS diseases. The accuracy of each ML algorithms was evaluated using ground truth data for the five severity classes of soybean FLS. The confusion matrix approach was used to assess the performance of a classification model by comparing the actual classes to the predictions of the ML model. The overall accuracy was computed by summing the number of correctly classified classes and dividing it by the total number of classes. This overall accuracy is the outcome of ML algorithms classifying the severity levels of soybean FLS using leaf hyperspectral data. The ROC measure is also used to quantify the prediction accuracy of a predictive model. It is based on the trade-off between the true positive rate and the false positive rate when probability threshold is used.

Results and Discussion

Spectral reflectance for raw, first and second derivatives of FLS disease

Spectral reflectance profile taken from sample spectra is shown graphically for each severity stages of soybean FLS (class 0, 1, 2, 3 and 4) in Figure 6. Basically, the spectral profile showed a low reflectance in the visible region with small peak in the green region indicating a sudden increase beginning at 690 nm reaching a peak in the NIR region. These are regular for green plant reflectance spectra. A comparison of profile showed larger difference in the reflectance between each severity classes of soybean FLS at some wavelengths compared to other wavelengths.

In the visible spectrum (607– 690 nm), soybean FLS with different severity stages were very similar and many overlapped each other, while in the infrared region (702 – 966 nm), the spectra of soybean FLS with different severity classes separated from each other. Healthy soybean had the highest NIR reflectance compared to others in 774 nm till 806 nm (Figure 6). The second highest were soybeans with class 1 and 2. Soybean FLS with class 4 had the lowest reflectance.

The first derivative of spectral reflectance is shown in Figure 7(a). Overall, the first derivative of spectral reflectance of FLS soybean disease exhibited a tiny reflectance peak about 515 nm and a substantial first derivative reflectance peak in the red-edge area (679 – 714 nm). Healthy soybean with class 0 indicates the highest peak at 717.87nm in the red edge region, which is more prone to shifting to the right as compared to FLS soybean disease. The second derivative of spectral reflectance of FLS soybean disease is shown in Figure 7(b). Second derivative reflectance spectra with FLS soybean disease showed distinct peaks at 685 nm and 732 nm.

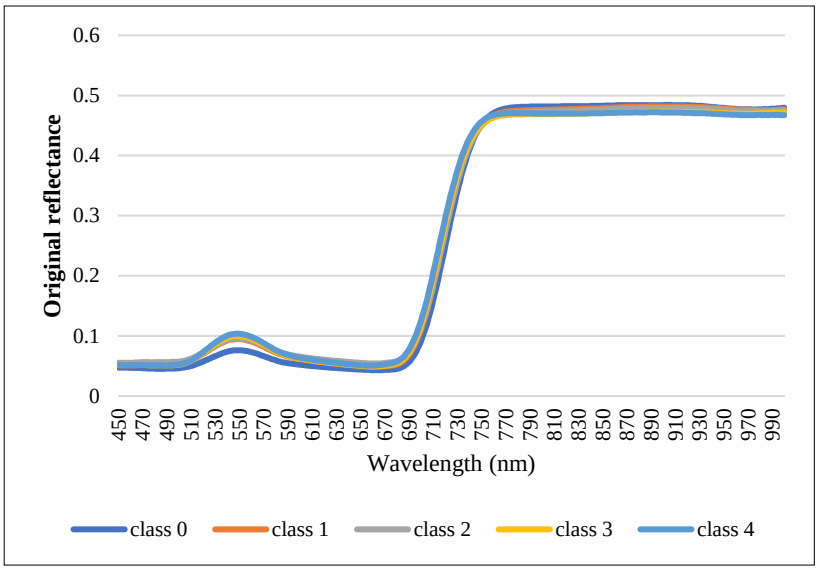

Figure 6. Original spectral reflectance of FLS disease

The first derivative equation is crucial in plant disease detection with space of the lesion density function at a fixed position [28]. The spectrum will become complicated and complex as the number of disease symptoms increases. Different stages of disease severity attributed to the collected spectrum variation when plants in the particular area facing disease spreads. Therefore, the first derivative can remove both additive and multiplicative effects in spectrum [29]. Lu et al. [30] showed that the first derivative between 500 – 1000 nm was better in discriminating leaf curl on tomatoes than the original reflectance spectrum. In general, the first and the second derivatives indicated the potential for estimating crop disease because of their insensitivity to the soil background [31, 32].

Classification of soybean FLS disease using ML models

Table 1 shows the overall accuracy of ML algorithms used in the classification of soybean FLS disease. Random forest and stacking achieved the best overall accuracy using the selected first and second derivatives of spectral reflectance. Random forests achieved an overall accuracy of 84.3% and 77.7% for both selected first and second derivatives of spectral reflectance, respectively. The stacking algorithms have improved to 85.9% and 79.1% from 70% and 56.1% on both selected first and second derivatives of spectral reflectance, respectively.

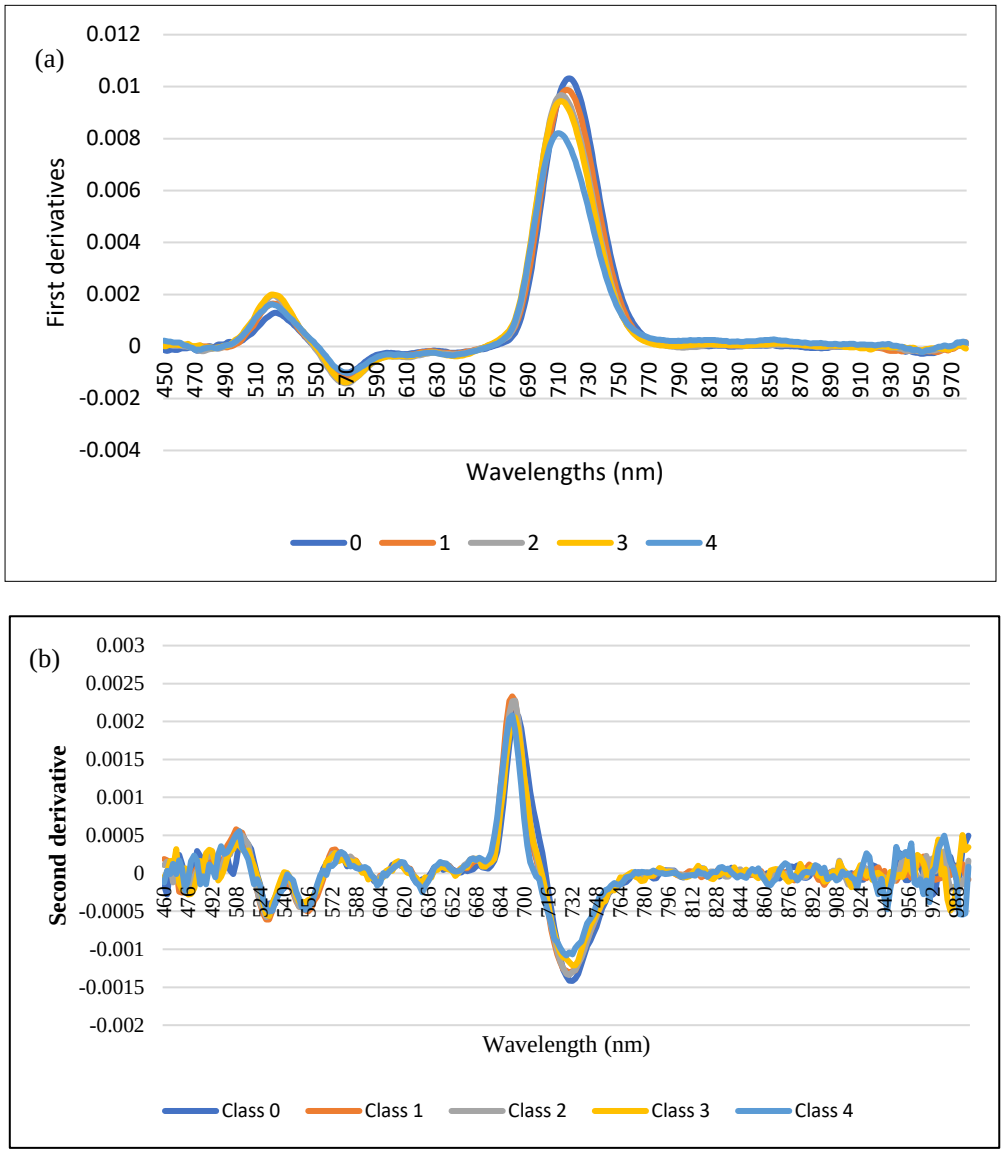

Figure 7. (a) First derivative of spectral reflectance of FLS disease and (b) Second derivative of spectral reflectance of FLS disease

Table 1. Overall accuracy of ML models

Data	Raw	First derivative (full)	Second derivative (full)	First derivative+ Savitzky-Golay+feature selection (genetic algorithms)	Second derivative+ Savitzky-Golay+feature selection (genetic algorithms)
Decision tree	55.4	64.7	55.9	65.0	62.7
Random forest	68.4	75.9	69.5	84.3	77.7
Stacking	69.7	70.0	56.1	85.9	79.1

Decision tree had the lowest and the poorest accuracy performance even after the feature selection algorithm was implemented. For example, only small increases with 0.2% for implementing the feature selection using the first derivative data. Noticeably, there was not much difference between the accuracy of decision tree algorithms using raw data and second derivative.

Based on the above results, incorporating genetic algorithms (GA) as feature selections has improved the overall accuracy for most of the ML algorithms since GA can effectively screen the useful characteristic bands for soybean FLS disease detection, thereby reducing the number of variables in the model, and thus producing high classification accuracy. Our result agrees with the studies of Chen et al. [33], who proved that genetic algorithms and following support vector machine is the best performance model with overall accuracy of 90.7% for leaves and 92.6% for stems.

Adding to performance analysis, Figure 8 illustrates the ROC curve for stacking algorithm, which is the best among the other algorithms. This analysis contributes an insight into how well the model classify the different severity classes (classes 0, 1, 2, 3 and 4) of soybean FLS. Overall, the curve reached a high value for the metric area under curve, in this case, 95% area of the graph was under the curve, showing the model is good in separating the soybean FLS classes.

Conclusions

Based on the results, it was concluded that stacking algorithm achieved the highest accuracy after genetic algorithm implementation. Future studies will assess different feature selection techniques to analyze hyperspectral reflectance in the classification of crop disease. Different preprocessing techniques will also be adopted to ensure the proper removal of noise in spectrum. Besides, several ML algorithms will be proposed and applied on the analysis of hyperspectral reflectance. KNIME integrations provide additional functionality such as processing of complex hyperspectral preprocessing (e.g. Savitzky-Golay), as well as the use of advanced ML algorithms. Therefore, the functionality of KNIME as a codeless tool for analyzing hyperspectral reflectance should be further investigated in order to confirm its practicality and usefulness. The results obtained make it possible to

provide fast implementation of workflow, including model development for evaluating the degree of crop disease using hyperspectral reflectance data. Future studies will utilize other advanced machine learning algorithms to improve the accuracy of the model.

Abstract

This review discusses the modified hierarchical framework of zeolite ZSM-5 through top-down and bottom-up techniques, which progressed via a soft template through a combination of dealumination and desilication. Several experiments have been reviewed to increase the catalytic cracking performance of Z SM-5 zeolite, including fluid catalytic cracking (FCC) activity. Template-assisted or post-treatment procedures may be used to create hierarchical zeolites, with mesopores or macropores boosting the accessibility of acid sites in micropores and the hierarchical pore structure. The physiochemical characterization investigation revealed that the hierarchical catalysts had a substantial surface area and pore characteristi cs compared to the parent samples, making them an attractive alternative to be used in the FCC catalyst. It is important to develop a low-cost and effective process for manufacturing hierarchical zeolite.

Keywords: Zeolite Socony mobile five, modification of hierarchical framework, fluid catalytic cracking, catalytic activity

Abstrak

Ulasan ini membincangkan kerangka hierarki zeolite ZSM-5 yang diubah melalui teknik atas ke bawah dan bawah ke atas, yang berkembang melalui templat lembut melalui gabungan dealuminasi dan desilikasi. Beberapa eksperimen telah dikaji untuk meningkatkan prestasi pemecahan pemangkin zeolite ZSM-5, termasuk aktiviti pemecahan pemangkin cecair (FCC). Prosedur yang dibantu templat atau pasca rawatan boleh digunakan untuk menghasilkan zeolite hierarki, dengan mesopori atau makropora meningkatkan capaian asid di mikropori dan struktur pori hierarki. Penyelidikan pencirian fisiokimia menunjukkan bahawa pemangkin hierarki mempunyai ciri luas permukaan dan liang yang besar jika dibandingkan dengan sampel induk, menjadikannya alternatif yang menarik untuk digunakan dalam pemangkin FCC. Dalam penghasilan hierarki zeolite,proses kos yang rendah dan berkesan adalah menjadi keutamaan.

Introduction

Zeolites are microporous aluminosilicate minerals that serve as heterogeneous catalysts in a variety of applications including petroleum refining, oil refineries, fluid catalytic cracking (FCC), oligomerization, esterification, alkylation, and acylation [1]. Zeolite is a crystalline inorganic polymer that is mostly composed of tetrahedral [SiO_4] and [AlO_4] ions and water molecules [2]. Recently, scientists have paid close attention to Zeolite Socony Mobil 5 (ZSM-5) because of its outstanding chemical conversion in several industrial sectors [3]. A prior study confirmed that the ZSM-5 zeolite has been expanding zeolite application as a catalyst and adsorbent in many areas due to its molecular sieving properties, great surface acidity, strong hydrothermal stability, large Si/Al proportions (from tens to hundreds), and environmentally friendly synthesis [4, 5].

Nowadays, research on zeolite is focusing on customizing its acidity and porosity beyond mesoporous capability [6]. In fact, its high acid centre and structure selectivity make it as an interesting catalyst in organic synthesis, primarily for cracking reactions. Another research also stated that zeolite ZSM-5 has been applied as a catalyst in a wide variety of chemical activities such as cracking, isomerization, and alkylation [7]. Meanwhile, a study done by Widayat et al. [8] discovered that cracking is a process that is widely applied in research and industrial applications, primarily in fields especially involved hydrocarbons. Regrettably, the hydrocracking process is typically forced to involve relatively high temperatures, which can be hazardous to the environment. Thereby, transition metals, silica, zeolite-modified zeolite, mesoporous mixed oxide catalyst, and metal organic frameworks have been used in catalytic cracking. As it is an effective catalyst for oil cracking due to its high temperature stability, microcrystalline shape, and propensity to precipitate reactants trapped in pores, ZSM-5 zeolite is thus particularly important for the catalytic cracking process [8]. Thus, this review is intentionally to gather all information and related data to ZSM-5 in catalytic cracking. Zeolites are extremely useful as catalysts for several important reactions involving organic molecules. The most important are cracking, isomerisation and hydrocarbon synthesis. Zeolites can promote a diverse range of catalytic reactions including acid-base and metal induced reactions.

Hierarchical ZSM-5 is a type of zeolite catalyst that has been modified to contain both micro- and mesopores, which increases its surface area and enhances its catalytic activity. This modification is achieved by a post-synthesis treatment, which involves the removal of some of the material that fills the micropores of the zeolite. While hierarchical ZSM-5 has shown promising results in various catalytic reactions, including the conversion of biomass to fuels and chemicals, there are some concerns about the reproducibility and scalability of the synthesis method. Some studies have reported variations in the performance of hierarchical ZSM-5 catalysts depending on the synthesis conditions, which may limit their practical application. Furthermore, the precise mechanisms by which the hierarchical structure enhances the catalytic activity of ZSM-5 are not yet fully understood. This makes it challenging to design and optimize hierarchical ZSM-5 catalysts for specific catalytic reactions. Therefore, a review of the hierarchical ZSM-5 synthesis method is needed to evaluate the reproducibility and scalability of the method and to provide insights into the mechanisms underlying the enhanced catalytic activity of hierarchical ZSM-5. Such a review can help to identify areas for further research and development, ultimately leading to more effective and practical catalysts for various industrial applications.

Development of hierarchical zeolite ZSM-5 (HR-ZSM-5)

A research revealed that the conventional microporous ZSM-5 has limited pores and diffusion channels, hence limiting its use [9]. According to Jia et al. [10], the typical crystal size of standard ZSM-5 zeolites is in micrometre or submicrometer, which lengthens the retention time of macromolecular intermediates and products in the inter channel. Consequently, the small pores of such zeolites are susceptible to be clogged rapidly due to coke deposition, accelerating the deactivation process of zeolite catalysts. Nonetheless, Speight's study discovered that catalytic cracking of gas oil can result in the production of coke because it is a

heat-absorbing process, indicating that heat is absorbed by the process and the temperature of the reaction mixture decreases as the reaction progresses, necessitating the need for a heat source [11]. This heat is generated by the burning of coke produced throughout the operation. Coke is a significant, yet unfavourable, by product of cracking because it occurs on the surface and in the pores of the catalyst throughout the cracking process, blocking active sites and disabling them. In the meantime, diffusion issues come up within the zeolite crystals when large reactants or products are applied, causing in pore clogging in both conventional and non-traditional chemical reactions. Widayat et al. [8] concurred that the function of zeolite as a catalyst is confined by its minute pores, which impede the diffusion of bigger particles during the mass transfer process. Hence, ZSM-5 zeolite will be modified to maximize the surface porosity. Several strategies have been investigated to enhance the structure of ZSM-5 zeolite. According to a new finding by Talebian-Kiakalaieh and Tarighi [1] found that modified zeolites encompass mesoporous materials, large-cavity, nanosized zeolites, hierarchical zeolites, and ultra large-pore zeolites. Nanosized zeolite crystals have low product yields, and zeolites generated with only a mesoporous framework are pricy, hence their applicability are confined. They suggested that the zeolite ZSM-5 framework will be developed to include hierarchical zeolites with microporous and mesoporous structures, which will have a high economic value. Přech et al. [12] also agreed that micropores and mesopores coexist in hierarchical zeolites, helping reactants and products to diffuse more efficiently. This triggered to development of hierarchical zeolite ZSM-5 as mentioned below.

The development of hierarchical ZSM-5 zeolite can be done in a variety of ways. Again, Jia et al. [10] postulated that hierarchical zeolite ZSM-5 can be produced using both bottom-up and top-down methods. These methods include desilication (base leaching) and dealumination (acid leaching). According to Talebian-Kiakalaieh and Tarighi [1], it is ideal to add a post-synthesis treatment that includes desilication and dealumination, coupled with soft tessellation with surfactant and steaming, in order to produce a stable zeolite ZSM-5. Furthermore, Peron et al. [13] emphasized that combining desilication with dealumination may be the optimum way for generating hierarchical zeolites with the appropriate balance of mesoporosity, crystallinity, and acidity. On the other hand, soft templating seems to be more versatile owing to the ease with which it can be implemented and, more importantly, due to the fact that it can alter mesoporosity from inside the zeolite framework [1].

In order to effectively synthesize hierarchical ZSM-5 zeolites with high mesoporous and hierarchy factors, a new soft template was developed and employed as a mesoporogen [14]. During the high-temperature hydrothermal crystallization process, the covalent link of Si-O-Si between the as-produced soft template and the mordenite framework inverted (MFI) frameworks maintains a constant connection. The structure of this soft-connection template's mode efficiently prevents the production of amorphous materials, and it may introduce several mesopores while using few micropores. The particles of as-synthesized hierarchical ZSM-5 zeolites about 1 µm in size and made of nanocrystals of 60-150 nm. These hierarchical samples exhibit excellent tolerance for hydrothermal treatment due to the nature of zeolite and it possesses a considerable microporosity. Additionally, the hierarchical structure exhibits excellent catalytic performance in the reactions of alkylation between benzene and benzyl alcohol, cracking of 1,3,5-tri-isopropylbenzenenzene, and thermal cracking of low-density polyethylene (LDPE), respectively, due to the intra-crystalline mesopores, large external surface areas, and abundantly accessible acid sites.

Acidity may be modified or rectified by the metal ion-exchange process and pre-treatment or post-synthesis treatment can be used to improve other structural properties. As an example, it can state unequivocally that alkali treatment is an efficient and straightforward way for creating mesoporous medium, which reduces channel length and corrects the diffusion restriction. As a result of this change, access to active sites has increased. Moreover, several attempts have been undertaken to optimize the Si/Al ratio or the synthesis

working parameters, such as temperature and stirring duration [15].

By adding ZSM-5 zeolite with 65:1 SiO_2/Al_2O_3 ratio, HR-ZSM-5 zeolite was successfully created [1]. The mesoporous structure of the synthesized ZSM-5 zeolite was induced in the second step using the desilication, dealumination, and soft tessellation techniques. This method produces desilicated ZSM-5 by heating synthesized ZSM-5 for an hour at 80 °C with 50 wt.% NaOH solution in deionized water. Before being dried overnight, the mixture was properly cleaned and filtered. They dealuminized the ZSM-5 zeolite in their experiment by soft-templating with surfactant after three hours of acid leaching with H_2SO_4 solution at 80 °C cetrimonium bromide (CTAB). Each 20 g of desilicated or dealuminated ZSM-5 was dissolved in a 0.3 M NH_4OH solution containing CTAB, and then subjected to a hydrothermal procedure at 150 °C. They claimed that the final HR-ZSM-5 has undergone three successive phases of ion exchange with 1 M NH_4OH solution (80 °C, 2 h), and the powder has then been calcined at 550 °C for five hours before being applied to the fluid catalytic cracking (FCC) catalyst.

Effect of HR-ZSM-5 on the physiochemical properties

Due to their exceptional physical and chemical characteristics, zeolites such as ZSM-5 and ZSM-11 are frequently explored for catalytic cracking of big molecules. Distribution, strength of active sites, and acidity of zeolites are the most crucial elements for improving the catalytic performance of a process [16, 17]. In addition, the pore size and shape of zeolites are critical in influencing the selectivity and yield of the desired products. Consequently, it is vital to comprehend the structure-activity connection of zeolites in order to build effective catalysts for a variety of industrial processes.

Initially, the ICP-OES was used to determine the chemical composition of the parent and hierarchical zeolites that were produced (Table 1) [1]. The hierarchical HR-ZSM-5 (86.34) and parent ZSM-5 (65.55) SiO_2/Al_2O_3 ratios demonstrated that the hierarchical sample had a higher SiO_2/Al_2O_3 ratio than the parent ZSM-5. The increasing of SiO_2/Al_2O_3 ratio was due to the acid leaching by H_2SO_4 after base leaching with NaOH. Research done by Talebian-Kiakalaieh and Tarighi [1] reported that the specific surface area (S_{BET}) (Table 1) of parent ZSM-5 zeolite was 399 m^2/g which then increased to 462 m^2/g. In fact, the pore volume (V_p) showed an improvement in value from 0.20 to 0.59 cm^3. The average pore diameter (D_p) of parent formed when compared to hierarchical samples, showed a significant rise from 2.01 to 5.07 nm [1]. Large pores which might be attributed to the big holes in HR-ZSM-5 via framework dealumination/desilication processes and broad pores which could be generated from the transition of micropores to mesopores initiated by using surfactant for alteration. In their experiment, the mesoporous pore showed significant development when the parent ZSM-5 increased from 0.06 to 0.47 cm^3/g of HR-ZSM-5. These findings revealed that acid/base treatments of ZSM-5 zeolites, as well as the soft templating process, resulting in the development of outstanding hierarchical zeolites. Meanwhile, Wang et al. [15] experiment postulated that the N_2 adsorption–desorption isotherm of ZSM-5 zeolite sample obtained, has features of both type I and type IV(a) profiles with two steep uptake steps, one at $P/P_0 < 0.02$ and the other at $0.45 < P/P_0 < 0.90$, which corresponded to micropore filling and mesopore capillary condensation, respectively. Unnikrishnan and Sabarish [18] agreed that the unaltered sample has the type I isotherm, which was the characteristic isotherm for microporous materials. The changed sample, on the other hand, has type IV isotherm. They added that BJH model was used to analyse the pore size distributions of the samples. Unmodified and adjusted sample pore diameters are predicted to be 2 and 10–20 nm, respectively. As a result, the increased mesoporosity in ZSM-5 zeolite was formed in their study. The porosity of ZSM-5 zeolite influences molecular adsorption, separation, and diffusion and among the dominating factors affecting its catalytic activity[19].

The PXRD patterns of parent ZSM-5, base/acid leached ZSM-5, and hierarchical HR-ZSM-5 samples, as shown in Figure 1a, were all identical to the standard ZSM-5 peaks, with no extra unexplained peaks, demonstrating

that all of the synthesised samples were true MFI-type material [13]. There were no significant changes in the intensity, breadth, or location of the XRD peaks after dealumination and desilication of the ZSM-5 catalyst. Moreover, no specific peaks associated with the amorphous phase have been discovered. According to Ghrib et al. [20], the growth of ZSM-5 crystallizations were more difficult to detect owing to their tiny size. Earlier study found that both the parent ZSM-5 zeolite and the hierarchical sample had a decrease in reflection intensity [1]. The insertion of mesopores into parent zeolite results in a decrease in crystallinity and a broadening of peak width, confirming the scission of Al-O bonds and the formation of hydroxyl nests (cavities), which caused the unit cell sizes to expand with the desilication treatment because of selective silicon extraction, resulting in larger unit cell sizes. Yang et al [6] discovered a dense pore opening on the surface crystallite of the hierarchical zeolite. FESEM and HRTEM images (Figure 1b) further confirmed mesopores structures have been observed throughout the zeolite matrix.

Meanwhile, Jia et al. [21] shown in their experiment that the asymmetric stretching of SiO_4 and AlO_4 tetrahedra in the zeolite framework is believed to be due to vibrational modes around 547 and 1222 cm^{-1}, respectively. Another research discovered the distinctive bands in the FTIR spectra of parent ZSM-5 and hierarchical HR-ZSM-5 samples corresponded to internal and exterior symmetric and asymmetric stretching, double ring vibrations, and T-O bending, as shown in Figure 1c, demonstrating that the pure ZSM-5 phase was found in both samples [1]. In Sabarish and Unnikrishnan's work [18], NH_3-TPD analysis was used to investigate the acidity of the synthesized parent and hierarchical ZSM-5 zeolite. They claimed that the hierarchical sample had a 16.5% lower total acidity than the parent sample. When the framework Al atom was removed, the overall acidity of the hierarchical zeolite was reduced. Figure 1d shows the acidity profiles of synthesized ZSM-5 and HR-ZSM-5, with two peaks in the weak and medium regions. According to them, the strength of medium acidity fell dramatically following the base/acid washing and soft templating processes. The low-temperature peak indicated NH_3 molecule desorption from weak acid sites, while the high-temperature peak represented NH_3 molecule desorption from strong acid sites [18]. The formation of a mesoporous framework resulted in a little decrease in the intensity of the surfactant-modified sample.

As mentioned earlier, the acidity plays a major role in the fluid cracking process. In this type of reaction, the existence of a strong acid sites can significantly alter the catalyst's performance. Based on NH_3-TPD analysis done by Emori et al. [22], the standard zeolite had acid sites capable of adsorbing ammonia on its surface. Their result showed low Si/Al ratio which explained the elevated acidity (large amount of acid sites). High acidity prevails when the aluminium acid sites, one of the acidity sources on zeolitic materials, are separated in this structure. These aluminium atoms were more acidic than those closer together in the zeolite structure. Again, Talebian-Kiakalaieh and Tarighi [1] also postulated that the HR-ZSM-5 sample demonstrated a 36% drop in overall acidity when compared to the parent ZSM-5 which due to the removal of Si or Al atoms from the zeolite framework [1]. Desilication resulted in a decline in Brönsted acidity, as well as a minor rise in Lewis acid sites, which had similar consequences.

Table 1. ICP-OES analysis and result of N_2 adsorption-desorption for the ZSM-5 and HR-ZSM-5[1]

Sample	**SiO_2**	**Al_2O_3**	**SiO_2/Al_2O_3**	**S_{BET} (m^2/g)**
ZSM-5	72.11	1.10	65.55	399
HR-ZSM-5	87.20	1.00	87.20	462

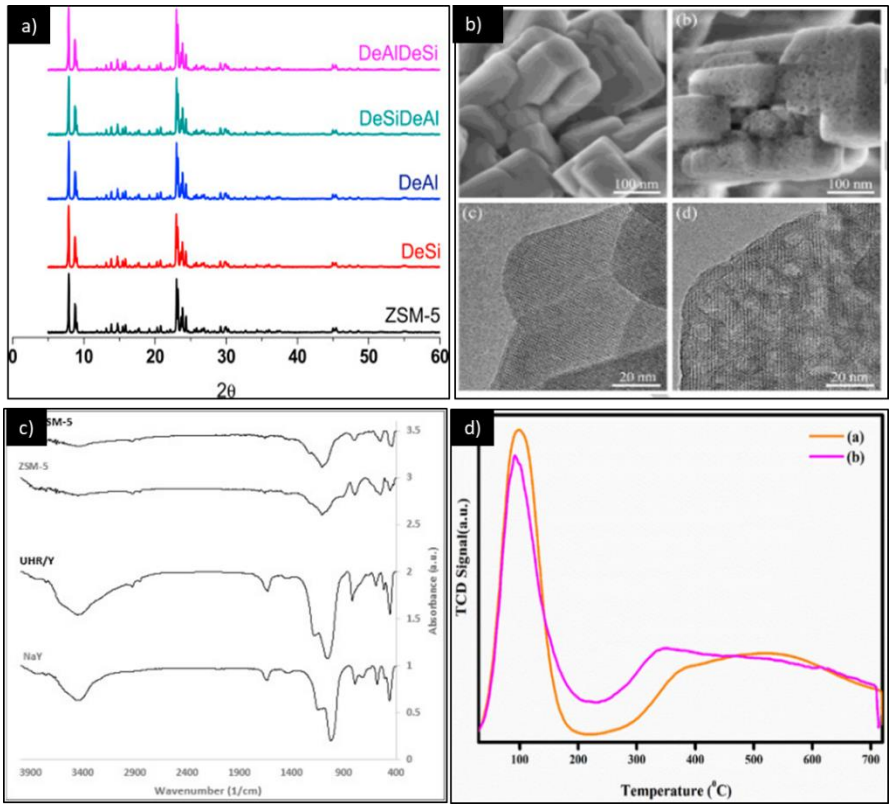

Figure 1. a) PXRD pattern for ZSM-5 [13], b) FESEM and HRTEM images of hierarchical zeolites [6], c) FTIR spectra for ZSM-5 and HR-ZSM-5 [1] and d) NH_3-TPD analysis of a) ZSM-5 b) HR-ZSM-5 [18]

According to Kantarelis et al. [23], the hydrothermal stability of the zeolite was critical for cleaning up coked catalysts. Moreover, they noted that post-treatment procedures increased the thermal stability of hierarchical samples by transforming the original zeolites' microporosity to a structure containing mesopores. Figure 2a depicted the impact of desilication on zeolite thermal stability, which they indicated had no influence on thermal stability as tested [23]. This is shown by the comparability of the mass and DSC curves following heating in an oxidative atmosphere. The observed differences in the two samples' actual thermal deterioration were linked to physiosorbed water, which happened when the samples were exposed to the atmosphere before being tested. Another study proposed that the synthesized parent and hierarchical zeolites in Figure 2b exhibited a single small weight loss in the 80-200 ℃ range, corresponding to physically adsorbed water and demonstrating the strong heat thermal of the catalysts [1]. Additionally, no weight loss was observed at temperatures beyond 200 °C, indicating that the catalysts were thermally stable. The high crystallinity explains the remarkable thermal stability of HR-ZSM-5. In contrast to the first assertion, Widayat and Annisa [8] proposed that the morphology of synthesized ZSM-5 was amorphous (Figure 2c-2d). The surface structure of the catalyst clustered together, while commercial ZSM-5 exhibited a separated structure owing to its very high crystallinity. However, as shown in Figure 2e-f, SEM pictures corroborated the hexagonal shape of ZSM-5 crystals with a size of that generated larger agglomerates [1].

Fluid catalytic cracking of gas oil

Fluid catalytic cracking (FCC) has emerged as the primary force behind oil refining performance improvement since its inception in 1942 [16, 24]. It has been discovered over time that FCC is a flexible process that can transform feeds of various origins, including vacuum oils, residual oils, crude oil, scrap tires, pyrolysis oil, polyethylene plastic waste, and biomass derived oils, into high value transportation fuels and light olefin feeds for the petrochemical industry [25, 26]. The feedstock quality has the greatest influence on the performance of the FCC unit (FCCU) across all independent factors [27]. The processing of secondary gas oils (from cokers, visbreakers, and residual hydrocrackers) is more difficult than the processing of straight run vacuum gas oils (SRVGOs) in the FCCU [16]. Secondary gas oils do in fact have larger levels of refractory condensed aromatic compounds and basic nitrogen [28]. Hence, the quantity and quality of the secondary gas oil fraction present in the FCC feed mix are directly associated to the performance of the FCCU [29, 30].

It has been reported that Microactivity Test (MAT) apparatus was used to catalyze the catalytic cracking of gas oil [12]. The catalyst activity test was conducted in the MAT unit (ASTM-D3907), which was a plug flow reactor (PFR) for cracking vacuum gas oil (VGO). The principal constituents of the cracking products, were hydrocarbons, oxygenated chemicals (mostly water, CO, and CO_2), and coke [12]. The gaseous hydrocarbon component was divided into dry gas (hydrogen, methane, ethane, and ethene) and liquefied petroleum gas fractions (LPG; propane, propene, butenes, and butanes). There are three different liquid hydrocarbons; C_{5+} gasoline (212 °C), light cycle oil (LCO; 221-360 °C), and heavy cycle oil (HCO; >360 °C), and these cracking products were examined using specific analytical tools including the MAT unit. The formula for the typical MAT conversion is (Y_{HCO} + Y_{LCO}) = 100%. The selectivity of propene has been calculated as a proportion of all C_3 hydrocarbons (C_3 olefinicity). The selectivity of butenes in total C_4 hydrocarbons is expressed as a percentage (C_4 olefinicity).

Meanwhile, according to Ibarra et al. [13], the catalytic cracking of the VGO was carried out in riser simulator. The product stream was collected from the reaction chamber using a fast-triggered vacuum pump attached to an auxiliary chamber (30 cm^3), and then evaluated online using gas chromatography (GC). They stated that the mass loss after burning of spent catalysts in a TGA-Q 5000 TA Instruments thermobalance, from 300°C to 550°C at a 3°C min^{-1} heating rate, was used to determine the amount of coke. Meanwhile, in literature experiment, they highlighted that VGO has been injected into the catalyst bed at a rate of 55 ml/h using a syringe pump in the presence of N_2 as the inert carrier gas (5–10 ml/min) at the correct temperature [1].

Equation. (1) and (2) have been used to determine the reaction conversion product yields:

$$Conversion(\%) = \frac{W_f - \frac{R \times W_i}{100} - W_Q}{W_f} \times 100 \quad (1)$$

$$Yield(\%) = \frac{W_i - X_i}{W_F} \times 100 \quad (2)$$

W_f is injected feed weight (g), W_L is liquid product weight (g), R is weight percentage (wt%) linked to the product evaporated up to 216℃, W_Q is liquid held up at reactor outflow (g) and W_i is each product's mass fraction [1].

Effect of HR-ZSM-5 mesoporous on the FCC activity

This section explored the effect of mesoporosity of synthesised hierarchical zeolites (HR-ZSM-5) on FCC catalyst activity and stability for the transformation of VGO to value-added chemicals such as gasoline, propylene, and olefins. It has been reported that zeolites with a mesoporous structure were able to boost the interaction between catalyst active sites and bulky molecules of feedstock (VGO) and ultimately increase the production of value-added chemicals such as gasoline, propylene, and olefins [1]. The reaction conversion (99.2%) and propylene yield (16.41 wt.%) obtained in their study were the highest than those obtained in the previous studies as shown in Figure 3, indicating that the synthesized FCC-4 catalyst had significant activity. Besides, García et al. [31] agreed that large molecules can be cracked more easily with hierarchical zeolites, which also provided selectivity for bulky intermediates. Furthermore, it was obvious that coke was formed at a faster rate for hierarchical catalysts but due to the presence of more saturated hydrocarbon molecules that resist in a hierarchical catalyst, coke that forms in a mesoporous structure would be easier to burn in the regenerator.

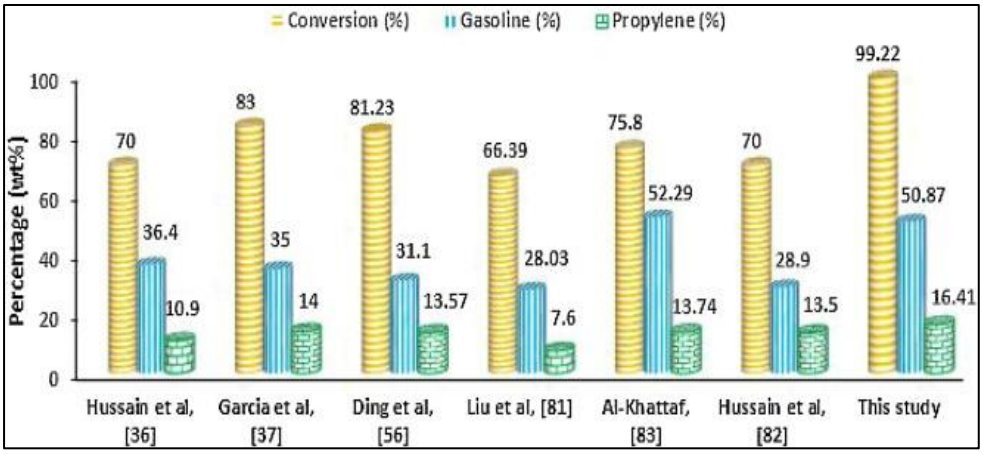

Figure 3. The analysis efficiency of FCC catalysts to other publications. The conversion, gasoline, and propylene yields were shown in comparison [1].

A recent study has discovered four different forms of fluid catalytic cracking (FCC) using HR-ZSM-5 zeolite, that was created by mixing the basic components, which include P_2O_5@ZSM-5, kaolin, Al_2O_3, $Ce(NO_3)_3.7H_2O$, and a binder [1]. Cerium has been used to control zeolite acidity while increasing catalyst acidity in the FCC catalyst framework. The FCC catalyst in a specific form was generated by placing the slurries in a spray dryer with an initial temperature of 210 °C and a mixing speed of 300 rpm. The catalyst was calcined for 4 hours at 650 °C. In another work, diammonium phosphate ($H_9N_2O_4P$) was immersed in distilled water to infuse with P_2O_5, then HR-ZSM-5 zeolite was added and refluxed for 2 hours [1]. The mixture was then dried for 12 hours at 70 °C before being calcined for 3 hours at 500 °C. Three distinct binders were employed in the manufacturing of FCC catalysts: alumina sol, a colloidal silica dispersion with an alkaline 40% aqueous dispersion (LUDOX-40), and alumina silica sol. It has been reported that the alumina sol binder was created by preparing 10 mL $Al(NO_3)_3.9H_2O$ solution (1 M), and 2.3 mL NH_4OH (25 wt.%) one drop at a time, and eventually adjusting the pH up to 4. Additionally, 1 g of aluminium sulphate was dissolved in 50 mL of water and the pH was adjusted to 2.5 by adding 20% H_2SO_4 dropwise. The physical and chemical characteristics of the FCC catalysts varied according to the use of various binders, with the alumina sol binder yielding the maximum activity and selectivity. The researchers also discovered that the calcination temperature had a substantial influence on catalyst performance, with higher temperatures leading to a lower activity and selectivity. This agglomeration in a meso and macroporous matrix results in the development of a hierarchical porous structure in the catalyst particle, which allows for sequential reactant dispersion and partial cracking of larger feedstock molecules, followed by cracking of the resulting chains within the catalyst's micropore structure.

Conclusion

Ultimately, the modified hierarchical framework of zeolite ZSM-5 through top-down and bottom-up techniques, which progressed via soft template through a combination of dealumination and desilication, has been comprehensively explained. Several experiments have been undertaken to increase the catalytic cracking performance of ZSM-5 zeolite, including catalytic cracking activity. Factors influencing ZSM-5 zeolite catalytic performance were reviewed from the viewpoints of ZSM-5 zeolite with particular shape, hierarchical ZSM-5 zeolite, and acid characteristics. By incorporating ZSM-5 zeolite with hierarchical structure, the diffusion length of a molecule may be lowered and the diffusion efficiency of a molecule can be raised. Template-assisted or post-treatment procedures may be used to create hierarchical ZSM-5 zeolites. The inclusion of mesopores or macropores boosted the

accessibility of acid sites in micropores, resulting in ZSM-5 zeolite with a hierarchical pore structure, which is particularly advantageous for post-treatment procedures that improve catalytic cracking efficiency. Characterization investigation revealed that the hierarchical catalysts had a substantial surface area and pore characteristics compared to parent samples. Moreover, the hierarchical zeolites demonstrated exceptional hydrothermal stability, making them an attractive alternativeto be used in FCC catalyst. Above all, options to increase catalytic cracking performance are still being evaluated in the laboratory, and it is critical to develop a low-cost and effective process for manufacturing hierarchical ZSM-5 zeolite. Hence, the catalytic cracking performance may be increased by inserting hierarchical ZSM-5 zeolite.

Abstract

The molecular structure of $Os_3(CO)_{11}(PPh_2(C_{10}H_7)).H_2O$ was investigated by a single crystal X-ray diffraction. The compound crystallizes in the triclinic, *P-1* space group with unit cell parameters a = 12.4377(14), b = 12.4413(13), c = 12.4718(13) Å, α = 87.3030(19), β = 63.7889(17) and γ =79.3982(19)°. The asymmetric unit of this structure consists of one-triangulo-triosmium complex molecule and one water molecules. The crystal packing of the title compound is stabilized by O–H···O and C–H···O hydrogen bonds as well as C–H···π interaction. The intermolecular interactions were investigated by Hirshfeld surfaces analysis, showing high contribution of O···H/H···O contacts. The molecular electrostatic potential and frontier molecular orbitals of the title compound were further investigated using Density Functional Theory (DFT), revealing that the nucleophilic regions are located at the carbonyl group. There is a large energy gap (6.095 eV) between HOMO and LUMO.

Keywords: triosmium, phosphine ligand, Hirschfeld surface analysis, crystal structure

Abstrak

Struktur molekul $Os_3(CO)_{11}(PPh_2(C_{10}H_7)).H_2O$ telah disiasat melalui pembelauan sinar-X hablur tunggal. Sebatian itu menghablur dalam kumpulan ruang triklinik, *P-1* dengan parameter sel unit a = 12.4377(14), b = 12.4413(13), c = 12.4718(13) Å, α = 87.3030(19), β = 63.7889(17) dan γ =79.3982(19)°. Unit asimetri struktur ini terdiri daripada satu molekul komplek *triangulo-triosmium* dan satu molekul air. Pembungkusan hablur sebatian distabilkan oleh ikatan hidrogen O–H···O dan C–H···O serta interaksi C–H···π. Interaksi antara molekul telah disiasat oleh analisis permukaan Hirshfeld, menunjukkan O···H/H···O adalah penyumbang utama interaksi. Potensi elektrostatik molekul dan orbital molekul sempadan bagi sebatian ini telah disiasat

selanjutnya menggunakan Teori Fungsian Ketumpatan (DFT), mendedahkan bahawa kawasan nukleofilik terletak pada kumpulan karbonil. Terdapat jurang tenaga yang besar (6.095 eV) antara HOMO dan LUMO.

Kata kunci: triosmium, ligan fosfina, analisis permukaan Hirshfeld, struktur hablur

Introduction

The chemistry of triosmium metal clusters with simple substituted tertiary phosphine has been thoroughly studied [1, 2, 3]. Several triosmium metal clusters were reported to exhibit a wide range of catalytic activity [4]. The geometric structure of the metal clusters significantly impact important catalytic activity in which certain geometric structures may interact with the intermediates in the catalytic process. Besides, metal clusters may give an insight to reaction mechanism that have limitations in mononuclear chemistry [5]. Due to their potential application in the catalysis, exploring new triosmium cluster with monodentate phosphine ligands is our research interest. In this study, the $PPh_2(C_{10}H_7)$ (diphenylphosphinonapthalene) ligand has been selected for substitution with $Os_3(CO)_{11}(CH_3CN)$ due to its versatility as a chiral ligand in some catalytic reaction [6, 7]. The reaction produced $Os_3(CO)_{11}(PPh_2(C_{10}H_7)).H_2O$ (**1**) in moderate yield and was successfully determined by a single-crystal X-ray diffraction. The crystal structure of this triosmium cluster was previously obtained from the reaction between $Os_3(CO)_{12}$ and 1,8-bis(diphenylphosphino)naphthalene (dppn) in the presence of trimethylamine oxide [8]. However, the previously reported crystal structure is slightly different from the title compound. The reported structure contains a dichloromethane whereas the title compound contains a water molecule. The title compound was synthesized using a different synthesis method. The present paper describes the X-ray crystallographic structure analysis, Hirshfeld surface analysis, and Density Functional Theory (DFT) calculations.

Materials and Methods

General techniques

All synthesis work was carried out under an oxygen-free-nitrogen (OFN) atmosphere using standard Schlenk techniques. Chemicals were purchased from Sigma-Aldrich and used as received. $Os_3(CO)_{11}(CH_3CN)$ and (diphenylphosphinonapthalene) ($PPh_2(C_{10}H_7)$) were prepared by the published procedure [6, 9]. The IR spectrum was recorded with a solid sample on an Attenuated Total Reflectance Fourier Transform Infrared (ATR-FTIR), Perkin Elmer 2000 FT-IR spectrometer. NMR spectra were recorded using a Bruker Ascend 500 MHz Spectrometer operating at 500 MHz (^{1}H) and at 202 MHz (^{31}P). Chemical shifts are given in ppm relative to TMS (^{1}H) and 85% H_3PO_4 (^{31}P). Product separation was performed on glass plates (20 X 20 cm) coated with 0.5 mm Silica Gel (Merck, $60GF_{254}$).

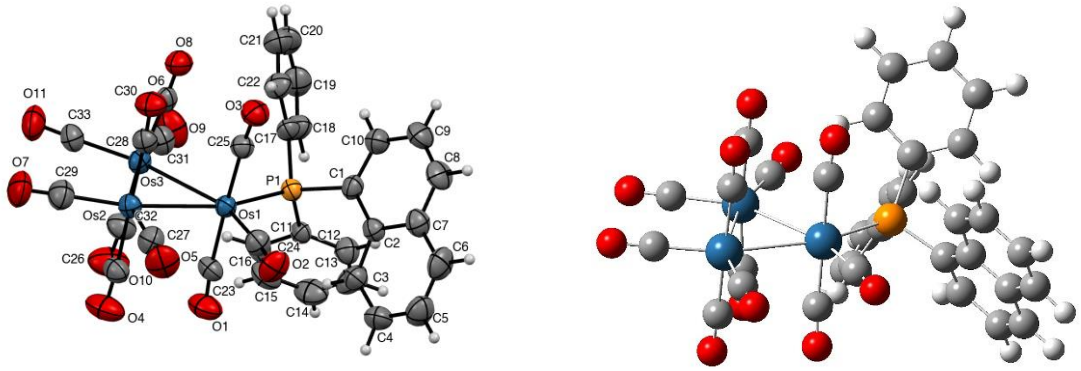
Synthesis and crystallization of 1

A solution of $Os_3(CO)_{11}(CH_3CN)$ (80 mg, 0.087 mmol) and $PPh_2(C_{10}H_7)$ (26 mg, 0.087 mmol) in dichloromethane (CH_2Cl_2) (25 mL) was stirred at room temperature for 60 min. The solution was dried in-*vacuo* and the residue chromatographed by preparative thin layer chromatography on silica gel with C_6H_{14}/CH_2Cl_2 (3:2) as the eluent. The desired product was isolated as the second (yellow) band in 50% yield and recrystallized from CH_2Cl_2/CH_3OH. IR (ATR): ν(CO) 2105m, 2050sh, 2011s, 2001s, 1984s, 1950s cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 7.98-7.41 (m, 17H, Ph, $C_{10}H_7$). ^{31}P NMR ($CDCl_3$): δ -2.34 ppm ($PPh_2(C_{10}H_7)$).

Single crystal X-ray diffraction

The single crystal X-ray diffraction study were grown from solvent-solvent diffusion of CH_2Cl_2/CH_3OH and collected on a Bruker SMART APEXII-DUO CCD area-detector diffractometer with graphite monochromatic Mo Kα radiation (λ = 0.71073 Å). The collected three-dimensional intensity data was performed using the APEX2 software [10], where the cell refinement and data reduction were performed using the SAINT program [10]. The structure was solved by direct method using the program SHELXLTL [11] and refined by full-matrix least-squares technique on F^2. The absorption correction was applied to the final crystal data using the SADABS software [10]. All the geometrical calculations were carried out using the program PLATON [12]. The anisotropic displacement parameters were refined for all non-hydrogen atoms. The molecular graphic and packing diagrams were drawn using

Mercury program [13].



Density functional theory (DFT) calculation

All DFT calculations were performed using the Gaussian09 [14] and the Gaussview5 software [15]. The initial molecular structure and geometry of **1** was obtained from the X-ray crystallographic data. The optimization of the geometry structure was achieved using M06-2X exchange correlation functional [16, 17] with LanL2DZ pseudopotential on Os and 6-31(d, p) Pople basis set for all other atoms [18, 19, 20]. The harmonic frequency calculations were performed at the same level of theory and the stationary points were verified to have no imaginary frequencies.

Results and Discussion

Single crystal X-ray diffraction

The molecular structure of the title compound consists a triangular arrangement of three Os atoms. The $PPh_2(C_{10}H_7)$ occupies the equatorial site with an assigned numbering scheme, as can be seen from Figure 1(a). Figure 1(b) is an optimize structure obtained by Density Functional Theory (DFT) calculation. The crystal structure of **1** is crystallized in a triclinic *P-1* space group and successfully refined with unit cell parameters, a= 12.4377(14) Å, b= 12.4413(13) Å, c= 12.4718(13) Å, α= 87.3030(19)°, β= 63.7889(17)°, γ = 79.3982(19)° and Z= 2. The crystal data and refinement details are presented in Table 1. The crystal of **1** differs to the previously reported structure by virtue of containing a water solvate. Selected bond length and bond angles are listed in Table 2. The bond length and bond angles from the X-ray diffraction are comparable to DFT calculation. The longest Os–Os bond (Os1–Os3) in **1** is Os–Os *cis* to $PPh_2(C_{10}H_7)$. This has been observed in many other $Os_3(CO)_9(PR_3)$ [where PR_3 = Group 15 monodentate ligand]. The elongation of this bond length has been ascribed to the effect of substituting a CO ligand with a PR_3 ligand [1, 21]. PR_3 ligand is a good σ-donor that promotes a higher electron density in the Os framework which is relieved by expansion [21]. The $PPh_2(C_{10}H_7)$ occupy equatorial position on Os1 with the value of Os–P bond length is 2.378 (2) Å and comparable to those in $Os_3(CO)_{11}PPh_3$ [2.370(2) Å] [1], $Os_3(CO)_{11}P(p\text{-}C_6H_4Me)_3$ [2.374(3) Å] [2], $Os_3(CO)_{11}(\eta^1\text{-}^tBu_2PC_2H_4CN)$ [2.394(5) Å] [6]. The Os–C(CO) bond lengths are in the range 1.880(8) - 1.963(10) Å, average 1,933 Å and in a good agreement with expected values [1, 2]. The Os–C–O bond angles (at equatorial) are essentially linear in the range from 176.97-179.65° whereas the Os–C–O bond angles (at axial) are 174.68-176.01°. In the crystal packing, the molecular structure of **1** is linked by O–H···O and C–H···O hydrogen bonds as shown in Figure 2. The presence of C–H···π interactions (Table 3) further stabilized the crystal structure.

Frontier molecular orbitals

The highest occupied molecular orbitals (HOMO) and the lowest unoccupied molecular orbitals (LUMO) are called as frontier molecular orbitals which principally determine the kinetic stability and reactivity of molecules [22]. The HOMO orbitals are mainly located at triangular Os atoms, CO groups and partially on the two phenyl rings. In contrast, the distribution of the LUMO orbitals are prominently accumulated at the naphthalene ring. The distribution of HOMO and LUMO are shown in Figure 3. The HOMO and LUMO orbitals are lying at -6.974 eV and -0.879 eV, respectively. Therefore, the energy gap is 6.095 eV. Generally, a larger energy gap implies a high kinetic stability and low chemical reactivity [23,24].

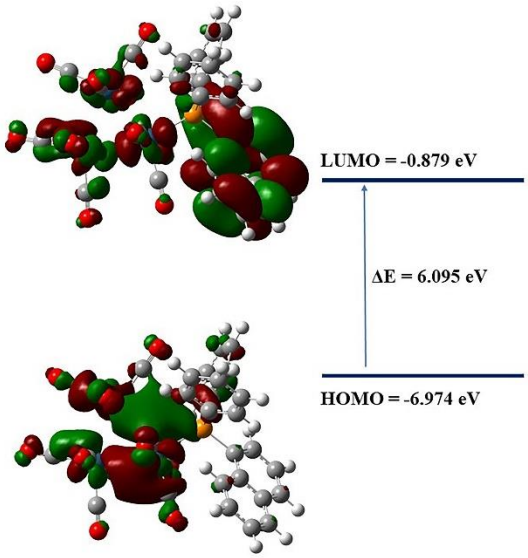

Figure 3. The HOMO-LUMO diagram of **1**

Molecular electrostatic potential

The molecular electrostatic potential (MEP) surfaces are regions around the molecule that provides a relevant guide about the net electrostatic effect at a point by the total charge distribution around the molecule. It also correlates with dipole moments, electronegativity, partial charges, and chemical reactivity of the molecule [25]. The MEP surface is computed using DFT at the 0.0004 a.u. isodensity surface, illustrated in Figure 4. As shown in the surface of **1**, the color code of the map gives the range values between -3.025×10^{-2} a.u (red) towards -3.025×10^{-2} a.u (blue). The regions of the respective colors indicating the most negative electrostatic potential (red) and the most positive electrostatic potential (blue) while zero electrostatic potential (green). The MEP surface showed the most negative regions (red) around the carbonyl groups which can be considered as possible nucleophilic sites. In contrast, the blue region indicates the positive regions suggesting electrophilic sites which are observed at the phenyl and naphthalene ring.

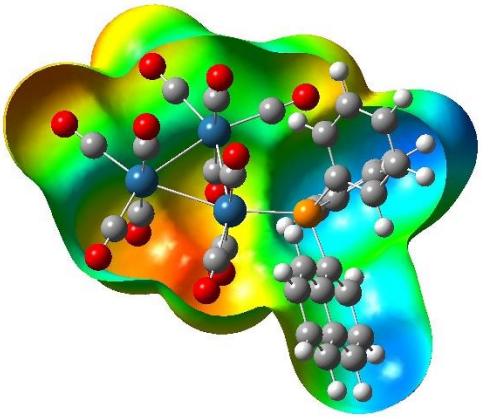

Figure 4. Molecular electrostatic potential diagram of **1**

Hirshfeld surface analysis

Hirshfeld surfaces and the associated 2D fingerprint were calculated using the CrystalExplorer 17.5 [26]. The Hirshfeld surface analysis was used to validate the contributions of the various intermolecular interactions in the crystal structure [27]. The 3D d_{norm} surface of the title compound is shown in Figure 5. The bright-red spot on the d_{norm} surface indicating the presence of strong hydrogen bond which connects the adjacent molecules *via* O1W–H1W1···O1W interaction. The 2D fingerprint plots of a Hirshfeld surfaces were successfully elucidated and delineated into O···H/H···O, H···H, C···H/H···C, O···O, O···C/C···O and C···C contacts are shown in Figure 6. The most dominant contributor on the Hirshfeld surface corresponding to the O···H/H···O contacts with the percentage of 42.8% correspond to C–H···O and O–H···O interactions. H··H (17.6%) contacts are the second largest contributor out of the overall Hirshfeld surface. The C···H/H···C (15.4%) contacts represented by the two wings of spike in the region (d_e~1.6 Å, d_i~ 1.0 Å). The other contacts which are O···O, and O···C/C···O, show the percentage contributions of 11.6% and 11.2%, respectively. The fingerprint of O···C/C···O shows a pair of spikes at (d_e~ 1.7 Å, d_i~ 1.5 Å). The least significant contributions come from the C···C contacts (1.3%) with respect to the total Hirshfeld surface area. On the other hand, the participation of C–H···π interactions can be further visualized under the shape-index surface mapping as illustrated in Figure 7. The presence of the orange spot indicates the existence of C–H···π interactions in the aromatic rings. These intermolecular interactions help to further stabilize the crystal structure of **1** [28].

Conclusion

A new structure of **1** was synthesized and confirmed by spectroscopy characterization and single crystal X-ray diffraction. The molecular structure optimized by DFT is consistent with the crystal X-ray diffraction data. Based on the comparison between the geometry parameters such as bond distances and bond angles, the values of the X-ray diffraction data fall within the expected range of the theoretical data by DFT. The Hirshfeld surface analysis reveal that the intermolecular interactions are dominated by O···H/H···O contacts with 42.8% contribution of total Hirshfeld surfaces, which stabilize the crystalline structure. In addition, the analysis on the frontier molecular orbital showed the title compound possess large energy gap (6.095 eV) which could be attributed to high kinetic stability.

Supplementary material

CCDC-2219979 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/consts/retrieving.html (or from the Cambridge Crystallographic data centre (CCDC), 12, Union Road, Cambridge CB2 IE2, UK, Fax: C44 (0)1223- 336033; email-deposit@ccdc.cam.ac.uk).

Abstract

By combining hydrogen bond donors such as D-sorbitol, glucose, and sucrose with hydrogen bond acceptors like L-proline and lactic acid, a successful preparation of six new types of eco-friendly solvent known as natural deep eutectic solvents (NADES) was achieved. Their capability as dispersive solvent substituting hazardous and non-biodegradability organic solvents was explored in vortex-assisted dispersive liquid-liquid microextraction (VADLLME) method for determination of anabolic steroid drugs in aqueous samples. Optimization combination of hydrogen bond donor-hydrogen bond acceptor and their molar ratio were investigated, and the result showed high viscosity of lactic acid: sorbitol at a molar ratio of 2:1, whereby recorded the highest extraction efficiency towards the determination of nandrolone and testosterone. This optimum NADES combination was then performed in three significant VADLLME procedures, including the volume of NADES as the dispersive solvent, type, and volume of extraction solvent. The VADLLME optimal conditions are as follows: NADES dispersive solvent volume of 500 µL, chloroform as an extraction solvent and extraction solvent volume at 200 µL. Under the optimum conditions, good linearity was achieved (0.5 - 10 mg/L) with the coefficient of determination (R^2) of 0.9990 and 0.9996 for the nandrolone and testosterone, respectively. The LOD values were recorded in the range of 0.0020 - 0.0117 mg/L, while LOQ values were recorded in the range of 0.0067 - 0.0392 mg/L, respectively. The developed NADES-VADLLME method was applied for the determination of nandrolone and testosterone in tap water samples, with relative recovery values ranging from 88.63 - 97.23%. Based on the results obtained, the developed method demonstrated excellent sensitivity for the extraction of nandrolone and testosterone in water samples. The prepared NADES showed great potential as an alternative green dispersive solvent for the extraction of anabolic steroids active contaminants in the aquatic system.

Keywords: natural deep eutectic solvents, dispersive liquid-liquid microextraction, anabolic steroid drugs, dispersive solvent, green analytical chemistry

Abstrak

Dengan menggabungkan penderma ikatan hidrogen seperti D-sorbitol, glukosa, dan sukrosa dengan penerima ikatan hidrogen seperti L-prolin dan asid laktik, penyediaan enam jenis pelarut mesra alam baharu dikenali sebagai pelarut eutektik dalam semulajadi (NADES) telah berjaya disediakan. Keupayaan mereka sebagai pelarut serakan menggantikan pelarut organik berbahaya dan tidak boleh terbiodegradasi telah diterokai dalam kaedah pengekstrakan mikro cecair-cecair serakan dibantu vorteks (VADLLME) untuk penentuan ubat steroid anabolik di dalam sampel akueus. Pengoptimuman gabungan penderma ikatan hidrogen dan nisbah molarnya telah disiasat dan hasilnya menunjukkan kelikatan asid latik:sorbitol yang tinggi pada nisbah molar 2:1 menunjukkan kecekapan pengkestrakan tertinggi terhadap penentuan nandrolon dan testosteron. Gabungan optimum NADES ini kemudiannya dilakukan dalam tiga prosedur utama VADLLME termasuk isipadu NADES sebagai pelarut serakan, jenis dan isipadu pelarut pengekstrakan. Keadaan optimum VADLLME seperti berikut: isipadu pelarut dispersif NADES 500 µL, kloroform sebagai pelarut pengekstrakan dan isipadu pelarut pengekstrakan pada 200 µL. Pada keadaan optimum, kelinearan yang baik telah dicapai (0.5 - 10 mg/L) dengan pekali penentuan (R^2) masing-masing 0.9990 dan 0.9996 untuk nandrolon dan testosteron. Nilai LOD direkodkan dalam julat 0.0020 - 0.0117 mg/L manakala nilai LOQ masing-masing direkodkan dalam julat 0.0067 - 0.0392 mg/L. Kaedah NADES-VADLLME yang dibangunkan telah digunakan untuk penentuan nandrolon dan testosteron di dalam sampel air paip, dengan nilai pemulihan antara 88.63 - 97.23%. Berdasarkan keputusan yang diperoleh, kaedah yang dibangunkan menunjukkan sensitiviti yang sangat baik untuk pengestrakan nandrolon dan testosteron dalam sampel air. NADES yang disediakan menunjukkan potensi besar sebagai pelarut dispersif hijau alternatif untuk pengestrakan bahan cemar aktif steroid anabolik dalam sistem akuatik.

Introduction

The misuse of anabolic drugs has been a crisis way before the pandemic, especially during international sports events. This drug is controlled and typically used to treat problems of hormone in males and Autoimmune Deficiency Syndrome (AIDS) patients that causes muscle loss [1]. Anabolic steroids, including testosterone, nandrolone, methandrostenolone, and others, were strictly used by professional bodybuilders for several decades. However, in recent times, recreational power athletes have regularly started using these drugs due to their impact on muscle growth and performance enhancement in sports [2-3]. The drug test was performed as a qualitative measurement in which it is a presumptive test that detects the drugs qualitatively, which includes opiates, methamphetamine, cocaine, amphetamines, marijuana, ecstasy, oxycodone, methadone, benzodiazepines, a tricyclic antidepressant, and PCP [4]. This urine test may provide a false-positive result that shows the presence of drugs even though a person has not used it, and this has raised some issues due to inaccurate results of the test, especially in forensic chemistry [5]. In order to identify the number of drugs present, the sample must be sent to the laboratory for further analysis and undergoes several steps prior to analysis. Nonetheless, drug testing has been improved in recent years, whereby the ability to identify long-term steroid metabolites, as well as more technologies, have enhanced that ability to detect metabolites at lower thresholds [6]. Nevertheless, these drugs are regularly being improvised to become accessible, which puts one step ahead of athletes to cheat. Each steroid tested in laboratories should store the baseline standards for reference in future testing and thus reducing the likelihood of a person to be tested positive only because the individual has higher levels of testosterone naturally compared to the general population. However, the laboratory test is time-consuming due to the multiple steps of analysis as well as the high labor and cost. Sample preparation takes up to 80% of the total analysis time and is critical in preparing the sample for analysis since it has a significant effect on analyte detection and quantification. These may include extraction, pre-concentration, clean-up, and derivatization steps before the analysis [7]. Therefore, the common conventional extraction methods such as liquid-liquid extraction (LLE) have been evolving into green extraction liquid-liquid microextraction (LLME) to determine drugs in

biological samples by miniaturizing the volume of the solvent and reducing the laborious steps.

Deep eutectic solvents (DESs) are a new class of green and inexpensive solvents. NADES has a variety of physiochemical properties, which gain its recognition as an alternative to ionic liquids and conventional organic solvents with biodegradability, non-flammability, and the potential as customizable for particular purposes [8]. Deep eutectic solvents (DES) consist of two non-toxic components that are mixed and form a new composition of solvent with a low melting point, low vapor pressure, low or negligible toxicity and biodegradable. The incredibly low melting point characteristic of this solvent is due to the formation of intramolecular hydrogen bonds within their molecular structure [9]. The hydrogen bonding between NADES effect varies in chemical properties such as polarity, viscosity, and hydrophilicity or hydrophobicity. In recent studies, DES has been applied as an extractant to substitute hazardous, costly, and non-environmentally friendly organic solvents in the extraction of organic pollutants [10]. For instance, Santana-Mayor et *al*. have successfully utilized DES as an extractant of phthalates and adipate from environmental water samples, with recoveries ranging from 70% to 127% [11]. Apart from that, Khezeli et al. employed DES as an extraction solvent of phenolic acids based on an ultrasonicated-assisted liquid-liquid microextraction method with high recoveries ranging from 94.7% to 104.6% in various vegetable oils samples [12]. Another type of deep eutectic solvent that is made up of primary metabolites components in living cells such as urea, amino acids, sugars, choline, and organic acids is called natural deep eutectic solvent (NADES) [13]. NADES is an alternative to DES due to continued safety concerns regarding DES. As a result, researchers have turned to natural sources and ingredients. A biodegradability in wastewater using microorganisms with closed bottle test, phytotoxicity test on wheat, and vitro toxicity test using fish and human cell lines were evaluated on choline chloride-based with glycerol, oxalic acid, and glucose and found that low toxicity in all tests, making them a great potential of green solvents in the applications of cosmetics, pharmaceutical, and food industry [14].

In this research, the utilization of NADES as a dispersive solvent is studied to substitute the toxic organic solvent in the DLLME method assisted by vortex agitation, abiding by the green chemistry principles. A dispersive solvent must be soluble in both organic solvent and aqueous phase [15]. NADES act as a disperser to assist the interaction of analytes in sample and extractant as well as favor the separation of two phases of sample solution and extraction solvent by allowing the formation of the cloudy solution containing tiny droplets, which speeds up the mass transfer process due to large contact surface area. The most common disperser solvents applied in DLLME are methanol, acetonitrile, and acetone [16]. Therefore, this study will focus on the vortex-assisted dispersive liquid-liquid microextraction (VADLLME) technique with the aid of DES as a dispersive solvent. The goal of this study was to develop a simple, rapid, inexpensive, and efficient sample preparation strategy for the measurement of testosterone and nandrolone in water samples prior to HPLC-DAD analysis. The technique is much simpler and eliminates the need for converting derivatization into a volatile phase during sample preparation. Additionally, it has the capability to simultaneously analyze multiple target analytes within a single run [17, 18]. Besides, this technique is trustworthy, particularly in clinical application fields such as toxicological diagnostic, therapeutic drug monitoring, and newborn screening. Various composition of NADES was studied from different hydrogen bond donor (D-sorbitol, glucose and sucrose) and hydrogen bond acceptor (proline and lactic acid), and molar ratio optimization was evaluated to obtain selective extraction on targeted analytes. The optimum NADES combination was then performed in three significant VADLLME procedures, including the volume of NADES as the dispersive solvent, type, and volume of extraction solvent.

Materials and Methods

Materials

Testosterone ($C_{19}H_{28}O_2$, ≥98%), nandrolone ($C_{18}H_{26}O_2$, ≥98%), lactic acid ($C_3H_6O_3$, 85%) solution ACS reagent, L-proline ($C_5H_9NO_2$, 99.5%) reagent standard, glucose ($C_6H_{12}O_6$, 99.5%) reagent standard, sucrose ($C_{12}H_{22}O_{12}$, 99.5%) reagent standard, D-sorbitol ($C_6H_{14}O_6$, 98%) reagent standard. Chloroform ($CHCl_3$, 98%), ethanol

(C_2H_6, 99.9%), acetonitrile (C_2H_3N, 99.9%) HPLC grade, 1-dodecanol ($C_{12}H_{26}O$, 98%), ethyl acetate ($C_4H_8O_2$, 98%), and dichloromethane (CH_2Cl_2, ≥ 99.8%) were all purchased from Sigma Aldrich.

HPLC instrumentation

The HPLC separations were carried out on a Dionex Bonded Silica C_{18} column (4.6 x 150 mm, 5 µm) (Acclaim™ Polar Advantage II) equipped with the ultraviolet detector and a 20 µL sample loop. The chromatographic condition was optimized by varying the mobile phase composition with acetonitrile-water, and the flow rate was set at 1.0 mL min^{-1} as well as the detection wavelength at 242 - 254 nm for all the analytes and recorded using Chromeleon software [19].

FTIR analysis

Attenuated Total Reflectance (ATR) Fourier Transform Infrared (FTIR) Spectroscopy (PerkinElmer, USA) was applied in this study to determine the functional groups and possible interactions between the NADES. The type of crystal used as zinc selenide. All the samples were scanned in the range of 650 to 4000 cm^{-1} for 16 times.

Preparation and optimization of NADES

NADES was prepared by varying a few parameters, such as the type of NADES and the molar ratio of NADES. Firstly, the optimization of different groups of hydrogen bond acceptor (HBA) (organic acid – lactic acid and amino acids – L-proline) with sugars (monosaccharide – glucose, disaccharide – sucrose, and alcohol sugar – D-sorbitol) as hydrogen bond donor (HBD) by mixing and heating the components at 80°C in sonicator until a homogenous solution is formed [20]. These selected NADES were proved to act as good dispersers in DLLME due to their properties of being highly soluble and denser than water which led the targeted analyte easily diffuse in extractant solvent and increased their recovery from environmental water samples [21]. The combinations of NADES studied were as follows: Proline: Sorbitol (Pro: Sor), Proline: Glucose (Pro: Glu), Proline: Lactic Acid (Pro: LA), Lactic Acid: Glucose (LA: Glu), Lactic Acid: Sucrose (LA: Suc), and Lactic Acid: Sorbitol (LA: Sor) followed by identifying the optimum HBA: HBD mixture as disperser solvent by using the different molar ratio as follow: HBA: HBD, 1:1, 1:2, 1:3, 2:1, 3:1. Figure 1 presenting the molecular structure of HBA components together with HBD components.

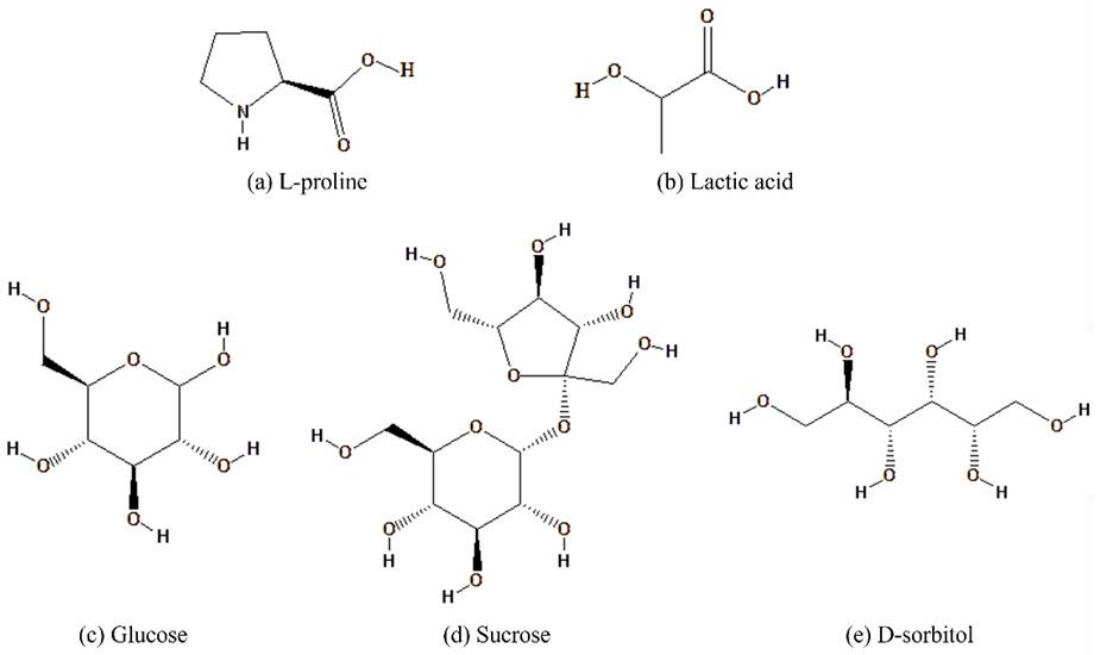

Figure 1. Molecular structure of HBA components: (a)-(b) and HBD components: (c)-(e)

Vortex-assisted dispersive liquid-liquid microextraction (VADLLME) procedure

The procedure began by adding extraction (chloroform) and dispersive (NADES) solvent into 5 mL of distilled water spiked with 1 mg/L of target analytes. The mixture was vortexed for 15 s until the formation of a cloudy solution and centrifuged for 10 min at 4000 rpm to form the two aqueous layers of phase. The bottom layer (organic phase containing analytes) was taken out and blown with nitrogen gas until dried. The dried organic phase was reconstituted in 50 µL of methanol and 50 µL of ultrapure water since chloroform cannot be directly injected into the instrument [19]. Then, the solution was injected into the HPLC system. Figure 1 shows the schematic diagram of VADLLME.

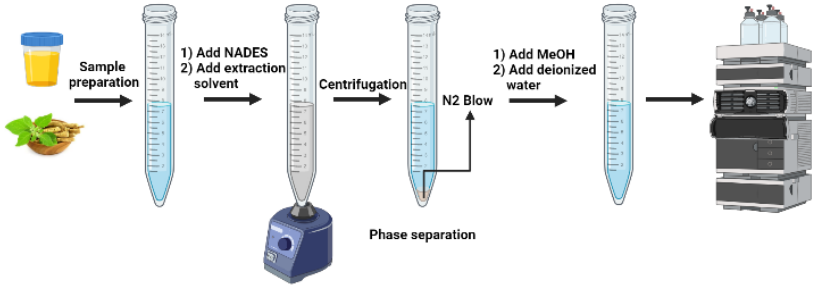

Figure 2. VADLLME process

Results and Discussion

FTIR analysis

FTIR analysis is commonly used to characterize a sample by determining the functional groups of the bonds and atoms within the molecules [22]. Thus, the hydrogen bonding formed in developed NADES was studied, including their functional groups. The wavenumbers for all synthesized NADES are recorded in Table 1. From the table, all the synthesized NADES showed a broad band at 3200 - 3600 cm^{-1}, indicating the formation of hydrogen bonds between the two components of HBA and HBD, as portrayed in Figure 3 (i). Apart from that, only Pro: Sor, Pro: Glu, and Pro: LA provided N-H bending at the range of 1609.3 - 1612.0 $cm^{-1,}$ which came from the functional group of L-proline and all synthesized NADES portrayed C-H stretching at the range of 2929.6 - 2992.1 cm^{-1}. The functional groups of all NADES except Pro: Sor and Pro: Glu displayed C=O of the carboxyl group between 1712.8 - 1723.7 cm^{-1}. Other medium-intense bands were observed at 1027.7 - 1222.9 cm^{-1} in which, indicating the C-O stretching of alcohol in their structure, as shown in Table 1. Besides, the C=O bond at 1719.8 cm^{-1} of lactic acid was shifted to the higher wavelength at 1721.7 cm^{-1} LA: Sor (1:1), as displayed in Figure 3 (ii), implying the formation of a hydrogen bond [23]. These prove that all the NADES were prepared successfully.

Table 1. Wavenumbers of IR for synthesized NADES

Type of NADES and Molar Ratio	Wavenumber (cm^{-1})				
	O-H Stretching	C-H Stretching	C=O Stretching	N-H Bending	C-O Stretching
Pro: Sor (1:1)	3288.2	2943.6	-	1612.0	1039.5
Pro: Glu (1:1)	3255.8	2929.6	-	1611.9	1027.7
Pro: LA (1:1)	3366.3	2992.1	1712.8	1609.3	1128.0
LA: Glu (1:1)	3335.9	2930.5	1721.2	-	1029.6
LA: Suc (1:1)	3320.5	2933.9	1723.7	-	1032.7
LA: Sor (1:1)	3336.2	2940.7	1721.7	-	1222.9
LA: Sor (2:1)	3352.2	2940.6	1721.5	-	1221.3

Figure 3 (ii) shows the correlation between lactic acid, sorbitol and LA: Sor mixture at molar ratios (1:1) and (2:1). In comparison between the molar ratio of LA: Sor (1:1 to 2:1), a few bands that significantly differed in intensity from each other was observed on Figure 3 (ii). In spectra for LA: Sor at molar ratio 1:1, the absorption band of OH at 3336.2 cm^{-1} was shifted to a higher wavenumber at 3352.2 cm^{-1} (molar ratio 2:1), proving the increasing number of hydrogen bonds formed in the NADES when the lactic acid molecule was increased as recorded in Table 1 [24-25]. Apart from that, the intensity at 1721.5 cm^{-1} and 1221.3 cm^{-1} of LA: Sor (2:1) were greater due to the greater number of the carboxyl group and C-O band, correspondingly because of the increasing number of the molecule of lactic acid [26]. Other than that, both spectra for LA: Sor molar ratio show identical absorption bands as parent lactic acid and sorbitol.

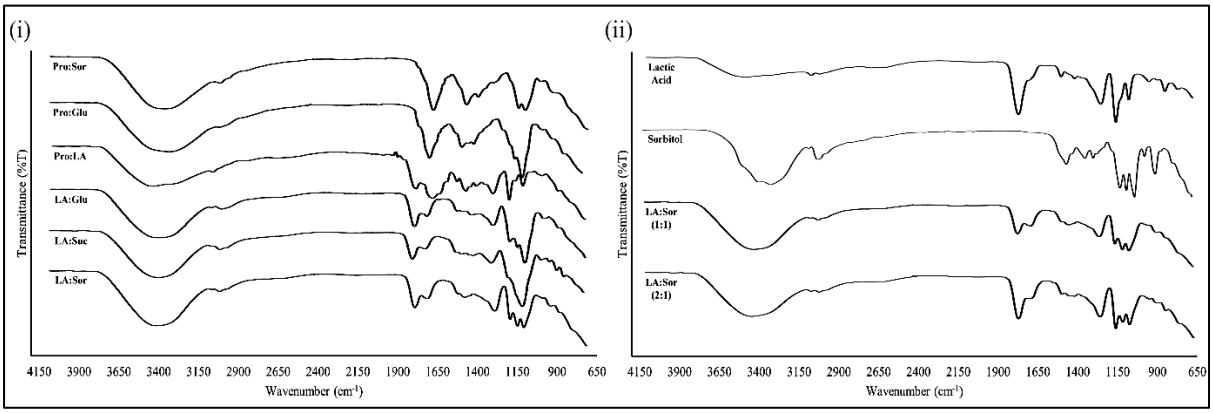

Figure 3. FTIR spectra of (i) synthesized NADES and (ii) lactic acid, sorbitol and optimized NADES (LA: Sor) at two different molar ratios (1:1 and 2:1)

Effect type of NADES (Different mixture of HBA: HBD) and it is the molar ratio

Disperser in DLLME is responsible for assisting the interaction of analyte towards extraction solvent. A tiny droplet of disperser properties contributes to the large surface area that enhances the mass transfer between two phases [27]. In order to determine the most appropriate NADES as the dispersive solvent, proline and lactic acid as HBA were prepared with various types of sugars (glucose, sucrose, and D-sorbitol) as HBD at the molar ratio of (1:1). The analytical results in Figure 4(i) showed the combination of NADES increasing as follows: (Pro: Sor < Pro: Glu < Pro: LA < LA: Glu < LA: Suc < LA: Sor). This indicates that the combination of organic acids with sugar alcohol as NADES prone to enhance the extraction efficiency of testosterone and nandrolone. Compared to all sugar in this study, sorbitol is a sugar alcohol which has a hydroxyl group with a straight chain structure compared to glucose and sucrose, which has a cyclic structure. This improves the solubility and viscosity of the sorbitol, which enhances the efficiency of lactic acid: sorbitol is a dispersive solvent [9, 28]. Therefore, LA: Sor NADES was selected for subsequent optimization of the molar ratio of NADES.

Herein, the most optimal molar ratio of HBA to HBD was determined to allow the appropriate number of hydrogen bonding formed in order to obtain higher extraction efficiency. It is explained that the more the hydrogen bonding, the more viscous the NADES resulting in a low capability to disperse in the sample solution [28]. Nonetheless, less hydrogen bonding formed means less viscous, and it could not provide the maximum efficiency as a disperser. Therefore, pertinent viscosity from the hydrogen bonding should be optimized from the molar ratio of the HBA and HBD. In this study, NADES with different molar ratios (1:1, 1:2, 2:1, 1:3, and 3:1) of lactic acid (HBA): sorbitol (HBD) were prepared accordingly, and their capability affecting the extraction of steroid drugs were determined. As demonstrated in Figure 4 (ii), the extraction efficiency has improved with an increasing number of moles up to two moles of lactic acid. This is explained by how the

structure of lactic acid consists of two HBA groups and by occupying those groups with one mole of sorbitol that might be existed as a stable compound [29]. When the molar ratio is 1:3 (LA: Sor) and 3:1, the analytical response declined slightly subsequently due to the high viscosity of sorbitol and lactic acid, respectively [30]. Hence, the desired molar ratio of lactic acid to sorbitol was chosen to be 2:1.

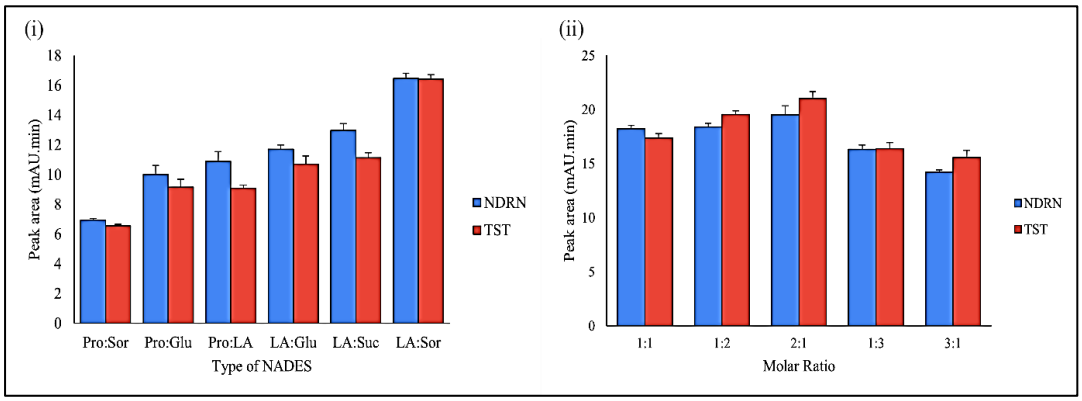

Figure 4. (i) Optimization of NADES combination and the (ii) molar ratio of optimized NADES (LA: Sor)

Effect volume of NADES

The volume of the disperser solvent causes changes in the sedimented phase volume (extraction solvent) and thus affects the extraction efficiency. Therefore, it is crucial to vary the disperser solvent volume and the extraction solvent volume simultaneously to achieve a constant volume of the sedimented phase containing analytes [16]. In the meantime, the ratio between the extraction solvent volume and the disperser solvent volume is also important, and it should be adjusted accordingly to form a cloudy solution. Hence, the impact of the volume of dispersion solvent on the extraction efficiency was investigated in the range of 200 - 600 µL. The volume of NADES that is lower than 200 µL was not evaluated as the volume of NADES must be the same or larger than the extractant to assist the partition coefficient of the analytes onto the extractant. During this optimization, one factor at a time approach was applied in the study, and thus, the extraction solvent was fixed at 200 µL. As depicted in Figure 5, the peak areas were gradually increased until 500 µL and declined slightly afterwards due to the dissolution of target analytes in the aqueous sample [31]. Therefore, the volume of NADES at 500 µL was optimized for further optimization.

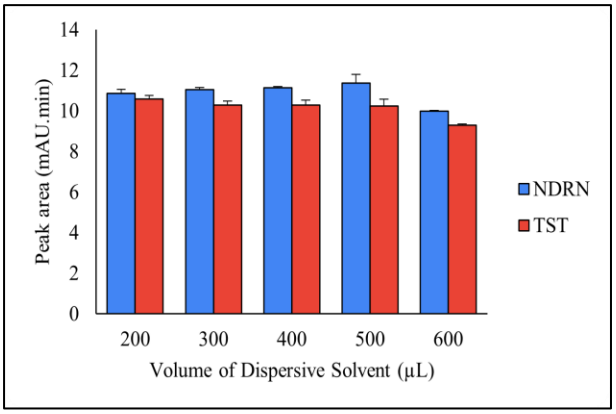

Figure 5. Optimization volume of dispersive solvent

Effect type and volume of extraction solvent

Choosing an appropriate organic solvent is significant to establish a successful microextraction method because its physicochemical properties should be suitable with the analytes for the extraction to occur. Various factors should be taken into consideration when selecting the appropriate extractant. For instance, the extraction solvent should be insoluble in water while having decent solubility of the target analytes, having a higher or lower density than the aqueous solution with high affinity for the analyte of interest and excellent chromatographic resolution. Furthermore, the extractant also must be soluble in the NADES prepared. For the extraction of steroid drugs, the selected solvent was investigated based on a previous study by [19, 32], including 1-dodecanol, ethyl acetate, hexane, dichloromethane and chloroform was experimented with as the potential extractant. However, only dichloromethane and chloroform formed a clear separation phase with an aqueous solution, while the other organic solvents did not form a clear separation phase at all or a very ambiguous phase separation formed. Based on the results tabulated in Figure 6 (i), chloroform provided the highest peak area for all the studied steroid drugs because chloroform is more non-polar and has high density than dichloromethane. This non-polar nature of chloroform significantly facilitates the isolation of non-polar anabolic steroid drugs resulting in good analytical response [29]. Thus, chloroform which provides high extraction capability for steroids, was selected as the extraction solvent for further optimization.

The volume of extraction solvent is key in extraction techniques. The amount of extraction solvent is required to be as minimal as possible for the purpose of environmental protection and to obtain an excellent analytical signal. Nonetheless, the amount should be large enough to ensure a sufficient amount of organic phase prior to chromatographic analysis and maximize the isolation of target compounds in the extractant [33]. Therefore, the impact of the volume of extractant on the extraction efficiency was studied in the range of 100 - 500 µL. The volume of chloroform that is lower than 100 µL was not evaluated as the amount of the extraction solvent left after extraction is insufficient, hindering the collection process. As outlined in Figure 6 (ii), 200 µL was observed to have a higher peak area, and there was an achievement in the equilibrium state of the extraction. At higher volume, the peaks of the analyte started to split and consequently, 200 µL of chloroform was employed in this study despite the volume of the sedimented phase [34].

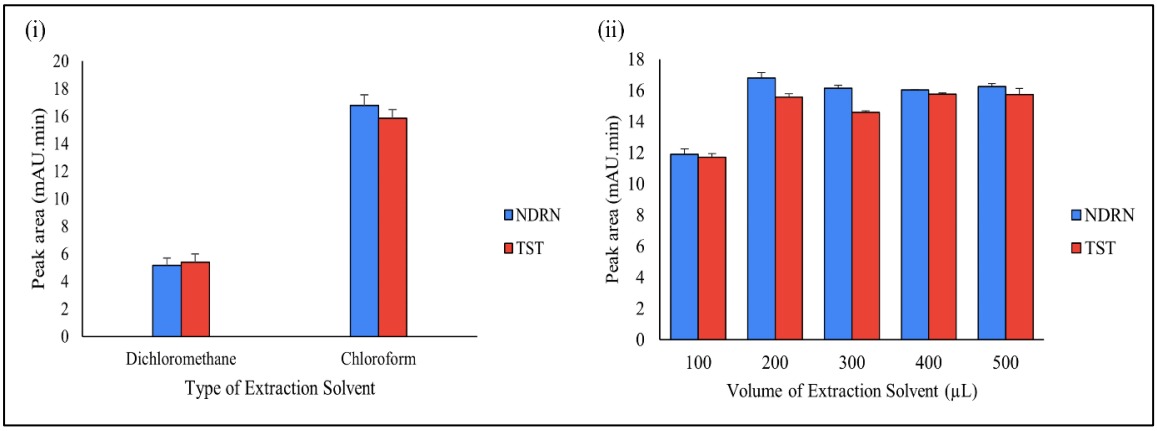

Figure 6. (i) Optimization type and (ii) volume of extraction solvent

Method validation

The capability of NADES (LA: Sor) as a disperser solvent was studied in a real sample solution to investigate the matrix effect on the extraction of anabolic steroids. Tap water samples were sonicated and filtered before being spiked with standard analyte concentrations ranging from 0.5 - 10 mg/L to construct a calibration curve. The analytical characteristics of the target steroid under optimized parameters are presented in Table 2. Both nandrolone and testosterone provide

dynamic linearity with an outstanding coefficient (R^2), 0.9996 and 0.9990, respectively. The value of LOD and LOQ was determined by using blank determination with the formula LOD = 3 *s/m,* while LOQ = 10 *s/m* is the standard deviation of blank signals, while *m* is the slope of the calibration curve. The values of LODs and LOQs showed to be in the range of 0.0020 - 0.0117 mg/L and 0.0067 - 0.0392 mg/L, respectively. The relative recoveries (RR) of both analytes have been found at 97% for nandrolone and 89% for testosterone at a spiking level of 1 mg/L with relative standard deviation (RSD), 0.79% and 0.42%, respectively. The precision of the method was determined in terms of intra-day and inter-day by spiking two analytes concentration (1 and 3 mg/L) into sample solution as listed in Table 3. Three replicates were employed to measure the intra-day on the same day and inter-day throughout 3 consecutive days. As shown in Table 3, the relative recovery of inter-precision for testosterone is considerably low, which can be explained by the degradation of the stock solution due to the nature of testosterone that is affected by light while conducting the experiment [35]. It is advised to keep the standard and stock solution short and out of light. The RSD values representing the precision of intra-day and inter-day appeared to be in the range of 0.05 - 0.20% and 0.07 - 0.35%, respectively. Figure 7 illustrates HPLC-DAD chromatograms of (i) unspiked, (ii) spiked with 1 mg/L and (iii) 3 mg/L of anabolic drugs of real samples. All peaks in spiked water sample extracts were finely separated with good resolution in less than 6 mins. Thus, the overall results suggest that this method could be satisfactorily applied for anabolic drug analysis and monitoring.

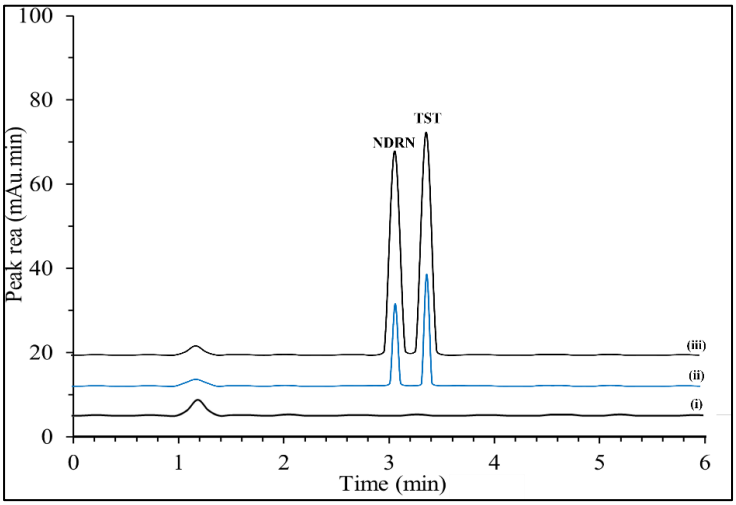

Figure 7. Chromatograms of HPLC-DAD of (i) unspiked, (ii) spiked with 1 mg/L and (iii) 3 mg/L of anabolic drugs in tap water under optimal conditions

Conclusion

The newly proposed NADES as a dispersive solvent in the DLLME technique provided remarkable linearity, acceptable LOD and LOQ, as well as outstanding precision values and satisfactory relative recoveries for the two target analytes under optimized conditions in which 97.23% for nandrolone and 88.63% for testosterone. The DLLME method in this research was employed successfully when extraction solvent was highly dispersed in the sample solution with the assistance of NADES as disperser by utilizing vigorous agitation of the vortex. Moreover, the newly prepared natural source of amino acid and organic acid-based NADES exhibited no toxicity to normal cell lines, affirming that the NADES used in this study is safe and green for the environment. Briefly, the proposed NADES in DLLME approach is environmentally favorable and practical for the extraction of drugs. NADES, in this study, is also expected to display great potential for the analysis of various organic contaminants, heavy metals, and other types of drugs.

Table 2. Analytical characteristics of the proposed procedure and recoveries of nandrolone and testosterone in tap water

Analyte	LOD (mg/L)	LOQ (mg/L)	Linear Range (mg/L)	R^2	RR (%)	RSD (%)
Nandrolone	0.0117	0.0392	0.5 - 10	0.9996	97.23	0.79
Testosterone	0.0020	0.0067	0.5 - 10	0.9990	88.63	0.42

Table 3. Precision (intra-day and inter-day) of the proposed method

Analyte	Concentration (mg/L)	Intra-Precision (n=3)		Inter-Precision (n=3)	
		RR (%)	RSD (%)	RR (%)	RSD (%)
Nandrolone	1	109.37	0.07	77.95	0.35
	3	94.12	0.05	93.59	0.07
Testosterone	1	116.41	0.20	61.09	0.25
	3	89.95	0.06	40.88	0.09

Abstract

Fluoroquinolones are used to treat and prevent serious bacterial infections. They are widely applied in the husbandry and veterinary areas as well as in the human medication scope. There is an emerging concern about the residues of fluoroquinolones in the environment. Once in the environment, especially in the water bodies, they will be taken up and accumulated in our livestock, which subsequently enters our body through our food resources. Therefore, the residues of fluoroquinolones in animal-based food are required to be monitored and assessed. The development of existing methods is crucial to provide accurate data on the fluoroquinolone residues in different food samples. This review presents an overview of the proposed methods from 2000 to 2022 for the analysis of fluoroquinolones in food samples. The extraction techniques were mostly combined with liquid chromatography and fluorescent detection. These methods allow for low detection limits and high recovery values. The ideal detection limit is less than 10 μg L^{-1}. The main drawback of the screening test is low sensitivity and it may provide false positive results. A quantitative analytical method is important in giving the most accurate result from the determination of fluoroquinolones residues in different food matrices. One of the important factors to allow a low detection limit is the extraction method used. The solid phase extraction methods are the most widely used method for sample preparation. In addition, the physical and chemical properties, classification, toxicology, side effect of fluoroquinolones and occurrence of these residues in food samples were discussed in this paper.

Keywords: antibiotics, fluoroquinolones, food, extraction

Abstrak

Fluorokuinolon digunakan untuk merawat dan mencegah jangkitan bakteria yang serius. Ia digunakan secara meluas dalam bidang penternakan dan veterinar serta dalam skop perubatan manusia. Terdapat kebimbangan yang timbul tentang sisa fluorokuinolon di alam sekitar. Apabila berada di alam sekitar, terutamanya di dalam air, ia akan diambil dan terkumpul dalam ternakan kita, dan seterusnya memasuki badan kita melalui sumber makanan kita. Oleh itu, sisa fluorokuinolon dalam makanan berasaskan haiwan perlu dipantau dan dinilai. Pembangunan kaedah sedia ada adalah penting untuk menyediakan data yang tepat tentang sisa fluorokuinolon dalam sampel makanan yang berbeza. Kajian ini membentangkan gambaran keseluruhan kaedah yang dicadangkan terutamanya dari 2000 hingga 2022 untuk analisis fluorokuinolon dalam sampel makanan. Kaedah pengekstrakan yang paling

banyak bergabungan dengan kromatografi cecair dan pengesanan pendarfluor. Kaedah ini membenarkan had pengesanan rendah dan nilai pemulihan yang tinggi. Had pengesanan yang ideal adalah kurang daripada 10 μg L^{-1}. Kelemahan utama ujian saringan ialah kepekaan yang rendah dan ia mungkin memberikan keputusan positif palsu. Kaedah analisis kuantitatif adalah penting dalam memberikan hasil yang paling tepat daripada penentuan sisa fluorokuinolon dalam matriks makanan yang berbeza. Salah satu faktor penting untuk membenarkan had pengesanan yang rendah ialah kaedah pengekstrakan yang digunakan. Kaedah pengekstrakan fasa pepejal ialah kaedah yang paling banyak digunakan untuk penyediaan sampel. Di samping itu, sifat fizikal dan kimia, klasifikasi, toksikologi, kesan sampingan fluorokuinolon dan kejadian sisa ini dalam sampel makanan turut dibincangkan dalam kertas ini.

Kata kunci: antibiotik, fluorokuinolon, makanan, pengekstrakan

Introduction

Antibiotics have been used since old times. The first modern antibiotic, namely penicillin was discovered by Alexander Fleming in the 20th century. Penicillin has been widely applied in wartime mainly because no significant medicine is available to treat infections such as pneumonia, gonorrhoea or rheumatic fever [1]. The introduction of antibiotics has been recognised as one of the greatest inventions due to its effectiveness in treating various diseases in the form of microbial. Since penicillin was recognised in World War II, it has been manufactured in massive-scale production, making it a life-saving substance from the limited supply into a widely available medicine.

Antibiotics are antimicrobial substances that fight against bacteria. It is one of the most efficacious medicines that fight against bacteria and infection. However, virus-form diseases such as flu cannot be treated by antibiotics. Generally, the immune system in our bodies produces natural killer cells to function as bacterial killers. However, when the rapid propagation of bacteria occurs in our bodies, our immune system fails to cope with the infection. Therefore, antibiotics are needed to assist in curing infections. Antibiotics can be classified into several groups based on the type of action, sources to make antibiotics, the spectrum of activity, chemical structure and function of the antibiotics [2]. In the early stage, antibiotics are introduced from the natural plant extract while in the latter day, it has been produced chemically either in the form of fully synthetic or semi-synthetic. To date, the application of antibiotics has been widespread and extended to prevent and treat bacterial infection in the veterinary, aquaculture and domestic fields. In the United States, antibiotics are employed in livestock to speed up growth and increase the size of animals bred for food [3]. In aquaculture enterprises, antibiotics are frequently applied to those aquafarming organisms with impairing immune systems. Some household cleaning products are fortified with synthetic antibacterial, antiseptic and antimicrobial substances especially triclosan against bacteria on the household surface [4].

The issue of antibacterial resistance detected in humans has become the biggest concern nowadays with the widespread application and improper use of antibiotics. In consequence, the bacteria may mutate and emerge into the immortal stage, making resistant bacteria survive antibiotic treatment. This will then threaten our lives, causing antibiotics to be ineffective in treating diseases. Fluoroquinolones are one of the frequently applied antibacterial in food animals. Fluoroquinolones are used to treat enteric infections and respiratory diseases. This antibiotic possesses low toxicity and it can fight a broad spectrum of pathogenic bacteria towards farmed animals [5]. Therefore, the food animals sold may retain the trace residue of fluoroquinolones and the transmission from food to humans may be biomagnified.

Physical and chemical properties of fluoroquinolones

Fluoroquinolones are a group of broad-spectrum antimicrobial drugs from the class of quinolones with the attachment of the fluorine group in the ring. It is active against Gram-negative and Gram-positive bacteria [6]. As shown in Figure 1, the position of R_1 increases the potency of the molecules where the alkyl substituent is usually attached to it. R_2 and X improve the activities of both Gram-negative and Gram-positive. F refers to the fluorine atom that increases the Gram-

negative activity and the position of R_3 increases only the Gram-positive activity [7]. Different classes of fluoroquinolones have different substituent rings attached to them and thus affect the physical and chemical properties in terms of solubility in different parts of the membrane in the body. Fluoroquinolones are effective in the inhibition of bacterial chromosome replication and long-established in treating respiratory diseases and bacterial infections in food animals [8]. Fluoroquinolones are synthetic antibacterial agents which are not derived from living organisms [9]. Recently, there is a report on quinolone resistance due to bacteria mutation as a result of improper overuse of this antibiotic [10].

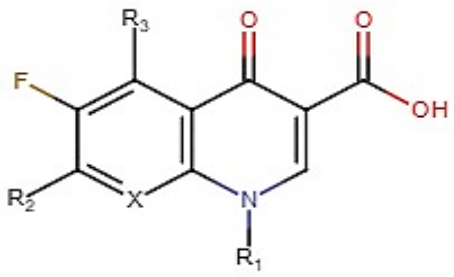

Figure 1. Molecular structure of fluoroquinolones. Ciprofloxacin denotes as X=C-H, R_1=cyclo propyl, R_2=piperazinyl, and R_3=H. Gatifloxacin denotes as X=C-OMe, R_1=cyclo propyl, R_2=piperazinyl, and R_3=H. Ofloxacin denote as X and R_1=benzoxazine, R_2=piperazinyl, and R_3=H

Generally, fluoroquinolones can be absorbed well in gastrointestinal and endocrine organs, as well as penetrate through the bones and cerebrospinal fluid. The partitioning coefficient (log K_{ow}) and bioconcentration factor (BCF) values of fluoroquinolone are considered low [11]. Fluoroquinolones are slightly water soluble over a pH range from 6 to 8 which is known as amphoteric character, acting as base and acid. They can be absorbed via oral administration [12] as well as injection. For instance, ciprofloxacin is a light-yellow crystalline substance with a melting point of 255-257°C and the water solubility is 86 mg L^{-1} at 25°C [13]. Flumequine is a white powder which is insoluble in water but soluble in organic solvents [14]. Thus, the flumequine is absorbed in the lipid membrane and it possesses strong stability. The melting point is 253-255°C.

Fluoroquinolone antibiotics

Fluoroquinolones are used to treat serious bacterial infections, especially infections in the skin, bone, joint, urinary tract and respiratory tract. It is also widely applied in husbandry and veterinary fields to prevent the action. Fluoroquinolone is a strong antibiotic where it can easily penetrate the body cells and destruct the DNA in the cell. However, it cannot treat serious contagious infections such as colds and flu [15].

Classification of fluoroquinolones

More and more fluoroquinolones are being invented and it is hard to prescribe antibiotics. The most common synthetic fluoroquinolone antimicrobial is ciprofloxacin which is the cheapest and most frequently employed in treating animals [16]. The position of fluorine atoms substituted in each molecule seems to enhance the phototoxicity and their origin modification [17]. This enhancement provides more effective microbial activities and broadens the spectrum of activities. However, this modification also increases bacteria resistance. Table 1 shows the classification of fluoroquinolones according to their antimicrobial spectrum.

Table 1. The classification of fluoroquinolones [18]

Classification	Examples of Agents	Antimicrobial Spectrum	Indication
First generation	Nalidixic acid, Cinoxacin	Gram-negative organisms except for Pseudomonas species.	Uncomplicated urinary tract infections.
Second generation	Norfloxacin, Lomefloxacin, Enoxacin, Ofloxacin, Ciprofloxacin	All gram-negative organisms but some gram-positive organisms.	Uncomplicated and complicated urinary tract infections, pyelonephritis, sexually transmitted diseases, prostatitis, and skin infection.
Third generation	Lexofloxacin, Sparfloxacin, Gatifloxacin, Moxifloxacin	Expanded spectrum in gram-positive coverage, atypical pathogens.	Acute exacerbations of chronic bronchitis, and pneumonia.
Fourth generation	Trovafloxacin	Broader coverage than the third generation.	Abdominal infections, nosocomial, pneumonia, pelvic infections.

Transmission route of fluoroquinolones into human

Fluoroquinolone's main administration is via oral but some fluoroquinolones are taken intravenously [19]. The fluoroquinolones are manufactured in tablet or capsule forms. The fluoroquinolones enhance their function by inhibiting the bacteria from building the cell wall and altering the ability to the reproduction of the bacteria. When fluoroquinolones are consumed, they penetrate the membrane and are stored in the gastrointestinal tract, which is then absorbed as nutrients. After a while, they circulate in the blood and reach the target bacteria [20].

Fluoroquinolones can be transferred through the maternal plasma into breast milk. The rate of transmission depends on the maternal factor, physiochemical properties and infant factor [21]. The composition of particular breast milk and the pH affect the number of antibiotics transferred. However, fluoroquinolones are most likely to concentrate in the plasma compared to breast milk because fluoroquinolones are weak acidic drugs [22]. Hence, the antibiotic has a lower chance to transmit to the infant. Indeed, fluoroquinolones are not recommended for breastfeeding mothers although ciprofloxacin is proven with no harm to both the breastfeeding mother and the infant [23-24].

Some of the transmission of fluoroquinolones is from food-producing animals such as livestock and poultry [25]. The by-products especially meat, dairy products and eggs may contain the residue of fluoroquinolones and thus food chain is also one of the transmission sources.

Transmission route of fluoroquinolones into animal

The fluoroquinolones used in livestock, poultry and veterinary are not only for the treatment of the illness of animals but also for illness prevention. This practice has been a part of the modern food-animal production industries. The utilization of the antibiotic as a therapy for preventing bacteria and promoting growth [26]. In general, antibiotics are added to feed for growth promotion [27]. The dosage applied for growth promo-

tion might be low, but it is a long-term application. Their accumulation of the antimicrobial is then causing drug resistance in the tissues of these animals. Fluoroquinolones are prescribed to treat gastrointestinal infections and microbiota modification in the intestine, as well as enhance the immune system [28]. The fluoroquinolones are given in form of oral, by injection, by drinking water, intra-mammary and mostly by feeding [25]. For example, enrofloxacin is injected into cattle for the treatment of bovine respiratory disease [29].

Effects of fluoroquinolones towards living organisms

Fluoroquinolone residues have brought a lot of negative effects on humans and animals. The maximum residue limits of some fluoroquinolones from liver, muscle and kidney tissues, such as enrofloxacin, and ciprofloxacin have been established as no more than 200, 100, and 300 μg kg^{-1}, respectively by European Union [30], as summarized in Table 2.

Table 2. Maximum residue limits of fluoroquinolones by the European Union [30]

Fluoroquinolone Active Substances	Marker Residue	Animal Species	MRL (μg/kg)	Target Tissues
Enrofloxacin	Sum of enrofloxacin and ciprofloxacin	Bovine, ovine, caprine	100	Muscle
			100	Fat
			300	Liver
			200	Kidney
			100	Milk
		Porcine, rabbit	100	Muscle
			100	Fat
			200	Liver
			300	Kidney
		Poultry	100	Muscle
			100	Skin and fat
			200	Liver
			300	Kidney
		All other food producing species	100	Muscle
			100	Fat
			200	Liver
			200	Kidney

Side effects on human

The most general side effects of fluoroquinolones are diarrhoea, vomiting, nausea and dyspepsia which belong to indigestion problems. One of the serious adverse side effects is the central nervous system (CNS) effect which will lead to headaches, dizziness, convulsion and confusion. Dairy products which consist of fluoroquinolones, especially the ciprofloxacin will cause accumulation in the cartilage of bones and arthropathy which then lead to joint's disease, as well as foetal impairment [31]. According to the United States Food and Drug Administration (USFDA) (2018), fluoroquinolones increase the risk of mental health including disturbances in attention, nervousness, disorientation, as well as memory impairment [32]. Some people get serious blood sugar disturbances such as hypoglycaemia, which is suffering from low blood sugar.

Side effects on animals

Fluoroquinolones are evenly applied in veterinary medicine, cattle management and aquaculture. The application of fluoroquinolones has resulted in diffuse retinal degeneration which then leads to blindness in animals [33]. However, it depends on the accumulation of drugs and the duration of the treatment. Some of the

side effects that occur in animals from the drug administration are similar to humans.

Antibiotics resistance of fluoroquinolones

The residues are risky to public health as the stimulation of bacterial resistance is getting worse and the bacteria may be mutated in the tissues [34]. Fluoroquinolones are broad-spectrum antibiotics which accelerate the spread and development of the multi-drug resistant strain. Overuse of antibiotics leads to the change and elimination of their effectiveness which then causes difficulty in curing the serious infection. For instance, medical advance treatments like organ transplantation, cancer chemotherapy and some major surgery need antibiotics for the prevention of infection [35]. The bacterial resistance may jeopardise these treatments. According to Institute for Medical Research (IMR), gram-negative bacilli such as E. coli have shown resistance to one of the fluoroquinolones, ciprofloxacin. The rise of fluoroquinolone resistance infections in Malaysia is mainly due to medical control practices and animal husbandry [36].

Restriction of fluoroquinolones in food products

To address the bacterial resistance issues, the Food and Drug Administration (FDA) has warned about the effect of overusing fluoroquinolones, that these antibiotics are only applied when there are no alternative treatment options [32]. Several restrictions have been applied to the use of fluoroquinolones by the FDA. Some of the classes of the fluoroquinolones such as Marbofloxacin which is generally applied in veterinary medicine and cattle management have been banned due to their high absorptivity and penetration into the tissue [33]. According to European Medicines Agency (EMA's) Pharmacovigilance Risk Assessment Committee (PRAC), fluoroquinolones are not recommended in treating mild infection and lower urinary infections [37]. According to the European Union (EU), fluoroquinolones as growth promoters have been banned in food processing animals because they are considered a non-essential antibiotic [36].

Poultry is the most important food industry in Malaysia as poultry including beef, chicken and pork are the main protein sources for Malaysian [38]. According to Lai (2020), 49.4 kg of poultry meat is consumed per person in 2020. The consumption of poultry has increased by 40% from 2006 to 2019 and it is estimated to exceed 50 kg in 2025 [39]. In poultry farming, fluoroquinolones are often used for therapeutic. The most common fluoroquinolone used in poultry production is enrofloxacin (ENRO). The application of other groups of fluoroquinolones such as flumequine (FLU), danofloxacin (DANO), difloxacin (DIFLO), oxolinic acid (OXO) and sarafloxacin (SARA) has been licensed in the European Union (EU) and these medicines are only allowed for veterinary medicinal treatment but not for growth promoter [40]. The use of ENRO for the treatment of bacterial infections in poultry has been banned in 2005 according to USFDA. This was due to the presence of Campylobacter resistance species in chickens cured with this antimicrobial. Fluoroquinolones no longer inhibit the growth of Campylobacter in poultry as the fluoroquinolones-resistance Campylobacters have been detected in poultry faeces [41]. This indicated that the antibiotics have accumulated in the animal body and contaminated the agricultural production indirectly as the excrement may be the organic fertilizers to the fruits and vegetables [42]. It caused antibiotic pollution in the soil and affected the nutrition intake of the crops. Apart from being released to the land, the antibiotics may be accumulated and they may either leach into groundwater or be transported to the surface waters [43]. Since poultry has been improved from a small food production unit to a large-scale supply chain over these years, the spread of antimicrobials is increasing dramatically. The use of antimicrobials in food-producing animals has to be controlled and restricted under Maximum Residue Limits (MRLs).

As mentioned earlier, the antibiotics that are not fully absorbed in the animals will be excreted in faeces and this will contaminate the soil system [44]. Soil manure which consists of animal faeces, compost and green manure is great in providing fertility to the soil. It contains the main nutrients required for vegetable growth. However, the repeated fertilisation in the agriculture farming system with the soil manure has led to the accumulation of antibiotics in the soil, and in turn,

to food such as vegetables and fruits [45]. There is lacking research on the accumulation of antibiotics in ripened plants, although the antibiotics uptakes are mainly via leaves and roots [46]. The presence of antibiotics has affected plant growth and the seed germination process indirectly. Although the detection of fluoroquinolones was only 0.2 mg kg^{-1} in soil manure, the biotransformation of antibiotics from the soil to the plants could occur, leading to the promotion of antibiotic resistance to humans, animals and the environment [47]. Although the residues of antibiotics in soil (8.4%) are more than in crops (5.6%), the accumulation can be increased with large-scale production of crops and the rise of crop consumption by humans [48].

Some of the antibiotic contamination in the environment is caused by antibiotic manufacture. According to Fick et al. the concentration of quinolones was found 14 mg L^{-1} in the wastewater effluent. It may be caused by the illegal dumping of antibiotic residues and this affected the surrounding environment including the groundwater and the soil [49]. Thus, the runoff of surface water or leaching of groundwater will affect the crop indirectly, affecting the consumers' health. Moreover, the transport of the residues in the waterway may influence the aquatic organisms [50].

Antibiotic residues can be detected in other food, especially honey and baby food. Honey is a natural by-product that is mainly used for nutritional and medicinal purposes. It contains hydrogen peroxide which was used to be an antibacterial treatment in old times. The unusual antibiotic residue found in honey was mainly caused by the environment and inappropriate beekeeping practices [51]. The sugar syrup solution which is mixed with the antibiotics is introduced into bee hives and consumed by bees [52]. This leads to antibiotic contamination in honey. Research revealed that the honey consisted of antibiotics residues namely oxytetracycline and chloramphenicol that exceeded regulatory values [53]. Although the European Community regulations did not set up the MRL for antibiotics in honey, the use of antibiotics in bee farming has been banned by some countries [54].

Some the fluoroquinolones such as ciprofloxacin, levofloxacin and moxifloxacin are used to treat infection of the urinary tract, pneumonia and mycobacterium tuberculosis in paediatrics. However, fluoroquinolones are banned for paediatrics in Korea because the study showed that fluoroquinolones have lost their function gradually in treating multidrug-resistant infections [55]. Some of the meat containing baby food such as beef and chicken might contain antibiotics residue too. There are lacking regulations and legislation concerning the tolerance value of fluoroquinolones in processed food [56]. Apart from meat and vegetables, the egg is an important protein source for children. When the animals are injected with veterinary drugs, the residues remain in various tissues in the body, carrying the residues to the eggs laid directly. Moreover, antibiotics are also used in farmed fish to treat diseases by treating the water or aquaculture. This results in the spread of the residues among humans and the environment [57].

Sample preparation for the extraction of fluoroquinolones in food

Several studies are reporting the detection of fluoroquinolones in animal-based food such as milk, honey, chicken, egg, beef and yoghurt. Therefore, it is important to determine the antibiotic residues in food to guarantee food safety and ensure the consumer health policy.

Screening assay testing

Screening assay testing is commonly applied as a semi-quantitative method to identify the presence of the analytes in the sample. Screening is one of the easiest, most rapid and low-cost assay methods that provides high reproducibility and reliable results.

The presence of ciprofloxacin can be detected by β-gal colorimetric assay. This assay is commonly used in inspecting cultured cells and recognising the recombinant fusion genes. It provides a linear correlation between the bacteria inside the fluoroquinolones and β-gal activity. Ortho-nitrophenyl-β-galactoside (ONPG) increases the sensitivity of β-gal activity detection in ciprofloxacin [58]. The interaction between bacteria strains with antimicrobial detection in milk has proven its specificity without giving false

positive results. One of the greatest benefits of using the screening method is less amount of additional reagent is required. The screening method usually examines the optical density (OD) and the growth curve of the bacterial strain [59]. Although screening testing is simple and able to give a rapid response, it only detects the presence of fluoroquinolones without sufficient sensitivity [60].

Chromatographic techniques

From 2000 to 2022, liquid chromatography is still the most frequently employed quantitation instrument for the determination of fluoroquinolones. It is always coupled to sample preparation such as solid phase extraction, micro-solid phase extraction, and dispersive liquid-liquid microextraction to eliminate matrix effects and improve sensitivity.

Solid phase extraction

Solid phase extraction (SPE) is a sample extraction technique that concentrates and purifies analytes from complex sample matrix by sorption onto sorbents loaded in a cartridge device. The SPE isolates a species from a sample or cleans up a sample before analysis using an instrument. The general steps in performing SPE are washing, conditioning, loading and eluting. Compared to liquid-liquid extraction which separates analytes from the sample via partitioning between two immiscible solvents, SPE does not require large amounts of organic solvents. SPE provides a more complete extraction of the analytes and a more efficient separation of the interferences from analytes because there is a variety of sorbents and elution solvents that differ in polarity.

SPE of fluoroquinolones is an effective way for both extraction and clean-up especially after the samples undergo deproteination with an acid such as trichloroacetic acid (TCA) and trifluoroacetic acid (TFA) [61]. The use of SPE offers clean extract to reduce instrument maintenance. According to Herrera-Herrera (2009), the use of SPE with pre-treatment using acids (TCA, TFA) resulted in high recovery that was more than 75% and ultra-trace LOD that was in the range of 0.5-6.8 μg L^{-1} [61].

The fluoroquinolones namely norfloxacin, ofloxacin, ciprofloxacin, pefloxacin, lomefloxacin, danofloxacin, enrofloxacin, sarafloxacin, difloxacin, oxolinic acid, and flumequine were separated with a reversed-phase HPLC coupled with fluorescence detection. The clean-up of the milk samples was succeeded by SPE with LODs ranging from 1-9 μg L^{-1} except for enrofloxacin which was 23 μg L^{-1}. The residues were not exceeding MRL established by Professional Regulation Commission (PRC) and European Union Legislation.

The combination of molecularly imprinted polymers (MIPs) with the SPE cartridge demonstrated high recovery of the ciprofloxacin, enrofloxacin, norfloxacin, lomefloxacin and sarafloxacin from milk samples that were more than 96%. The LODs were ranging 10 and 20 ng mL^{-1}, indicating that MIP-based SPE offered superior purification and sensitivity to the normal SPE [62]. MIP is a synthetic polymer for targeted molecules or selectively given analyte or a group of compounds [63]. MIP is capable to withstand various conditions such as extreme sample pH values, high temperature, and high pressure and it can be reused multiple times [64]. MIP allows better sample clean-up and enhances the detection sensitivity of the analytes. There were several studies reveal that MIP-based SPE was successful as a sample clean-up tool for the isolation of tetracycline antibiotics in lobster, duck, honey and egg. The recovery was above 95% and the LODs were in the range of 0.1-0.3 μg kg^{-1} [65]. The determination of tetracycline in milk and honey with the molecularly imprinted monolith SPE achieved the recoveries of 73.3% - 90.6% from the milk samples and 62.6-82.3% from the honey samples [66]. The MIP monolithic column was polymerised directly and saved lots of procedures like grinding and sieving. However, some studies were reporting the limitation of using MIP such as template leaching problems, low loading capacity, high consumption of organic solvents in conditioning, low affinity binding and the application being limited to polar compounds [42, 56].

The development of magnetic graphene dispersive SPE provides higher stability, larger surface area for adsorption and resistance to acid and alkali. Most of the studies have proven that magnetic graphene is efficient

in extracting pesticides, oxytetracycline in water samples and sulfonamides in milk samples [67-69]. The determination of fluoroquinolones in bovine milk, chicken muscle and egg using magnetic graphene dispersive SPE shows that the recoveries, LOQs and LODs ranged 82.4-108.5%, 0.2-0.8 ng g^{-1}, and 0.05-0.3 ng $g^{-1,}$ respectively. The development of ionic liquid-modified Fe_3O_4 as the adsorbent in magnetic SPE for the determination of fluoroquinolones in milk and pork offered good sensitivity with LODs ranged 0.33-0.78 ng mL^{-1} and LOQs ranged 1.09-2.60 ng mL^{-1}, where the analytes responses were enriched for 29.1-43.9 folds, succeeding the ultra-trace detection of fluoroquinolones in complicated food samples. The recovery of fluoroquinolones from milk and pork samples gained insignificant matrices ranging from 85.4-105.9% and 85.2-103.7%, respectively [70].

The detection of five fluoroquinolones namely norfloxacin, ciprofloxacin, enrofloxacin, danofloxacin and sarafloxacin in fish using ultra-performance liquid chromatography (UPLC) with a fluorescence detector (FD) demonstrated fast analysis and high-resolution selectivity. The fish samples underwent microwave-assisted extraction and clean-up with SPE. The combination of both techniques resulted in a clean extract with recoveries ranged 90-107%. The microwave-assisted extraction utilized a shorter extraction time and minimal solvent. Nevertheless, the sample required further SPE clean-up to eliminate the matrix effect from fish [71].

The development of another sample preparation technique known as QuEChERS is quick, easy, cheap, effective, rugged and safe. This method is rapid and easy to use to separate the sample matrix. Generally, this method is widely applied in the clean-up of food samples with high water content such as fruits and vegetables, especially for the determination of pesticide residues. However, this method is lacking attention to determining the residues of the antibiotics in the food samples. According to Aguilera-Luiz et al. the clean-up step is straightforward with QuEChERS by the addition of EDTA in the extractant solution. It acts as a buffer to QuEChERS and increases the recoveries of the analytes. The recovery study was performed using a spiked milk sample and acceptable recoveries were attained in the range of 70.6-111.3%. However, the intra-day repeatability was recorded as 20% which was considered high as compared to inter-day repeatability [72]. The coupling of QuEChERS clean-up and the UPLC-MS/MS was applied for the determination of veterinary drugs in fish and shrimp samples. Enrofloxacin which is not permitted for use was found in freshwater and marine seafood as high as 7% [73]. In conclusion, the QuEChERS technique is simple, eco-friendly, low cost and fast. There is no filtration and condensation step as well as lesser solvent is consumed. It can be applied to a wide range of complex matrices especially those with high moisture content. Nevertheless, this method could be further modified and improved for better precision.

Apart from clean-up, sample pre-treatment is also required attention to remove interferences with larger particle sizes. For instance, the combination of methanol and trichloroacetic acid (TCA) can easily clear unwanted precipitation and reduce the interaction of lipids and proteins [74]. The combination of methanol with base has shown ineffective sensitivity. Ultra-filtration is needed to increase the detectability of fluoroquinolones without any other protein and lipids component [75].

Liquid-liquid extraction

Liquid-liquid extraction (LLE) is an extraction method that separates compounds according to their solubility in two different immiscible solvents. It is commonly used in the petroleum industry because of its versatility and effectiveness in reducing complex samples [76]. However, there is lacking studies on the extraction of fluoroquinolones in food samples by LLE probably due to the efficiency in extracting organic compounds from complicated matrices.

18 types of veterinary drugs including tylosin, oxolinic acid, flumequine and sulphadimidine were extracted from baby food by LLE. Acidified acetonitrile was added as sample pre-treatment steps to denature the precipitation of proteins and enzymes in the sample. The interferences were reduced before the UPLC tandem mass spectrometer analysis. The results revealed that

this sample pre-treatment step successfully offered a cleaner extract and recovered 120% of one of the fluoroquinolones, flumequine from the samples [77]. Although LLE provides high recovery, the drawbacks of this method include high solvent consumption and waste generation as compared to SPE. It also results in poorer selectivity, emulsion formation and high labour costs [78]. Hence, the SPE is far better than LLE. SPE can extract diverse organic analytes from different samples with superior selectivity compared to LLE [79].

Micro-solid phase extraction

Micro-solid phase extraction (μ-SPE) is developed for rapid sample preparation procedures with minimal solvent. It is known as a miniature SPE. According to Vakh (2018), the fluoroquinolones were extracted by automated magnetic dispersive μ-SPE where the sample solution was injected into a fluidized reactor followed by online separation based on fluidized beds using magnetic nanoparticles, Zr-Fe-C that acted as adsorbents. The LODs and LOQs were in the range of 1.5 to 3.0 μg L^{-1} and 5 to 10 μg L^{-1}. High recovery was obtained for all of the analytes [80]. A core-shell magnetic porous organic polymer has been utilized to extract fluoroquinolone antibiotics in honey samples. The technique was integrated with HPLC-FD and achieved superior sensitivity with LODs in the range of 1.5 to 5.4 ng L^{-1} and enrichment of 84.4-91.7 for ofloxacin, ciprofloxacin and lomefloxacin, and enrofloxacin [81]. The magnetic nanoparticles offered a large ratio of surface area to sample solution volume, a safer technique with low toxic levels and cost-effectiveness [80]. Although μ-SPE applies minute amounts of solvent and indirectly enhances the sensitivity, the major drawbacks are the relative recovery is slightly lower and the insignificant reproducibility problem [42]. Apart from these, μ-SPE is also lacking commercially available stationary phases [82].

Dispersive liquid-liquid microextraction

Dispersive liquid-liquid microextraction (DLLME) was introduced by Assadi et al. to isolate polyaromatic hydrocarbons (PAHs) from water samples [83]. The main advantage of DLLME is its simple, rapid and inexpensive operation [84]. The criteria for an extraction solvent in DLLME is it must have low solubility in the aqueous phase, whereas the dispersive solvent must be miscible with both the extraction solvent and aqueous sample [85]. The DLLME only involves two steps, where both the extraction solvent and disperser solvent are injected rapidly into the sample solution with a syringe. The formation of a cloudy solution containing fine droplets of extraction will be fully dispersed and removed by centrifugation to separate the solutions based on their densities [86].

Yu demonstrated DLLME by employing the deep eutectic solvent (DES) as the extraction solvent. The technique provided fast kinetics to enhance mass transfer because of the large surface area with fine droplets [87]. This method produced good reproducibility which was less than 7.6%. The enrichment factor was in the range of 531-838 folds. DES used in this method is non-toxic and environmentally friendly. Except for milk samples, the DLLME offered good linearity ranged 0.02 to 3.2 μg mL^{-1} and 0.03 to 4.8 μg mL^{-1} with LOD less than 0.01 μg mL^{-1} in determining fluoroquinolones in the honey and water samples [87].

The development of DLLME with the use of switchable polarity dispersive solvent (DLLME-SPDS) has overcome the drawback of conventional DLLME. The centrifugation step was eliminated to simplify the procedure. The determination of ofloxacin in chicken meat samples has applied acrylic acid as the solvent and sodium hydroxide as the alkaline agent in this method. The recoveries obtained were satisfactory in the range of 90.4-102.1% for the spiked chicken meat samples [88]. Despite the various advantages, DLLME is lacking selectivity for complicated matrices [42].

Accelerated solvent extraction

Accelerated solvent extraction (ASE) works at elevated temperatures and high pressure to keep the solvent in a liquid state. The high pressure and increased temperature increase the extraction yield and shorten the extraction time [89]. This method had been applied for the extraction of 15 types of fluoroquinolones in swine, bovine and chicken. The ASE extract required further clean-up by SPE before HPLC-UV analysis. The

recoveries obtained ranged from 70.7-111.1%. The ASE coupled with SPE provided high recoveries and the ASE system was fully automated to ease the operation. The combination of these techniques can separate efficiently, characterise and quantify multiple residues in the food samples [90]. The ASE combined with magnetic SPE was also applied for the extraction of 10 fluoroquinolones in aquatic products. The recoveries obtained were satisfactory in the range of 81.6-105.8% [70]. Overall, the ASE increases the extraction yield, enhances the quality of the extracts, and it is rapid and fully automated. The main drawbacks are the preparation of the extraction cell is time-consuming and a clean-up process is needed. This extraction method is considered limited due to the high operation cost. The high pressure has to be maintained and the temperature is kept elevated along the process. Table 3 summarizes the previously reported techniques for the determination of fluoroquinolones in food.

Conclusion

The lack of analysis of fluoroquinolones in our food samples has to be a concern to maintain a healthy life. The development of a more efficient and effective quantitative analysis is important to obtain reliable residue data. Even though some of the techniques allow for low detection limits and high recovery values, many come with challenging extraction methods to gain better results for ultra-trace levels in food analysis. Most of the studies applied SPE as sample preparation. However, the modified SPE such as magnetic SPE and MIP-SPE are proven to be better than the conventional cartridge-based SPE especially in sensitivity attained. µ-SPE provides a greener technique but the extraction capacity is limited, leading to lower recovery and selectivity as compared to SPE. SPE can extract diverse analytes from different samples and this approach is simple compared to the other techniques. However, it is time-consuming and labour-intensive. Thus, more studies are needed regarding the advanced modification of SPE in sample preparation of food samples as SPE is the most widely used method from 2000 till 2022. In view of that, synthesis of selective adsorbent and liquid extractant for the recognition and extraction of fluoroquinolones is the way forward to enhance the clean-up procedure to offer clean extracts and ultra-trace detection from food samples. On top of that, consolidating automation into sample preparation could further simplify the routine analysis and increase the sample throughput to overcome the shortcoming of microextraction techniques.

Table 3. Summary of previously reported techniques for the determination of fluoroquinolones in food

Food	Analytes	Extraction	Recovery (%)	LOD and LOQ (µg L^{-1})	Instrumentation	References
Milk	Enrofloxacin, Ciprofloxacin, Sarafloxacin, Difloxacin	Acidified ethanol, isolation & retention on cation exchange solid phase extraction, elution with basic ethanol	70-90	0.3-1.2 5.0	HPLC-FD	[91]
Bovine Milk	Fleroxacin, Ciprofloxacin, Lomefloxacin, Danofloxacin, Enrofloxacin, Sarafloxacin, Difloxacin	Deproteinization with TCA, solid phase extraction	73-113	0.5-6.8 1.7-22.2	HPLC-FD	[61]
Milk	Norfloxacin, Ofloxacin, Ciprofloxacin, Pefloxacin,	Solid phase extraction	69-88	1-9 except for enrofloxacin which is 23	HPLC-FD	[92]

	Lomefloxacin, Danofloxacin, Enrofloxacin, Sarafloxacin, Difloxacin, Oxolinic acid, Flumequine					
Milk	Ciprofloxacin, Norfloxacin, Enrofloxacin, Lomefloxacin	MIP-SPE	96	10-20 20-50	HPLC	[62]
Baby Food	Fleroxacin, Norfloxacin, Ofloxacin	Automated magnetic dispersive (SPME)	86-122	1.5-3 5-10	HPLC-FD	[80]
Honey, Milk, Water.	Enrofloxacin, Ciprofloxacin, Lomefloxacin, Gatifloxacin, Sparfloxacin	SO-DLLME-DES-BE	90-110 95-104 87-114	<10 <30	MECC	[87]
Baby Food	18 types of veterinary drugs	LLE with acidified acetonitrile	120	1.0 3.3	UPLC-MS/MS	[77]
Milk	18 types of veterinary drugs	QuEChERS, addition of EDTA as buffer	70.6-111.3	1-4 3-10	UPLC-MS/MS	[72]
Lobster, Duck, Honey, Egg	Tetracycline	MIP-SPE		0.1-0.3	HPLC-MS/MS	[65]
Milk, Honey	Tetracycline	MIP-SPE	73.3-90.6; and 62.6-82.3	10.2-18.8	HPLC-DAD	[66]
Chicken Meat	Ofloxacin	DLLME with switchable polarity dispersive solvent. (DLLME-SPDS)	90.4-92.6 for 5μg/kg 98.7-102.1 for 50 μg/kg	0.071-0.214	HPLC-FD	[88]
Fish	Norfloxacin, Ciprofloxacin, Enrofloxacin, Danofloxacin, Sarafloxacin	Microwave-assisted extraction-SPE	90-107	0.1-1.2 0.2-20.2	UPLC-FD	[71]
Goat Milk	Enrofloxacin, Ciprofloxacin	SPE	84-88	15 20	HPLC-DAD	[93]
Milk, Pork	Norfloxacin, Ciprofloxacin, Lomefloxacin, Enrofloxacin	Magnetic solid phase extraction, Fe_3O_4 as sorbent	85.4-105.9 85.2-103.7	0.33-0.78 1.09-2.60	HPLC-DAD	[94]

Water, Meat	Ofloxacin, Norfloxacin, Ciprofloxacin, Enrofloxacin, Difloxacin, Sarafloxacin, Pefloxacin, Danofloxacin	Magnetic solid phase extraction, Fe_3O_4 as sorbent	82.5-112.5 75.3-104.7	0.0007-0.006 0.0025-0.02	HPLC-MS	[95]
Milk	Fleroxacin, Enoxacin, Pefloxacin, Norfloxacin, Ciprofloxacin, Lomefloxacin, Enrofloxacin, Gatifloxacin, Sparfloxacin, Levofloxacin	MIP-SPE	84.1-104.7	1.34 7.35	HPLC-DAD	[96]
Fish, Shrimp	Flumeuquine, Ciprofloxacin, Enrofloxacin, Ofloxacin	QuEChERS	72-114	0.01-0.3	UPLC-MS/MS	[73]
Swine, Bovine, Chicken	15 types of fluroquinolones	Accelerated solvent extraction, clean up with solid phase extraction	70.7-111.1	3 10	HPLC-UV	[90]
Aquatic Products	Sarafloxacin, Ofloxacin, Enrofloxacin, Danofloxacin, Lomefloxacin, Pefloxacin, Ciprofloxacin, Enoxacin, Norfloxacin, Difloxacin	Accelerated solvent extraction and magnetic solid-phase extraction.	81.6-105.8	0.02-0.29	HPLC-MS	[70]

Abstract

Conventional plastic is made from petrochemical substances. Its non-biodegradable properties negatively impact the environment, causing landfill pollution and affecting wildlife and aquatic life. It uses non-renewable sources that will be depleted in a few years if there is no solution to this situation. This study was carried out to produce bio-plastic made from renewable sources: 10 g of corn starch, 5 ml of glycerol and vinegar, and 60 ml of distilled water. The produced bio-plastic was exposed to gamma radiation to observe the difference between irradiated and non-irradiated bio-plastics. Surface morphology and chemical properties like absorption spectra, functional group and chemical bonding were characterized using Opto Digital Microscope, Ultra-Violate Visible (UV-Vis) Spectrophotometer and Fourier Transform Infrared Spectroscopy (FTIR). The results indicate that exposure to gamma radiation causes the bio-plastic surface to be darker with some degradation. Irradiated bio-plastic degrades faster than the ones not irradiated. The samples were characterized using UV-Vis, prepared in different glycerol concentrations to determine which concentration gave the best absorption peak. The absorption peaked at 270 nm wavelength in the highest glycerol concentration. Functional groups like alcohols, carbonyl and ester were also found in the sample's solution. All functional groups that contribute to the bio-plastic properties could be stretched and bent to enhance their performances as a packaging application. Overall, exposure to gamma radiation improves the bio-plastic quality as a packaging application that can be used in the food and pharmaceutical industries.

Keywords: Effect of gamma radiation, bioplastics, radiation, ionizing

Abstrak

Plastik konvensional diperbuat daripada bahan petrokimia. Sifat tidak terbiodegradasinya memberi kesan negatif kepada alam sekitar, menyebabkan pencemaran tapak pelupusan dan menjejaskan hidupan liar dan akuatik. Ia menggunakan sumber tidak boleh diperbaharui yang akan habis dalam beberapa tahun jika tiada penyelesaian kepada keadaan ini. Kajian ini dijalankan untuk menghasilkan bio-plastik yang diperbuat daripada sumber boleh diperbaharui: 10 g kanji jagung, 5 ml gliserol dan cuka, dan 60 ml air suling. Bio-plastik yang dihasilkan telah didedahkan kepada sinaran gamma untuk melihat perbezaan antara bio-plastik yang disinari dan tidak disinari. Morfologi permukaan dan sifat kimia seperti spektrum serapan, kumpulan berfungsi dan ikatan kimia telah dicirikan menggunakan Mikroskop Opto Digital, Spektrofotometer Cahaya Nampak-Ultraungu (UV-Vis) dan Inframerah Transformasi Fourier (FTIR). Keputusan menunjukkan bahawa pendedahan kepada sinaran gamma menyebabkan permukaan bio-plastik menjadi lebih gelap dengan sedikit degradasi. Bio-plastik yang disinari merosot lebih cepat daripada yang tidak disinari. Sampel telah dicirikan menggunakan UV-Vis, disediakan dalam kepekatan gliserol yang berbeza untuk menentukan kepekatan

yang memberikan puncak penyerapan terbaik. Penyerapan memuncak pada panjang gelombang 270 nm dalam kepekatan gliserol tertinggi. Kumpulan berfungsi seperti alkohol, karbonil dan ester juga ditemui dalam larutan sampel. Semua kumpulan berfungsi yang menyumbang kepada sifat bio-plastik boleh diregangkan dan dibengkokkan untuk meningkatkan prestasi mereka sebagai aplikasi pembungkusan. Secara keseluruhan, pendedahan kepada sinaran gamma meningkatkan kualiti bio-plastik sebagai aplikasi pembungkusan yang boleh digunakan dalam industri makanan dan farmaseutikal.

Kata kunci: Kesan sinaran gama, bioplastik, sinaran, pengionan

Introduction

Radiation processing is used for packaging applications, especially for medical products and in the food industry [1]. Presently, packaging materials are mostly made from synthetic plastic, making it crucial to see the effect of irradiation on these materials. Apart from radiation treatment, a few other methods can be applied for packaging applications, such as UV-ray, ionizing ray, and light pulse. There was an attempt to use UV-ray for surface sterilization. It depends on the intensity rate applied for the packaging applications. However, the UV ray's penetration ability is limited [2]. Hence, it is only suitable for packaging materials with very low contamination.

Using an ionizing ray is another method for packaging applications. It uses Cobalt-60 as a source that emits gamma radiation. It is very convenient for killing bacteria [2]. Ionizing radiation is commonly used for bulk packaging of acidic foods such as aseptic bag-in-box. This method applies a radiation dose of 25 kGy equivalent to 2.5 mrad. However, the effects of gamma radiation on food have been a huge concern in the manufacturing process because it needs heavy shielding to prevent radiation leakage. It also requires careful process design, high maintenance, and expensive equipment.

Radiation treatment is chosen to radiate packaging materials because it does not leave any residue on the treated surface nor affect the immediate environment, making it the perfect solution for packaging materials. Packaging materials are any material used to protect something. Many sources have been used in packaging materials, including glass, metals, papers and plastics. However, a special variety of plastics have been introduced in the manufacturing industry for packaging. These plastics are made from petroleum and other chemicals with unhealthy side effects for the product and its surrounding, leading to the invention of bio-plastic, a more convenient and safer packaging material.

Plastics have been widely used for packaging applications for 70 years [3, 4]. Its versatility and durability give it an advantage over other materials. It is inexpensive, lightweight, heat-sealable and has good flexibility for fabrication into various shapes [5]. However, petroleum-based plastics are detrimental to the environment. Conventional plastics are made from petroleum, making them non-biodegradable and non-renewable [6, 7]. This disadvantage leads to huge environmental problems and municipal waste. The solution to this problem is to produce a new type of plastic made from bio-based materials. Unfortunately, recent studies found that no bio-based plastics could combine all the features and functionalities of conventional plastics [8]. Hence, there is ongoing research on producing bio-based plastics that achieve all the required properties of conventional plastics.

Another definition of bio-plastic can be explained from two perspectives. The first one is its functionality. Bio-plastic is biodegradable plastic from organic waste, while the second one is by its source materials. It uses renewable or biomass materials that are processed into plastic. Bio-plastics are a type of biological material that is degradable and eco-friendly in its chemical nature. They are produced using a few methods, such as microorganisms cultured under different nutrients and environmental conditions [9]. Bio-based plastics are man-made or man-processed, derived from biological resources. Bio-plastics are classified into two types: photodegradable and semi-biodegradable [10]. The history of bio-based plastics is much earlier than our conventional plastics. The first bio-based plastics, called thermoplastics, were made from celluloid in the 1860s [11]. Unfortunately, the numerous inventions of bio-based plastics stayed in the laboratory and was not

commercially exploited because, in the 1950s, the petrochemical industry had developed cheap and synthetic polymers made up from crude oils.

What we have now are synthetic plastics that are usually made from petroleum. 4% of the world's petroleum sources are reserved for manufacturing plastics [12]. More than 200 billion pounds of plastics are produced yearly [13], indicating how crucial plastic is worldwide. Within a few years, sources will deplete if nothing is done about it. These synthetic plastics contribute to environmental pollution because they are not eco-friendly. The chemicals used to make synthetic plastics are non-biodegradable, taking a long time to decay. Some plastics take up to 1000 years to decay [14]. On top of that, plastics also affect wildlife, destroying habitats, especially the marine ecosystem. Aquatic life often mistakes plastics for food, causing them to suffocate or entangled by the plastics [15].

Conventional plastics are compounded with several additives to improve their product performance and tensile strength. These factors lead to health hazards for humans. In addition, a very cautious handling process is needed during the plastic manufacturing, which may cause industrial accidents [16]. Our study is important for several reasons. Firstly, inventing a bio-plastic requires a study of its properties and functions to ensure it is similar to or better than conventional plastic for use as packaging. Hopefully, over time, bio-plastic will replace conventional plastic. Secondly, bio-plastic can help lessen global environmental pollution because it uses natural sources as its base. Therefore, bio-plastics are eco-friendly (bio-degradable) and take less time to decay. Thus, overcoming conventional plastic adverse effects on the marine ecosystem.

Thirdly, although producing bio-plastics may require a higher capital, it should not be a problem due to ample bio-based sources. Currently, there is a high demand for bio-plastic from the industry. Moreover, petroleum price is expected to increase due to its depletion and high demand. Finally, bio-plastic is irradiated using gamma radiation by emitting a high photon energy that can penetrate the material, ensuring the entire packaging has been radiated. It is a non-polluting radiation, making it safer for the products inside the packaging [9]. Furthermore, the properties of the packaging application were studied so that they could be customized for use in different applications, making it particularly beneficial to the food processing industry.

The objectives of this research are including produce biodegradable plastic using corn starch, analyze the chemical properties of irradiated bio-plastic by using ultraviolet-visible spectrophotometer (UV-Vis) and Fourier transform infrared spectroscopy (FTIR), and study the bio-plastic surface morphology using Opto Digital Microscope.

Materials and Methods

This study employed 10 g of corn starch, 60 mL of distilled water, 5 mL of glycerol, and vinegar. The sample was prepared by adding 60 ml of distilled water and corn starch. The mixture was stirred until it formed a uniform and homogenous suspension. Following that, glycerol was added to the mixture and stirred well. Then, vinegar was added to the mixture. After thoroughly combining all materials, the heat was turned on, and the stirring procedure was resumed. During the stirring process, the temperature was raised from 30ºC to 95ºC. After a while, a thick viscous glue-like substance formed. The mixture was then poured and spread over an aluminum foil. The mixture was left to dry for a few days, as shown in Figure 1. The bio-plastic sample was cut into smaller pieces and sliced into 5 cm x 5 cm squares to facilitate the radiation procedure. They were divided into radiation and non-radiation samples. The samples were then irradiated.

The shielding blocks were arranged properly for irradiation purposes to ensure no radiation leakage while running the experiment. Cobalt-60 was chosen as the radiation source. The samples were left for a week for irradiation. Finally, all samples were sent for analysis before and after each radiation process. The radiated samples were sent for analysis to study their properties and investigate the radiation effects on the sample using Ultraviolet-Visible Spectrophotometer (UV-Vis), Opto Digital Microscope and Fourier Transformation Infrared Spectroscopy (FTIR).

The drying process took several days

Results and Discussion

Ultraviolet-Visible spectrophotometer analysis

10 samples were analyzed using UV-Vis spectroscopy. The samples were divided into radiated and non-radiated samples. Five samples were radiated using Cobalt-60 and exposed to gamma radiation for a week. Then, the samples were prepared for analysis using a UV-Vis Spectrophotometer to observe the bio-plastics absorbance range under different glycerol concentrations at 200-800 nm. UV-Vis uses visible and ultraviolet lights to analyze the bio-plastics chemical structure.

Table 1. Wavelength and absorption peak of non-radiated and radiated bio-plastics

Samples Glycerol (mL)	Non-Radiated Bio-Plastic		Radiated Bio-Plastic	
	Wavelength (nm)	Absorption Peak (a.u)	Wavelength (nm)	Absorption Peak (a.u)
1.0	280	0.031	270	0.057
0.8	270	0.022	270	0.030
0.6	270	0.019	270	0.028
0.4	270	0.018	270	0.012
0.2	270	0.016	270	0.010

Table 1 shows that glycerol influenced the UV absorptivity in bio-plastics [17]. This result also indicates that glycerol concentration is directly proportional to the bio-plastics ability to absorb UV (Figure 2). The highest peak for the non-radiated bio-plastics is 0.031 a.u with 1.0 ml presence of glycerol, found at 280 nm wavelength. The glycerol is directly proportional to the level of bio-plastic transparency [18]. Studying the bio-plastic absorbance range is important because UV absorption has a significant relationship to the plastic's UV degradation. Plastics that did not absorb UV radiation are insusceptible to photo degradation [19].

This research found that bio-plastic with 1.0 ml glycerol concentration had the highest peak. We conclude that glycerol in bio-plastic resulted in better UV absorption (Figure 3). The bio-plastics ability to absorb UV is very beneficial, especially if it is used for food packaging, due to their ability to protect food products from UV radiation. It could prevent photo-oxidative degradation that might change the product's taste and smell, and induce free radicals formation. The highest peak obtained is at wavelength 270 nm with a peak 0.057 a.u. The highest peak obtained had the same glycerol concentration as non-radiated bio-plastic. This signifies

that with exposure to gamma radiation, glycerol's presence in bio-plastic plays an important role in absorbing UV radiation.

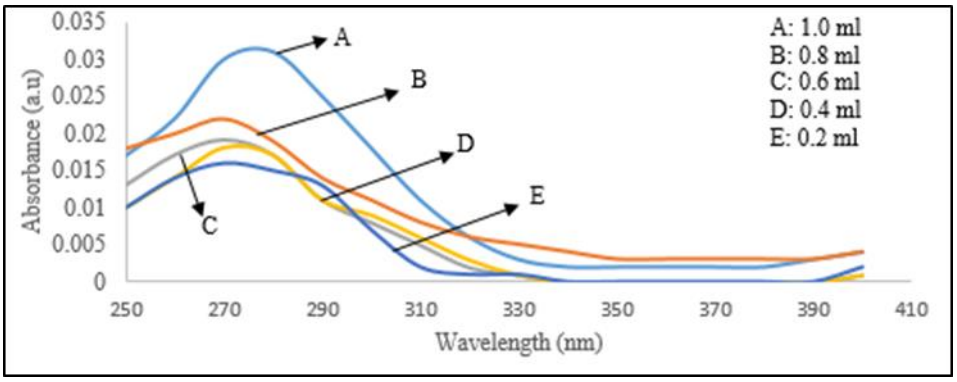

Figure 2. Concentration of different glycerol in non-radiated bio-plastics

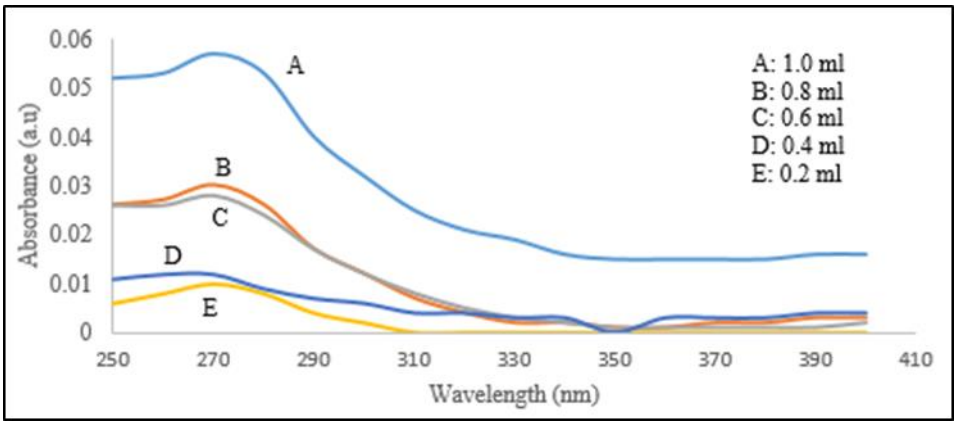

Figure 3. Concentration of different glycerol in irradiated bio-plastics

Opto-Digital Microscope DSX100

The opto-digital microscope is used to characterize the bio-plastic surface morphology. The particle distribution and deterioration effects from radiation could be seen using DSX100. The advantage of using this microscope is it magnifies and measures images in real-time. It also stores and transmits images for future viewing, making microscopy possible for beginners. The bio-plastics produced were transparent, smooth, thick and deformable, whereas conventional plastics were firm, stretchable, thin and transparent. Bio-plastic is quite soft compared to conventional plastics, making it difficult to compare the irradiation effects on both types of plastic.

The samples were analyzed for both irradiated and non-irradiated conditions. Figure 4(a) shows the surface condition of conventional plastic made of petrochemical substances. This sample was not exposed to a gamma source. Hence, the surface morphology was affected by the radiation. The surface was free of degradation effect and had a firm structure.

Figure 4. Surface morphology of (a) non-irradiated and (b) irradiated conventional plastic. While (c) non-irradiated (d) irradiated surface morphology of bio-plastic

Figure 4(b) shows the radiation effects on plastic. The plastic exposed to radiation deteriorated on its surface due to the oxygen reacting with the free radicals [6]. The free radical formation could significantly change the molecular structure [20]. Several parallel strips developed on the plastic's surface, possibly due to the radiation effects. Figure 4(c) shows the bio-plastic surface morphology in natural conditions. The surface is rigid due to using glycerol as a plasticizer agent. It shows the fracture surface of dispersed fibers without the incidence of gamma radiation [21]. The sample was brittle due to bubbles, which is problematic for the bio-plastic-making process.

The bio-plastic sample shown in Figure 4(d) has the embrittlement effect due to irradiation. Gamma rays induced chain scission and degradation effect [9], resulting in the melt viscosity and embrittlement observed in Figure 4(d). Because of radiation-induced oxidation, the surface is deepened with oxygen-containing hydrophilic groups [22], indicating that the bio-plastic surface becomes hydrophilic after irradiation. The surface of the irradiated bio-plastic also appeared darker than the non-irradiated ones because of the irradiation degradation effect. The exposure to gamma energy improved the degradation process. When exposed to radiation, the bio-plastics could be degraded by photolysis, giving the samples a lower molecular weight, thus enhancing and quickening the bio-plastics degradation process [23].

The bubbles on the surface resulted from the inadequate method when handling the samples during the drying process. The samples were left at room temperature for several days, promoting the bio-plastic surface's oxidation process. It is more convenient to dry the sample using an oven to avoid bubble formation [24]. The atmosphere in which the radiation took place modifies the effects. The differences are usually observed in the presence or absence of oxygen. However, the findings are inconsistent with some plastics degradation that was enhanced in the presence of air. This research used the natural drying process to manage the equilibrium of moisture content, which was critical to determine the ideal microbe development, material deterioration and degradation circumstances. It also aids in determining food stability at a certain moisture level in a specific environment.

Fourier transform infrared spectroscopy analysis

FTIR is chosen to describe the functional group present at the material surface before and after drying [24]. All samples were recorded in absorbance units from 4000 to 450 cm^{-1}. Four samples were analyzed which are irradiated bio-plastic and conventional plastic also non-irradiated bio-plastic and conventional plastic. Figure 5 shows the band at 3000-3600 cm^{-1} range spectra of irradiated bio-plastic indicate the O-H stretching which is broader than other absorption bands [25]. It is somehow overlaps the N-H stretching in the same region. There are four primary peaks shown in table 2 and 3 as similar to previous study [26]. The peak at 3293.22 cm^{-1} signifies the presence of alcohols group in the sample as glycerol was involved in the process of making the bio-plastic.

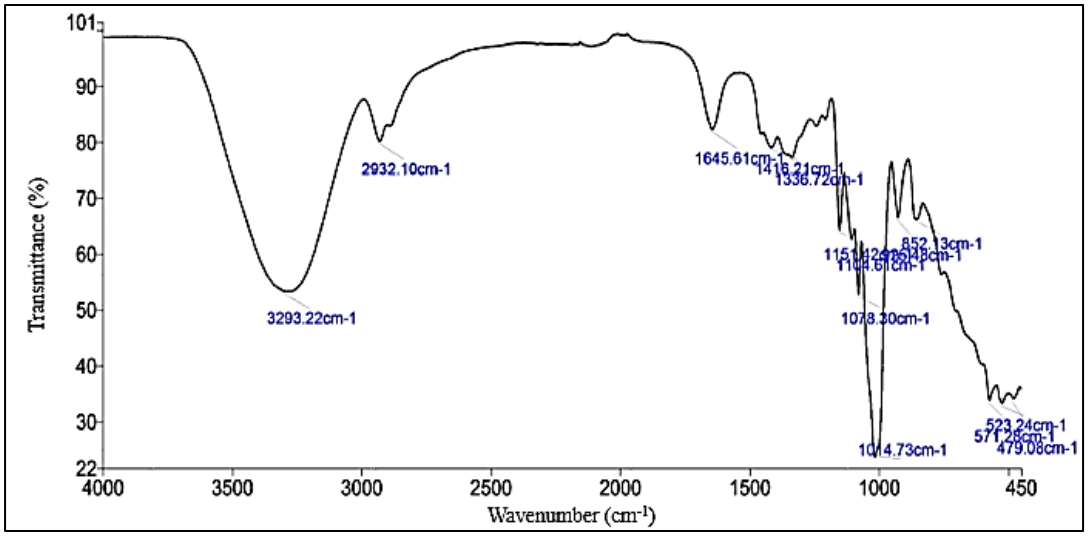

Figure 5. FTIR spectrum for irradiated bio-plastic

Another peak at 2932.10 cm^{-1} indicates the presence of the alkanes group, i.e., the C-H bond, which has medium to strong infrared absorption intensity [27]. The C=O bond at 1645.61 cm^{-1} is attributed to the stretching vibrations of strong carbonyl compounds due to the presence of ketones or aldehydes compounds produced due to thermal decomposition during the sample preparation [28, 29]. Peaks at 1014.73 cm^{-1} were due to the presence of alcohol groups C-O bond involved during the polymerization process, meaning that the starch alcohols group was involved in the hydrogen bond formation. Still, it is not as broad as the O-H bond.

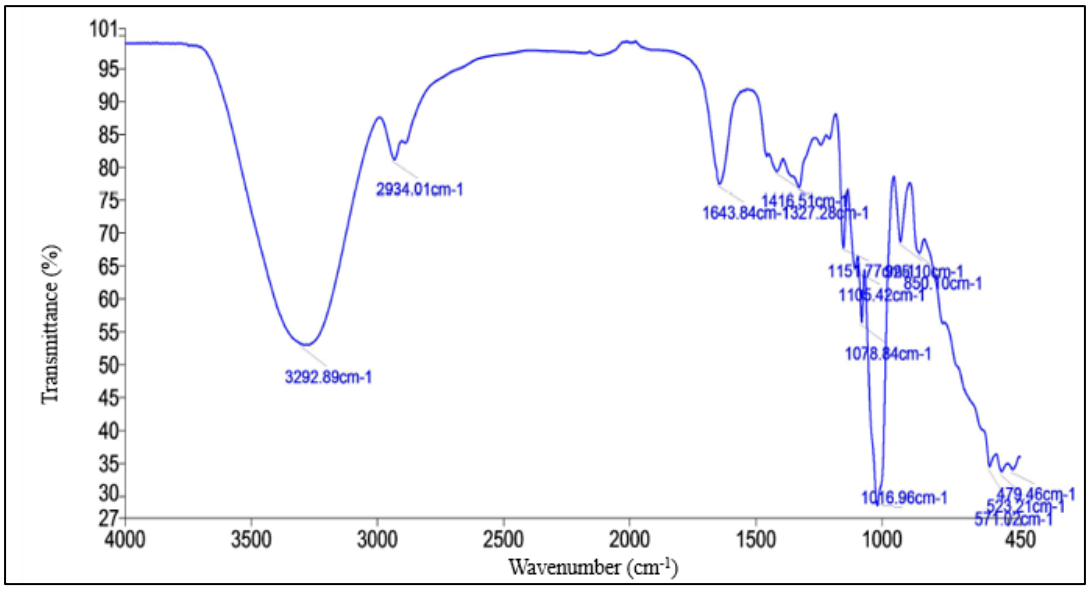

Figure 6. FTIR spectrum for non-irradiated bio-plastic

Table 2 shows the absorption spectrum for non-irradiated bio-plastic. Figure 6 shows no significant changes occurred from irradiated and non-irradiated samples except the slightly different values of wavenumber shown by the four primary peaks. However, a lower wave number indicates a stronger hydrogen bond interaction [30]. Starting from the first peak, there is a decreasing value of the alcohol group

absorption band for the non-irradiated bio-plastic and a decreasing carboxylic acids presence. Table 2 shows a radical cation, likely generated on the carbonyl function under gamma radiation. Another effect was the generation of radical cation-beta on the ester oxygen, providing an alkyl radical and an oxonium ion. The latter collapsed to release acetic acid and a carbocation. The free radical generated an oxyl radical with a carbocation in an alpha position.

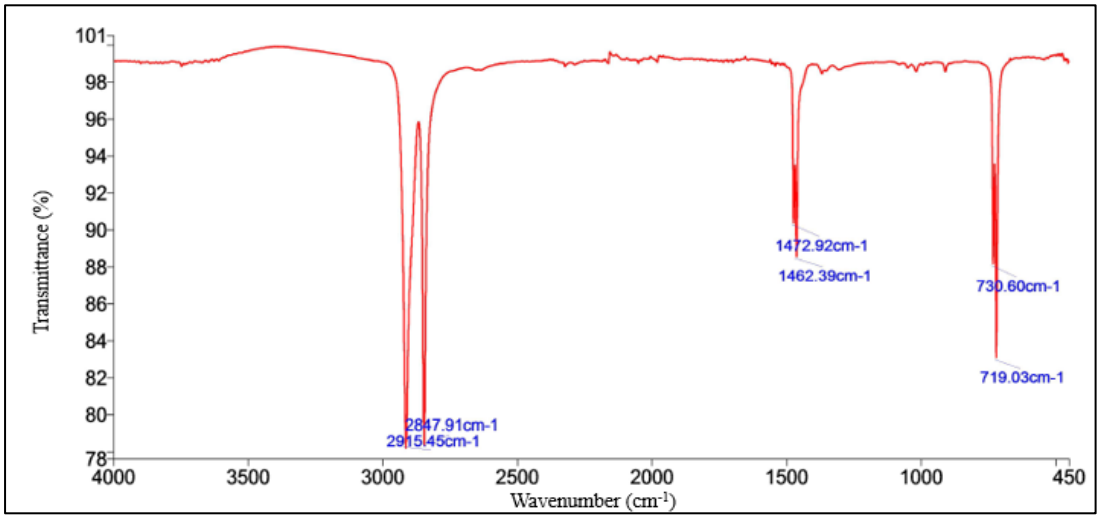

Figure 7. FTIR spectrum for irradiated conventional plastic

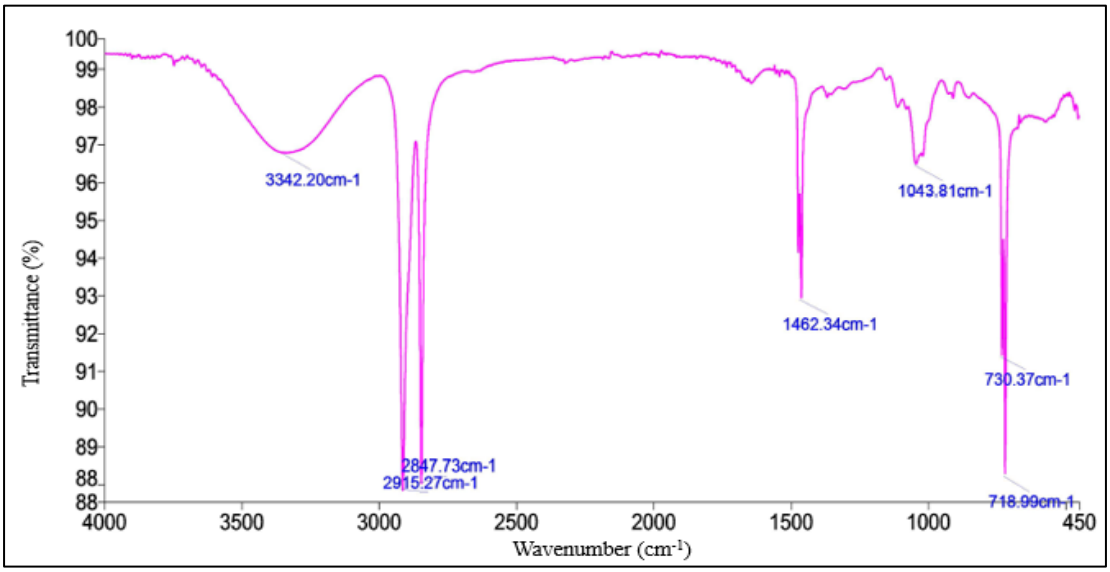

Figure 8. FTIR spectrum for non-irradiated plastic

Table 3 shows the IR spectra for both irradiated and non-irradiated plastics. No significant changes were obtained from both results except a few reduced peaks at certain wave numbers of absorption bands (Figure 7). This agrees with a previous study that there were completely unchanged peaks even after the gamma exposure [30]. The most significant difference is the reduced peak at 3342.20 cm^{-1} of non-irradiated plastic exposed to gamma radiation. The gamma exposure caused O-H scission, resulting in the formation of double bonds. The

peaks in the range of 2847-2915 cm^{-1} are similar in both plastics. These show the presence of phenolic groups O-H, which has a very broad and strong absorption bands intensity. This is due to the plastics being irradiated with gamma exposure, leading to radical oxygen formation caused by the ester linkages breaking and, possibly, forming ester radicals.

Table 2. Summary of functional groups of bio-plastics

Functional Group (Absorption Range)	Wavenumbers (cm^{-1})	
	Irradiated Bio-Plastic	Non-Irradiated Bio-Plastic
Alcohols (O-H stretch)	3293.22	3292.89
Alkanes (C-H stretch)	2932.10	2934.01
Carbonyl compounds (C=O stretch)	1645.61	1643.84
Esters (C-O stretch)	1014.73	1016.96

The oxygen radicals can easily combine with hydrogen radicals to form phenolic groups [29]. There is a shift towards a higher wavenumber from the peak at 1043.81 and 1472.92 cm^{-1} of non-irradiated and irradiated plastics, respectively (Figure 8). This shift is due to the C=O group formation. The peaks at range 718-730 cm^{-1} indicate the plastic's bending vibration bands. It has a medium intensity of alkyl halide groups. Table 2 compares the irradiated and non-irradiated bio-plastic functional groups. The wavenumber differences indicate a radiation effect on the bio-plastics. Table 3 compares the irradiated and non-irradiated conventional plastic functional groups. The most significant difference was reduced alcohol bond in the irradiated conventional plastic.

Table 3. Summary of functional groups of conventional plastics

Functional Group (Absorption Range)	Wavenumbers (cm^{-1})	
	Irradiated Plastic	Non-Irradiated Plastic
Alcohols (O-H stretch)	-	3342.20
Carboxylic acids (O-H stretch)	2915.45 & 2847.91	2915.27 & 2847.73
Alkanes (H-C-H bend)	1462.39	1462.34
Alkyl halides (C-Cl bend)	730.60 & 719.03	730.37 & 718.09

Conclusion

Results show that the irradiated bio-plastic had a higher absorption peak at wavelength 270 nm than non-irradiated bio-plastic, signifying that glycerol concentration was directly proportional to the absorption peak. Glycerol concentration was also directly proportional to the bio-plastic transparency [19], resulting in better UV absorption. Regarding surface morphology, both types of plastic showed degradation effects on their surfaces after they were irradiated. Several long gashes on the conventional plastic indicated that it absorbed the gamma radiation. Due to the gamma radiation's degradation effect, the irradiated bio-plastic surface was slightly darker than the non-irradiated bio-plastic surface. The gamma radiation caused an embrittlement effect. There were bubbles due to the problematic process of drying the bio-plastic. Irradiated bio-plastic samples displayed slightly decreased absorption spectra at 2932.10 and 1014.73 cm^{-1}. However, increased absorption peaks at 3293.22 and 1645.61 cm^{-1} indicated the presence of alcohols and carbonyl groups in the bio-plastics. For irradiated conventional plastic, there was a drastically reduced peak at 3342.20 cm^{-1}, indicating that the alcohol group was eliminated due to the plastic absorbing the gamma radiation. On the other hand, irradiation did not cause significant changes in other peaks.

Abstract

Diclofenac is a non-steroidal anti-inflammatory drug (NSAID) used to treat pain and inflammatory disorders. Due to a general increase in the usage of pharmaceuticals and incomplete removal of such compounds from through treatment of wastewater, drugs such as diclofenac have been labelled as emerging contaminants of concern. This review covers the chromatographic methods that have been reported in recent literature for the determination of diclofenac in biological fluids of humans. This could be beneficial for researchers interested in the detection and quantification of diclofenac for epidemiological studies to determine the extent of contamination within human populations.

Keywords: diclofenac, chromatographic methods, human fluids

Abstrak

Diclofenac adalah sejenis ubatan anti-keradangan bukan steroid yang digunakan bagi merawat kesakitan dan gejala keradangan. Peningkatan penggunaan farmaseutikal dan kegagalan penyingkiran sepenuhnya sebatian farmaseutikal dari rawatan sisa buangan mengakibatkan diclofenac dilabel sebagai bahan pencemar baru muncul. Ulasan ini meliputi kaedah kromatografi yang telah dilaporkan dalam penerbitan terkini untuk penentuan kepekatan diclofenac dalam sampel cecair tubuh manusia. Ulasan ini diharap memberi faedah buat penyelidik yang melakukan pengesanan dan pengkuantitian diclofenac untuk kajian epidemiologi bagi penentuan kesan pencemaran ini kepada populasi manusia.

Kata kunci: diclofenac, kaedah kromatografi, sampel cecair manusia

Introduction

Diclofenac, with chemical name 2-[2-(2,6-dichloroanilino)phenyl]acetic acid (Figure 1), is a non-steroidal anti-inflammatory drug (NSAID) used to treat pain and inflammatory disorders. Its mechanism of action involves inhibiting the activity of

cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2) [1]. Diclofenac is often formulated as either the sodium or potassium salt, with the difference between these two formulations being the rate of absorption and onset of action. Diclofenac potassium is more water soluble than diclofenac sodium, allowing for quicker absorption and rapid onset of pain relief [2]. Although diclofenac has useful medical applications, it has also been shown to possibly act as an endocrine-disrupting chemical (EDC). In vivo and in vitro studies have described diclofenac's potential as an EDC, with the possibility of affecting estrogen, androgen, glucocorticoid, and thyroid hormone receptors [3, 4].

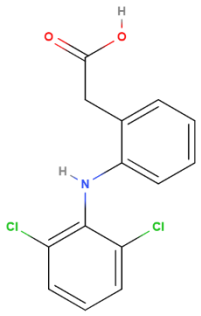

Figure 1. Chemical structure of diclofenac.

The metabolism of diclofenac in humans results in a range of metabolites, including those which are hydroxylated, methoxylated, and acyl glucuronide conjugated. The main metabolites of diclofenac are predominantly 4'-hydroxydiclofenac and 5-hydroxydiclofenac [5]. Most studies in the literature have focused on the toxic effects of diclofenac and its metabolites on avian [6, 7] and marine [8, 9] species. In humans, diclofenac shows acute toxicity. Overdose on NSAIDs such as diclofenac have been reported to result in gastrointestinal, renal, and neurological toxicity [10].

As reviewed by Sathishkumar et al. there is global occurrence of diclofenac contamination in various environmental compartments; thus, diclofenac has been labelled as a contaminant of emerging concern. Diclofenac and other pharmaceuticals can enter water environments through sources such as industrial production sites, wastewater treatment plant effluents, hospitals, and household waste. The presence of diclofenac in water environments can be attributed to a general increase in the usage of pharmaceuticals and incomplete removal of such compounds from wastewater [11]. Studies into the removal of pharmaceuticals from wastewater treatment plants have found that diclofenac and its metabolites are compounds with low removal potential and therefore high detection frequencies in wastewater [12].

Diclofenac and its metabolites have been detected in the drinking water supply of various countries. The unintended exposure of the general population to EDCs such as pharmaceuticals through drinking water supplies is of great concern. In Malaysia, a number of studies have detected diclofenac in drinking water; the maximum concentrations observed were 21.39 ng/L [13], 9.8 ng/L [14], 0.18 ng/L [15], and 0.0821 ng/L [16]. In other Asian countries, such as China, diclofenac has been detected at a maximum level of 3.7 ng/L [17]. At a Japanese drinking water purification plant, the maximum observed level of diclofenac was 16 ng/L [18]. For European countries, diclofenac was detected in surface water and groundwater intended for human consumption in France, with a maximum measured value of 56 ng/L [19]. However, another French study detected comparatively lower concentrations of diclofenac, with a maximum value of 2.5 ng/L being observed [20]. In Spain, a study found that the average concentrations of diclofenac in mineral and tap water were 25 ng/L and 18 ng/L respectively [21].

Although contamination levels of pharmaceuticals are generally lower than the typical dosages that are prescribed for medication, the long-term impacts of such exposure are still not well understood. Therefore, it is of interest to monitor the levels of pharmaceuticals, such as diclofenac, in the general population to determine whether there are long-term impacts. The aim of this review is to give a general overview on the chromatographic methods that have been reported in literature within the past decade for the determination of diclofenac in biological fluids of humans.

Determination of diclofenac in biological samples

Sample preparation

Human biological samples are complex matrices which often require preparation before analysis. The aim of

sample preparation is to obtain a sample that is free of interference and will not damage the instrument chosen for carrying out the analysis. Ideally, the sample preparation steps are minimal; and whilst 100% recovery of analytes from the sample is ideal, oftentimes reproducibility of recovery is more important [22]. In terms of determining analytes from biological samples using chromatographic methods, such as liquid chromatography-mass spectrometry (LC-MS), sample preparation is an important aspect; unwanted components that remain in the sample may interfere with the results obtained. Matrix effects are often caused by the presence of co-eluting compounds in the matrix that alter the ionization efficiency of target analytes in the sample. Matrix effects can be observed as either a loss or increase in response, ultimately affecting the accuracy, precision, and sensitivity of a method [23].

One of the most widely used methods for the extraction of analytes from biological samples is protein precipitation. It is considered as one of the fastest and simplest methods for the removal of proteins from biological samples (such as plasma or serum). However, protein precipitation often provides poor selectivity for extraction of target analytes. Another popular method for the extraction of analytes from biological samples is liquid-liquid extraction (LLE), both conventional methods and newer advances such as liquid-liquid microextraction (LLME). Conventional LLE often requires large volumes of organic solvents and is typically a time-consuming process; hence, newer advances – such as LLME – provides solutions to some the issues of LLE by consuming less solvent. Alternatively, solid-phase extraction (SPE) is another established method for the extraction of target analytes from biological samples. Advantages of SPE include high selectivity and lower organic solvent consumption compared to LLE. Additionally, SPE cartridges may also act as a filtration step, preventing suspended solids in the biological sample from clogging the analytical instrumentation. On the other hand, SPE is a time-consuming extraction process, with high running costs as cartridges are often designed for single use. Newer advances in SPE methods to provide solutions to the issue of conventional SPE include solid-phase microextraction (SPME) [24].

Gas chromatography

Gas chromatography (GC) is an analytical technique used for the separation of volatile compounds from a mixture which is in the gas phase. As a chromatographic method, GC makes use of a mobile and stationary phase; where the mobile phase is an inert gas, and the stationary phase can either be a solid or a liquid. Upon injection into the GC system, the sample is vaporized and carried through the column by the mobile phase, and compounds are separated based on their interactions with the stationary phase. Benefits of GC include relatively fast run times, good peak separation, and it works in combination with various selective detection methods. However, GC requires the compounds of interest to be thermally stable and sufficiently volatile, which can be an issue [25].

Several GC methods for the determination of diclofenac in human fluids have been developed and reported in literature within the past decade (Table 1). These include methods for serum, plasma, urine, and most recently, whole blood samples. All of the studies from Table 1 made use of capillary columns. For GC, there are two types of columns that can be used: packed columns or capillary columns. A packed column contains a fully-packed stationary phase made up of fine particles. On the other hand, a capillary column contains a stationary phase that that is coated on the inner column wall. Due to the fully-packed stationary phase, packed columns have higher internal pressures than capillary columns. Most packed columns are 2 – 6 m in length with internal diameters of 2 – 4 mm, whilst capillary columns are typically 15 – 100 m in length with internal diameters of 150 – 300 μm. In general, longer columns provide better separation as they have higher theoretical plates per meter. Owing to their internal diameters, packed columns can handle larger sample volumes than capillary columns. However, if too much sample is injected tailing may be observed, resulting in poorer separation. Therefore, capillary columns are often preferred as they provide better resolution, require smaller amounts of sample, and lower pressures compared to packed columns [31].

In terms of the stationary phase, all of the studies in Table 1 used non-polar columns based on

dimethylpolysiloxane. In general, non-polar analytes are more easily separated using a non-polar stationary phase [31]. In terms of the mobile phase, three of the studies used helium [26, 29, 30], whilst one used nitrogen [27]. Helium is often chosen as the inert gas to be used as it is more efficient than nitrogen and is safer than hydrogen. However, helium is more expensive than nitrogen, which may be a point of consideration [32].

In the studies included, the GC system is paired with either a flame ionization detector (FID) or mass spectrometer (MS) for the detection of diclofenac. The study which employed GC-tandem MS (GC-MS/MS) for the analysis diclofenac in whole blood samples reported the lowest limit of quantification (LOQ) of 0.1 µg/L [26]. In comparison, the lowest LOQ reported using GC-FID was 5.0 µg/L, for the analysis of diclofenac in urine samples [30]. Another advantage of GC-MS is its ability to provide structural information, which can be important in cases where there are co-eluting compounds; GC-FID is unable to differentiate compounds with the same retention time. This is especially significant when dealing with human biological samples, as there is often a limited sample amount. With GC-MS, the profiling of multiple EDCs from a single sample is possible even with co-eluting compounds. However, the instrumentation for GC-MS is often much more expensive than GC-FID [33].

Liquid chromatography

Liquid chromatography (LC) is an analytical method used for the separation of a mixture of compounds which are soluble in solvent. LC, like GC, makes use of a mobile and stationary phase; the difference lies in the mobile phase being a solvent or solvent mixture, and the stationary phase is a porous solid. The separation of compounds from a mixture relies on the interactions between the compounds of interest with both the mobile and stationary phases. Compounds which have higher affinity for the mobile phase will be eluted more quickly, whereas those with higher affinity for the stationary phase will remain in the column for a longer period of time [33].

Several LC methods for the determination of diclofenac in human fluids have been developed and reported in literature within the past decade (Table 2). Plasma samples have been the focus of these studies, although there are also methods for serum and urine samples reported.

Many of the studies used reversed-phase high-performance liquid chromatography (HPLC); this means that the stationary phase is hydrophobic, whilst the mobile phase is polar. The more hydrophobic the molecules being carried by the mobile phase, the more strongly adsorbed to the stationary phase they are and the longer their retention times [33]. The most common column employed by the studies in Table 2 was the octadecyl silane (ODS) column, which is often referred to as a C_{18} column. One study used an octyl silane column, also known as a C_8 column [40]. The difference between a C_{18} and C_8 column is the number of alkyl chains which are bonded to the silica. C_{18} columns are more densely packed and hydrophobic in comparison to C_8 columns; therefore, the retention times of non-polar compounds will be greater in the C_{18} column [33]. One study used a hydrophilic interaction liquid chromatography (HILIC) system, which is another mode of chromatography used for the analysis of polar and hydrophilic compounds [39]. The advantage of using HILIC over reversed-phase HPLC for the detection of polar pharmaceutical compounds, such as diclofenac, is that the analytes are better retained by the column [41].

Two of the studies used methanol/water for the solvent system [34, 35], whilst the other five studies used acetonitrile/water for the solvent system [36-40]. Historically, the most common organic solvents chosen for reversed-phase LC are methanol, acetonitrile, and tetrahydrofuran; of the three, methanol has the weakest elution strength whilst tetrahydrofuran has the strongest elution strength. However, tetrahydrofuran is rarely used nowadays due to toxicity and safety issues. The choice of acetonitrile as the organic solvent for the mobile phase is often made due to the stronger elution strength compared to methanol; furthermore, acetonitrile is less viscous than methanol resulting in improved column efficiency. Nevertheless, methanol may also be chosen as the organic solvent for the mobile phase as it is less expensive compared to acetonitrile [42].

Table 1. An overview on GC methods for the determination of diclofenac in human fluids within the past decade

Formulation	Matrix	Sample Treatment	Recovery (%)	Detector	Column	Carrier Gas	Temperature (°C)	LOQ (µg/L)	Ref.
Diclofenac sodium	Whole blood	1. LLE	92.2 – 105.9	MS/MS (m/z 277 → 242)	SH-RXI-5MS (30 m × 0.25 mm i.d., 0.25 µm film thickness)	Helium	Start at 60°C. Held for 2 min. Increased to 320°C at 15°C/min. Held for 2 min.	0.1	[26]
Diclofenac sodium	Serum, Urine	1. Derivatization (ethyl chloroformate) 2. LLE	Serum: 99 Urine: 97	FID (310 nm)	DB-1 (30 m x 0.32 mm i.d., with 0.25 µm film thickness)	Nitrogen	Start at 150°C. Held for 3 min. Increased to 280°C at 20°C/min. Held for 5 min.	1500	[27]
Diclofenac	Serum	1. LLE 2. Derivatization (N,O-Bis(trimethylsilyl)trifluoroacetamide (BSTFA) with 1% Trimethylchlorosilane (TMCS))	70.3	MS	Agilent J&W HP-5ms UI (30 m x 0.25 µm i.d., with 0.25 µm film thickness)	Not stated	Start at 120°C. Held for 1 min. Increased to 300°C at 15°C/min.	10	[28]
Diclofenac sodium	Plasma	1. Deproteination (phosphoric acid and acetone) 2. LLE 3. Derivatization (pentafluoropropionic anhydride (PFPA))	89 – 95	MS (m/z 277)	BP-1 fused silica (15 m x 0.25 µm i.d., with 0.25 µm film thickness)	Helium	Start at 150°C. Held for 4 min. Increased to 180°C at 4°C/min. Held for 0.5 min. Increased to 300°C at 60°C/min. Held for 0.5 min.	0.25	[29]
Diclofenac sodium	Urine	Ultrasound-enhanced air-assisted liquid–liquid microextraction (USE-AALLME)	74	FID	BP-20 SGE fused-silica capillary column (30 m x 0.32 mm i.d., with 0.25 µm film thickness)	Helium	Start at 100°C. Increased to 230°C at 30°C/min. Held for 10 min. Increased to 260°C at 30°C/min. Held for 7 min.	5.0	[30]

Two of the studies [39,40] made use of ammonium acetate as buffer solutions to improve peak shape [43]. The study by Klencsár et al. [38] made use of formic acid as an additive; formic acid is often used for MS studies as it provides protons for the MS analysis when carried out in positive mode [44]. It should be noted that diclofenac is a weak acid, with pKa value of 4.15 and logP value of 4.51 [45]. Three of the studies used mobile phases with pH values below 4, which means that the diclofenac is in its non-ionized form and has improved retention on the non-polar stationary phase [35, 37, 40]. Only one study used a mobile phase of pH 6.8, where the diclofenac would be in its ionized form [39]. This choice was made because the mode of chromatography used was a HILIC system, where the retention of analytes is dependent on the electrostatic interactions between the positively charged aminopropyl groups of the stationary phase and the negatively charged carboxylic acid functional groups of NSAIDs such as diclofenac.

In the studies included, the most popular LC technique is high-performance liquid chromatography (HPLC), paired with an ultraviolet (UV) detector. The main advantages of UV detectors are that they are relatively inexpensive and simple to operate [46]. However, specificity may be an issue, as there is no way to confirm that the absorption is not due to possible contaminants that also absorb across the wavelengths being observed. Another detector that can be paired with LC is an MS detector. Much like GC-MS, an advantage of liquid chromatography-mass spectrometry (LC-MS) is its ability to provide structural information, and therefore increase specificity when compared to HPLC-UV. Furthermore, MS detectors are often more sensitive than UV detectors, and lower LOQs can be obtained. However, the instrumentation for LC-MS is often much more expensive than HPLC-UV [33]. Klencsár et al. developed a novel quantification method for the detection of diclofenac using HPLC coupled to tandem inductively coupled plasma-mass spectrometry (ICP-MS), which is another type of MS that uses inductively coupled plasma to ionize the sample [38]. ICP-MS is an analytical technique for the determination of trace level elements in environmental and biological samples. Diclofenac contains chlorine (Cl) atoms, enabling the use of ICP-MS detection.

The study which employed HILIC-MS/MS reported the lowest LOQ of 0.000125 µg/L [39]. In comparison, the lowest LOQ reported using HPLC-UV was 0.0358 µg/L, for the determination of NSAIDs, including diclofenac, in human serum [35]. The lowest LOQ reported using a photodiode array (PDA) as the detector was 0.002 µg/L, for the determination of NSAIDs, including diclofenac, in human plasma and urine [37].

One of the main benefits of using LC over GC for the detection of diclofenac from human biological samples is that the samples are already in liquid form and can be injected into the LC system without the need for vaporization [33]. Furthermore, due to GC requiring volatile samples, temperatures required to run the analysis are often much higher than LC. On the other hand, the speed of elution is often much faster for GC than LC [25].

Conclusion

Several chromatographic techniques for the determination of diclofenac in human fluids have been reported in literature over the past decade such as hyphenated GC and LC techniques. Generally, the studies employing LC techniques achieved lower LOQs than those using GC. The most popular detector for the detection of diclofenac was either a UV or MS detector. Whilst UV detectors are relatively inexpensive and simple to operate, MS detectors offer improved selectivity and specificity. This is especially important as expected exposure to pharmaceuticals, such as diclofenac, through contamination of drinking water is relatively low. Therefore, the levels of diclofenac present in human biological fluids would also be expected to be at trace levels and require high sensitivity for accurate analysis.

Table 2. An overview on LC methods for the determination of diclofenac in human fluids within the past decade

Formulation	Matrix	Sample Treatment	Recovery (%)	Detector	Column	Mobile Phase	LOQ (µg/L)	Ref.
Diclofenac	Plasma, Urine	1. Protein precipitation 2. Stir bar sorptive extraction (SBSE)	69 – 74	UV (220 nm)	C_{18} (250 x 4.6 mm; 10 µm)	Methanol/0.2% acid acetic/water (70/0.2/29.8, v/v)	0.65 (Plasma), 0.45 (Urine)	[34]
Diclofenac sodium	Serum	1. Protein precipitation	98 – 99	UV (230 nm)	Shimadzu Shim-pack CLC-ODS (M) (4.6 mm i.d. x 0.25mm)	Methanol/water pH 3.5 (80:20, v/v)	0.0358	[35]
Diclofenac	Plasma, Serum, Urine	1. Protein precipitation 2. Solid-phase microextraction (SPME)	Plasma: 98 – 99 Serum: 97 – 98 Urine: 95 – 98	UV (280 nm)	Eurosphere C_{18} (250 × 4.6 mm)	Acetonitrile/water (50/50, v/v)	0.14	[36]
Diclofenac	Plasma, Urine	1. Protein precipitation 2. Magnetic solid phase extraction (MSPE)	Plasma: 99 – 101 Urine: 99 – 100	Photodiode array (275 nm)	Luna Omega C_{18} (100 mm x 2.1 mm, 1.7 µm)	Acetonitrile and potassium dihydrogen phosphate (10 mM pH 2) in water (50/50, v/v)	0.002	[37]
Diclofenac sodium	Plasma	1. Protein precipitation	93 – 96	ICP-MS/MS (m/z 35 (Cl^+) → 37 (ClH_2^+)	Pre-concentration: Waters XBridge BEH C_{18} (4.6 x 20 mm; 3.5 µm) Separation: Waters XBridge BEH C_{18} (4.6 x 150 mm; 3.5 µm)	A: 0.1% (v/v) formic acid in MQ water B: 0.1% (v/v) formic acid in acetonitrile	2	[38]
Diclofenac	Plasma	1. Protein precipitation	97 – 101	MS/MS (m/z 294 → 250)	Unison UK-Amino column (50 mm × 3 mm; 3 µm)	A: 10 mM ammonium acetate solution (pH 6.8) B: Acetonitrile	0.000125	[39]
Diclofenac potassium	Plasma	1. LLE		UV (230 nm)	Thermo BDS Hypersil C8 (250 x 4.6 mmm; 5 µm)	Acetonitrile and 0.02M ammonium acetate buffer pH 3.5 (53:47, v/v)	25	[40]

Abstract

Accumulated drug residues on contaminated clothing put the wearer at adverse health risk. Therefore, monitoring on laboratory coat contamination shall be in place to safeguard the analysts who have routine exposure in forensic laboratory environment. Using methamphetamine as surrogate drug, this study was aimed to detect the presence of methamphetamine from laboratory coat materials through a response surface methodology optimized dispersive liquid-liquid microextraction (DLLME) in couple with gas chromatography-mass spectrometry (GC-MS). In this study, a Plackett-Burman design was used to optimize the DLLME conditions, including the volumes of extraction and dispersive solvents, the duration of vortex agitation, as well as the speed and time of centrifugation. Residues collected upon DLLME procedure was priorly derivatized with trifluoroacetic acid anhydride followed by GC-MS analysis. Seven types of fabric materials which were contaminated with methamphetamine were extracted and compared. From this study, a volume of 685 µL dichloromethane as extraction solvent, 1000 µL 2-propanol as dispersive solvent, vortex agitation for 90 seconds, and centrifugation at 500 rpm for 5 minutes were determined as the optimum conditions for DLLME. Trace methamphetamine residues were successfully extracted and detected from the different types of laboratory coat materials with recovery percentage of at least 45%. The method could be proposed to laboratories for their evaluation on possible contamination to establish baseline for necessary in-house monitoring and decontamination procedures.

Abstrak

Sisa-sisa dadah yang terkumpul pada pakaian tercemar membawa risiko mudarat kepada pemakai. Justeru, pemantauan pencemaran kot makmal harus diberi perhatian untuk melindungi penganalisis yang mempunyai pendedahan rutin dalam persekitaran makmal forensik. Dengan menggunakan metamfetamin sebagai dadah surogat, kajian ini bertujuan untuk mengesan kehadiran metamfetamin daripada bahan kot makmal melalui pengekstrakan mikro cecair-cecair serakan (DLLME) yang digandingkan dengan kromatografi gas-spektrometri jisim (GC-MS) yang telah dioptimumkan dengan kaedah gerak balas permukaan merangkumi isipadu pelarut pengekstrakan dan pelarut serakan, tempoh pengadukan pusaran, serta kelajuan dan masa pengemparan. Sisa-sisa yang dikumpulkan setelah prosedur DLLME telah diterbitkan terlebih dahulu dengan asid trifluoroasetik anhidrida diikuti dengan analisis GC-MS. Tujuh jenis bahan fabrik yang telah dicemari dengan metamfetamin telah diekstrak dan dibandingkan. Daripada kajian ini, 685 µL diklorometha sebagai pelarut pengekstrakan, 1000 µL 2-propanol sebagai pelarut serakan, pergerakan vorteks selama 90 saat, serta pengemparan pada 500 rpm selama 5 minit telah ditentukan sebagai keadaan optimum bagi DLLME. Sisa-sisa surih metamfetamin telah berjaya diekstrak dan dikesan daripada jenis bahan kot makmal yang berbeza dengan peratusan pemulihan semula sekurang-kurangnya 45%. Kaedah tersebut boleh dicadangkan kepada makmal-makmal untuk penilaian mereka terhadap pencemaran yang berkemungkinan untuk menetapkan garis dasar untuk pemantauan dalaman dan prosedur penyahcemaran yang diperlukan.

Introduction

Handling and processing illicit drugs in a drug testing laboratory are known to have potentially contaminated various surfaces within the laboratory [1-3]. It is important to note that illicit drugs often with unknown formulation or synthesis pathway could pose serious health and safety risk to individual who had direct or even indirect contact with the constituents. Besides the cooks and operators of a clandestine drug laboratory, other vulnerable groups such as occupants residing around the clandestine laboratory, law enforcement personnel who investigate drug scene or even the laboratory analysts who perform routine analyses on illicit drugs or their associate chemical are all exposed to additional risk capable of leading to chronic health effects [4, 5]. Consensus standard for occupational exposure limits for common illicit drugs and their precursors for forensic laboratory settings are yet to be established although a study by the National Institute for Occupational Safety and Health (NIOSH) had reported that the detectable cocaine, fentanyl, heroin, and methamphetamine are present at nanogram level, respectively, in the air and on surfaces within drug testing laboratories [2].

In relation to illicit drug contamination to the public, investigations in waste waters and surface water environment to explore the health effects and the trends of drug usage in the local communities were reported [6-8]. Studies were also conducted on various daily high contact surfaces that were found to contain detectable levels of illicit drugs [9, 10], suggesting the possibility of transferring and persisting of these substances. Airborne particles of illicit drugs were also found to be persisting in the forms of residual powder or condensed aerosol [11-13]. Clandestine drug laboratories, in the stage of active or dormant, were contaminated following the activities during cooking and subsequent processing steps [4, 14], where the surface deposition of drug was reported to be as high as 860.0 µg of methamphetamine on a surface of 100 cm^2 [15]. It was also important to note that the illicit drugs and by-products during the clandestine activities could have contaminated the soil, water, and air within or proximate areas to a clandestine drug laboratory site [4, 16].

In the setting of forensic testing laboratories, there are personnel who face higher risk of drug exposure, especially individuals who handle and perform routine drug analyses [1-3]. Residual smoke pollutant could be present on the surfaces and in dust which tend to be released again into the gas phase interacting with other

contaminants and oxidants to form secondary pollutant [17, 18]. Studies have shown that the aerosolized release of illicit drug substance was evident, and drug particles could spread throughout the laboratory via touch, direct transfer, and/or suspension of particulate in the air [1-3], where the analytical balance and its surrounding area were most contaminated. Furthermore, it has been reported that the drug substance can adhere to clothing and other fabrics, even at low and sustained levels of air concentration [17, 18]. This could lead to re-exposure through contact with these contaminated materials and clothing [18].

In the United States, a study conducted by Sisco and Najarro [3] involving over 700 samples from 20 laboratories showed that the contamination levels were at the highest within the drug unit, measured with at least 10 nanograms levels in nearly all sampled areas. Cocaine and heroin were detected more frequently with the highest surface concentrations in these laboratories [3]. These two drugs were highly prevalent on the surfaces and in the air of drug testing laboratories as indicated by NIOSH [2], where 11 out 12 tested laboratories were found to contain cocaine, and heroin was found in nine laboratories. Additionally, airborne fentanyl and methamphetamine were found in four and three laboratories, respectively. All the targeted drugs i.e. cocaine, heroin, fentanyl, and methamphetamine were detected on the bench surfaces in all the twelve laboratories, except one laboratory without detectable level of methamphetamine [2]. In Australia, residues of illicit drugs were detected in police stations [16, 19], where handling of drug evidence could contribute to an elevated background level at the police stations at a level less than 50 ng. Contamination in crime scene vans and storage lockers, report preparation desks, and toxicology units were also reported [1].

Although studies have investigated on various areas within a drug testing laboratory and toxicology units for the presence of drugs, contamination level of laboratory coat worn as personal protection equipment was understudied. This study was initiated to provide some insight on drug contamination levels from a frequently overlooked perspective, specifically from the laboratory coat worn by the laboratory personnel, using methamphetamine as an indicator of the degree of contamination, since methamphetamine is among the most widely abused drug as indicated by its users followed by opiates, amphetamine-type simulant (ATS), cannabis and others [20].

Applications of DLLME in analytical chemistry included the examination of narcotics, illicit drugs, hallucinogens, and cannabinoids [21-23]. In DLLME, the mixing of extraction and dispersive solvents and addition to the aqueous sample solution led to the formation of tiny droplets dispersed throughout the aqueous phase. The creation of a large contact area allows for a fast equilibrium within short extraction time. Additionally, vortex agitation contributes to a rapid partition equilibrium while the centrifugation step facilitates the phase separation after extraction. Upon DLLME, the enriched analytes can be collected with a microsyringe from the sedimented phase and subjected to further examination [22-24].

Using dispersive liquid–liquid microextraction (DLLME) and gas chromatography-mass spectrometry (GC-MS), we reported a Plackett-Burman Design (PBD) for method optimization which was implemented for the determination of methamphetamine from the laboratory coat materials. PBD is a two-level factorial design that only requires N=4t runs (a multiple of 4 for the number of runs) to separate main effects from the interaction effects. Previous studies have also suggested its applicability and practicality in enhancing an analytical technique, particularly during the optimization step [25, 26]. It is hoped that the study would aid in proposing an analytical method to provide a quick snapshot on possible laboratory coat contamination or as a long-term monitoring program incorporated into the quality management system for appropriate laboratory clothing decontamination procedures.

Materials and Methods

Materials and chemicals

Methamphetamine hydrochloride (99.2% purity) was supplied by the Department of Chemistry Malaysia. Tetradecane standard, as the internal standard, was purchased from Dr. Ehrenstorfer GmbH (Augsburg,

Germany). Chromatography-grade acetonitrile, chloroform, dichloromethane, methanol, and 2-proponal were purchased from Merck (Whitehouse Station, NJ, USA). Trifluoroacetic acid anhydride (TFAA) (>99%) used as derivatization agent was purchased from Sigma Aldrich (St. Louis, MO, USA). All chemicals used as they are. A stock solution of methamphetamine was prepared at 50 mg/mL by dissolving 500 mg of methamphetamine standard in methanol and diluting to 10 mL in a volumetric flask. Working standard solutions were prepared by appropriately diluting the stock solution into the pre-defined concentration levels.

Laboratory coat materials

Seven types of fabric materials commonly used for making laboratory coat were obtained from local clothing retailer. These materials were then cut into squares (10 x 10 cm). Prior to the analyses, the laboratory coat materials were washed, dried, and kept in a resealable plastic bag.

Plackett-Burman design of DLLME optimization

The choice of solvents is crucial in DLLME for good extraction efficiency. A preliminary experiment on the selection of extraction (chloroform and dichloromethane) and dispersive (acetonitrile, methanol, and 2-propanol) solvents were firstly carried out. For each combination, 300 µL of each extraction solvent was used in coupled with 300 µL of dispersive solvent which was adapted from the study [21]. The combination which gave the high extraction efficiency was determined through the determination of peak area ratio, considering the peak area of methamphetamine against the peak area of internal standard. Based on the outcome, DLLME was optimized through a PBD using Minitab® 18 software (Minitab Inc., State College, PA, USA). Five factors, covering the volume of extraction solvent, volume of dispersive solvent, duration of vortex agitation, centrifugation time, and centrifugation speed were evaluated with 2 replicates and 2 center points, totaling at 26 runs as demonstrated in Table 1.

Table 1. Plackett-Burman design with five factors of variables.

Factor	Low (-1)	Medium (0)	High (+1)
Volume of extraction solvent (µL)	110	555	1000
Volume of dispersive solvent (µL)	100	550	1000
Duration of vortex agitation (s)	0	45	90
Centrifugation time (min)	5	7.5	10
Centrifugation speed (rpm)	500	1250	2000

Recovery study: Sample preparation procedure

A volume of 100 µL methamphetamine at three different concentrations, namely 5 µg/mL, 15 µg/mL, and 30 µg/mL, was separately spread over the defined area on the laboratory coat materials following the method used in surface contamination study conducted before [27]. The deposited solution was then allowed to dry for 5 mins prior to extraction, leading to the presence of defined masses of methamphetamine (0.5 µg, 1,5 µg and 3.0 µg) on each laboratory coat material. It was noted that the maximum acceptable amounts of surface methamphetamine were varied among the countries worldwide, ranging from 0.5 µg to 4.0 µg per an area of 100 cm^2 [14]. Upon drying, a 7 mL aliquot of 4% (m/v) of sodium hydroxide solution was added to culture tube with the cloth samples followed by 5 mins sonication (200 W) for basic extraction of the drug. The sonicated samples were then transferred into a 10 mL glass syringe, where the syringe plunger was depressed as much as possible to dispense the solution into a 20 cm glass culture tube. The step was repeated by transferring the laboratory coat materials from the syringe into the culture tube followed by an additional of 7 mL 4% of NaOH solution. The sample solution was again dispensed and combined. Prepared solution was then subjected to the optimized DLLME procedure. Subsequently, the extraction phase-dispersed particles found sedimented at the bottom which then were collected and evaporated to dryness under a gentle stream of purified nitrogen gas.

Sample derivatization by TFAA

The sample derivatization procedure was adapted from Abdullah and Miskelly [27]. For derivatization, the residue was added with 100 µL of dichloromethane followed by 100 µL of ethyl acetate and 50 µL of TFAA. The sample was then subjected to a 30-min incubation at 38°C in an oven. Upon incubation, the excessive solvents and TFAA were carefully evaporated using a gentle stream of nitrogen flow. The residue was then reconstituted with 1 mL of ethyl acetate containing 0.25 µL/mL of tetradecane.

GC-MS analysis

Gas chromatographic analyses were performed using a 7890B GC system equipped with a 5977-mass selective detector (MSD) and split/spitless injector (Agilent Technologies, Santa Clara, CA, USA). A HP-5MS capillary column (30 m x 0.32 mm 0.25 µm film thickness) was used for separation and purified helium gas as the carrier gas was flowed at a constant rate of 1.0 mL/min. The front inlet was set at 250°C while the oven temperature was programmed as follows: 70°C for 2 mins, increased at 20°C/min to 280°C, and then hold at 280°C for 2 mins. MassHunter Workstation Software (Version 3.1, Agilent Technologies, Santa Clara, CA, USA) was used for data acquisition and interpretation, where the results were at a rate of 1.0 sec/scan and the mass spectra was collected in scan mode from m/z 41 to m/z 500. The resulting peaks were confirmed through the comparison of retention times and determination by the National Institute of Standards and Technology (NIST) MS Search Version 2.0 along with the NIST mass spectral library (NIST17) (Gaithersburg, MD, USA).

Upon reconstitution, the sample vial was flushed with nitrogen gas, capped, and shaken well prior to GC-MS analysis. Utilizing the optimized DLLME conditions, the recovery percentages (% recovery), calculated by dividing the mass of methamphetamine determined from the standard calibration curve with the known amount of methamphetamine in percentage, and the relative standard deviations (%RSD) from the seven types of laboratory coat materials were evaluated and compared.

Results and Discussion

Selection of extraction and dispersive solvents

In a DLLME technique, extraction solvent and dispersive solvents with adequate water miscibility and higher density than water are crucial to achieve a good extraction efficiency and good GC chromatogram [28]. The extraction solvent, i.e. dichloromethane has high capability for extracting analytes with a low water solubility while being soluble in the dispersive solvent. The phase separation requires a significant density difference between the extracting solvent and water [29]. In this study, extraction efficiencies of each combination of extraction and dispersive solvents were compared and evaluated (Figure 1). It was found that a combination of dichloromethane (extraction solvent) and 2-propanol (dispersive solvent) demonstrated the highest extraction efficiency for methamphetamine at a peak area ratio of 6.127 as compared to other solvent combinations. Dichloromethane demonstrated its good extraction capability for the target analytes, and able to form an emulsion with the presence of the dispersive solvent [30,31]. On the other hand, the dispersive solvent (2-propanol) has low interfacial tension, allowing for the dissolution of both organic phase (extraction solvent) and the aqueous phase (sample solution) [32].

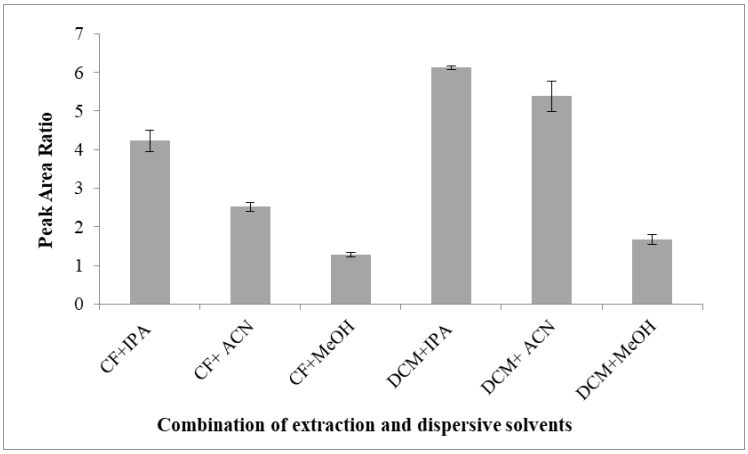

Figure 1. Extraction efficiencies with various combination of extraction and dispersive solvents at 1:1 ratio (n=7) (CF: chloroform; DCM: dichloromethane; IPA: 2-propanol; CAN: acetonitrile; MeOH: methanol)

PBD of DLLME optimization

A response surface methodology, namely the PBD was used to determine the experimental settings involving five variables for the greatest extraction efficiency of methamphetamine. The design allowed for the collection of the maximum amount of information with a minimum number of analyses [33]. The influences of each factor, including volume of the extraction solvent (x_1), volume of dispersive solvent (x_2), duration of vortex agitation (x_3), centrifugation time (x_4), and centrifugation speed (x_5), were tested. The collected experimental data were utilized to develop an estimate for a model that can adequately estimate the response variable given in the second order polynomial function as in the following equation:

Methamphetamine peak area: $$-3.202 + 0.03356x_1 + 0.002848x_2 + 0.00032x_3 + 0.3514x_4 - 0.000946x_5 - 0.00028x_1 * x_1 + 0.000002x_1 * x_2 + 0.000052x_1 * x_3 - 0.000458x_1 * x_4 + 0.000001x_1 * x_5 - 0.000002x_2 * x_3 - 0.000558x_2 * x_4$$

Analysis of variance (ANOVA) statistical test revealed that the fitted response surface model of second order was highly significant with F-value = 182.31 (p<0.001). The model explained 99.41% of the variation, with a predicted R^2 of 97.64%. The large predicted R^2 values suggested a good predictive ability of the model. Figure 2 shows the Pareto chart of the standardized effects comparing the relative magnitude and the statistical significance of main, square, and interaction effects in this study. The reference line at standardized effect of 2.16 indicated the significant effect as a significance level of 0.05. From the Pareto chart, the largest effect was contributed by the squared term for volume of extraction solvent followed by main effects of the volume of extraction volume and the time of vortex agitation.

The association between the detection of methamphetamine and each term was then determined and Table 2 demonstrates the output of the ANOVA statistical test. By considering a variable to be statistically significant at a 5% level of significance, the coefficient for the linear effect of the variables included extraction volume (p <0.001), vortex time (p <0.001) and centrifugation time (p <0.001) which were highly significant. The centrifugation speed was also statistically significant (p = 0.041), where no significant association between the volume of dispersive solvent (p = 0.375) with the recovery of methamphetamine upon DLLME procedure. The squared terms for the volume of extraction solvent were also significant at the α = 0.05 significance level (p <0.001), suggesting that the relationship between this factor and the detection of methamphetamine followed a curved line. In addition, five interaction terms were found significant in their respective coefficients which suggested their relation-

ships between the two factors. The contour plots of these interaction terms are shown in Figure 3.

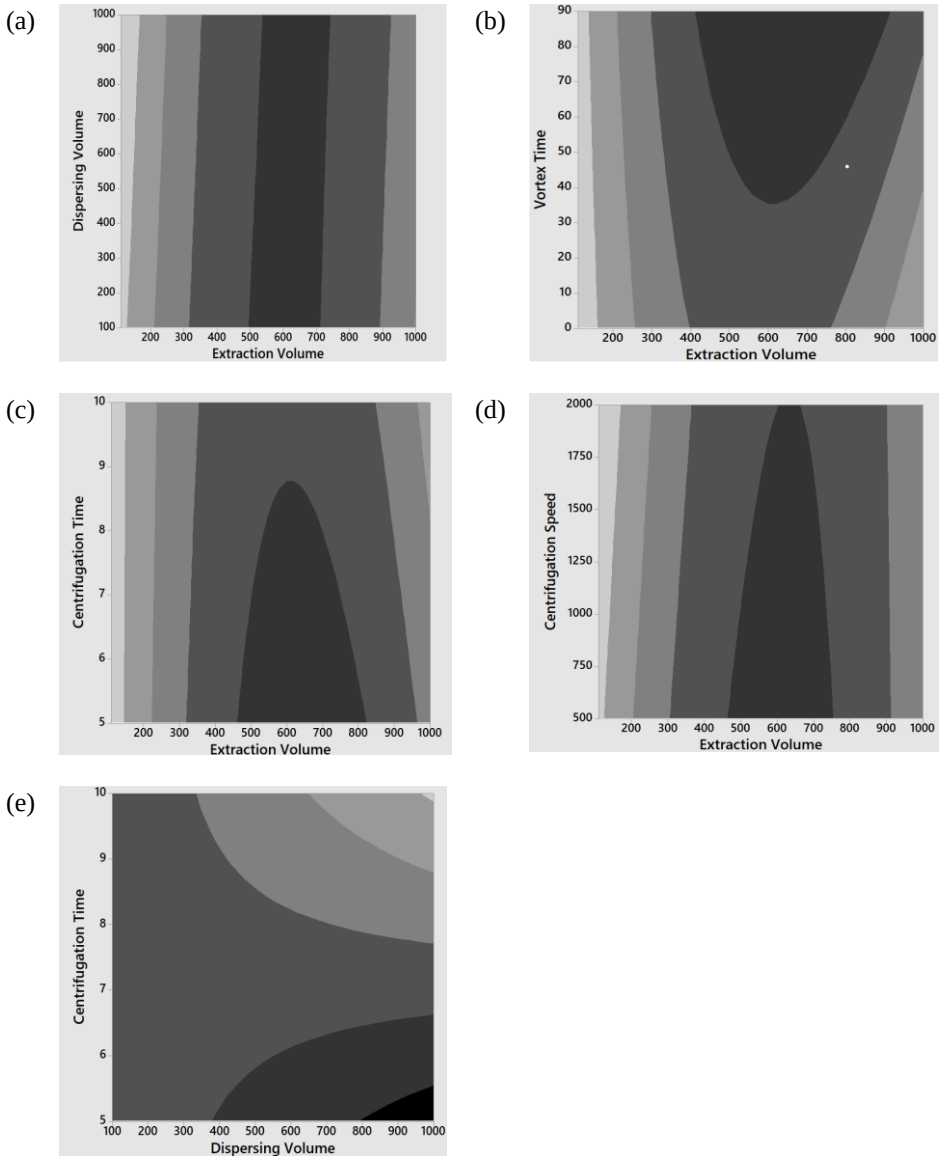

Figure 3. Contour plots showing interaction between (a) volume of extraction solvent vs volume of dispersive solvent (p<0.001); (b) volume of extraction solvent vs duration of vortex agitation (p<0.001); (c) volume of extraction solvent vs centrifugation time (p<0.001); (d) volume of extraction solvent vs centrifugation speed (p= 0.006); and (e) volume of dispersive solvent vs centrifugation time (p < 0.001)

Interaction between volume of extraction solvent and four variables (i.e. volume of dispersive solvent, duration of vortex agitation, centrifugation time, and centrifugation speed) were significant as shown in Figure 3(a)-(d). The darker regions in each figure indicated the higher extraction efficiency for methamphetamine. Based on Figure 3(a), the extraction efficiency increased with the increase of the volume of extraction solvent until certain point at approximately 700 µL and get reduced afterwards. Note also that a longer duration of vortex agitation, optimized at 90 s [Figure 3(b)], followed by a slower centrifugation time for 5 mins and shorter and centrifugation speed at 500 rpm, respectively [Figure 3(c)-(d)] were found to have

increased the extraction efficiency. The interaction between dispersive volume and centrifugation time was also highly significant [Figure 3(e)]. It was evident that with an increase in the dispersive volume up to a volume of 1000 µL and a decrease in centrifugation time to 5 mins, respectively, the efficiency of methamphetamine extraction was raised significantly.

Using the DLLME optimized conditions which shown in Table 3, a mixture containing 685 µL dichloromethane (extraction solvent) and 1000 µL 2-propanol (dispersive solvent) was injected into the sample solution. The ternary system was subjected to vortex agitation for 90 seconds, followed by centrifugation at 500 rpm for 5 mins. Note that the volume of extraction solvent was optimized to 685 µL, where this is the point indicating that when the extraction volume was too low, the extractant amount was very small and therefore unable to extract the analyte efficiently. On the contrary, the analyte would become diluted with high volume of extraction solvent, minimizing the amount of target substance to be extracted [34]. It was also observed that a longer duration of vortex agitation could aid in handling the complex matrices of the extraction, where a shorter period of centrifugation time could achieve the full separation of emulsion [35]. The equilibrium state could be immediately achieved after the addition of solvent and vortex agitation of the sample solution; therefore, a short centrifugation duration and speed were found sufficient to achieve a high extraction efficiency [36].

Table 3. Multiple response prediction for the response of methamphetamine detection.

Factor	Optimized Settings
Volume of extraction solvent	685 µL
Volume of dispersive solvent	1000 µL
Duration of vortex agitation	90 s
Centrifugation time	5 min
Centrifugation speed	500 rpm

Recovery of methamphetamine from laboratory coat materials

Laboratory coat material samples deposited with defined masses of methamphetamine (0.5 µg, 1,5 µg and 3.0 µg) were treated with proposed DLLME protocol, derivatized with TFAA, and subjected to GC-MS analysis. Figure 4 shows the mean percentages of recovery with seven type of laboratory coat materials. On average, at least 45% of methamphetamine were successfully recovered from the laboratory coat materials, depending on the concentration levels and types of fabric materials. Previously, solvent extraction [37] and liquid-liquid extraction (LLE) [38] were also used to extract methamphetamine from fabric materials followed by its detection through instrumental techniques. When compared to these conventional sample extraction methods, our DLLME procedure is less laborious while avoiding the drawbacks suffered from the conventional LLE, such as the need for excessive quantities of chemicals, reagents and sample, slow and long extraction time, and the formation of emulsions.

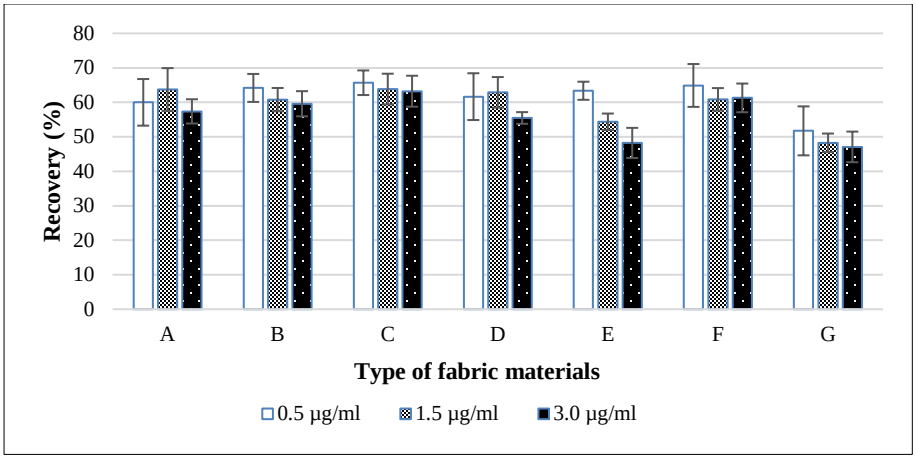

Figure 4. Mean percentages of recovery for methamphetamine from seven type of laboratory coat materials

Extraction efficiency of methamphetamine from the laboratory coat materials could be impacted by the physio-chemical interactions of solute of drugs with the surfaces and their penetration or diffusion into porous substrates [39]. It is also worth noting that the penetration is a complex phenomenon involving the interaction between solvent and porous substrates, depending on surface tension and the contact angle between each other [40]. As compared to studies which emphasized on the extraction of the drug substance from non-porous surfaces, the extraction efficiencies were also reported to be varied based on the surfaces, where only approximately 60% of the methamphetamine could be recovered from the varnished wood substrate [27].

Our study showed slightly variation in term of the amount of methamphetamine which successfully recovered from different laboratory coat materials through the application of proposed extraction protocol. In general, the %RSD reported was in an acceptable range, falling between 3.14-9.90%. Sorption of methamphetamine compounds on a fabric could have been influenced by its physical properties of the fibers, including its porosity [41]. Fabric materials with polar and slightly basic in nature, methamphetamine might also have great affinity for cotton that made up of polar cellulose, waxes, proteins, and fatty acids [42]. These factors certainly deserve further studies.

Although the DLLME procedure was found to be effective in extracting methamphetamine from the laboratory coat materials. As compared to other extraction techniques such as conventional LLE, DLLME procedure can be completed in a relatively quicker manner, consuming low volume of solvent, and requiring shorter extraction time. It is cost effective and environmentally friendly, and therefore widely applied in trace analysis [43]. DLLME also aids in minimizing the tendency of forming emulsion as frequently encountered during LLE procedure [44]. Based on our findings, it can be predicted that there is at least two-fold of drugs actually present on the laboratory coat materials than those detected by the protocol here. The laboratory monitoring program should therefore take corrective actions if recovered concentration exceeds the safe exposure level. As a future recommendation, the composition and characteristics of laboratory coat materials should be further explored to provide details insight on the influential factors that might affect the recovery of analytes.

It was noted that the proposed method was destructive in nature if the fabric material has to be cut out for extraction. Bitter [39] had proposed a wiping procedure in which a surface contaminated with methamphetamine was wiped and analyzed; however, the methamphetamine was detected at a very low amount with low recoveries, indicating the extraction might not adequately efficient to recover the target substance from porous samples. To apply the proposed method in the operational settings, similar fabric material can be

patched onto a laboratory coat and detached for extraction and analysis during routine monitoring to avoid destruction of the laboratory coats. The protocol of methamphetamine deposition used here was adapted from studies on household surfaces, and shall also be explored in future studies, especially on the contamination mechanisms and how they affect the recoveries of target substances. In general, this study has successfully demonstrated the possibility of determining methamphetamine as an indicator of clothing contamination from the fabrics, where it would benefit the screening of methamphetamine contamination on laboratory coats, and subsequently in planning the appropriate corrective or preventive actions and recommendations to address the contamination issues.

Conclusion

Determination of methamphetamine from laboratory coat materials was successfully carried out using a PBD optimized DLLME procedure coupled with GC-MS analysis. An addition of a combination of 685 µL dichloromethane (extraction solvent) and 1000 µL 2-propanol (dispersive solvent) into the sample solution followed by a 90s vortex agitation and a centrifugation at 500 rpm for 5 mins produced the highest extraction efficiency for methamphetamine. Based on the proposed procedure, at least 45% of methamphetamine could also be successfully recovered from the fabric materials. Repeatable recoveries of the drug substance were achieved from the laboratory coat materials, varied on their respective composition. As future recommendation, the properties of fabric materials that could influence the recovery of methamphetamine shall be investigated, in addition to the exploration on the contamination mechanisms of drug substances on these fabric materials.

Abstract

Photo-esterification of Waste Cooking Oil (WCO) with TiO_2/EFBA500 photocatalyst as heterogeneous photo-catalyst has been investigated in this study. WCO is nonedible oil with high free fatty acid (FFA) content which needs esterification to reduce its FFA content followed by transesterification to produce Fatty Acid Methyl Ester (FAME). WCO was esterified with methanol through photocatalytic process with UV light irradiation as the light source. TiO_2/EFBA500 photocatalyst was synthesized using simple wet impregnation method. The samples were characterized by X-Ray Diffraction (XRD), Scanning Electron Microscope (SEM), Energy Dispersive X-ray Spectroscopy (EDX) and Ultraviolet Diffuse Reflectance Spectroscopy (UV-Vis DRS) analysis. Characterization results revealed that the bandgap energy of TiO_2/EFBA500 was successfully reduced from 3.0 eV to 2.88 eV which was suitable in UV light irradiation and needed low energy in the process. TiO_2 semiconductor composite doped with Empty Fruit Bunches Ash (EFBA) showed a very high catalytic activity for FFAs photo-esterification. Experimental results showed that the optimum condition of photo-esterification with catalyst loading to oil was 4 wt.%, 20:1 methanol to oil molar ratio and 2 h reaction time achieved the reduction of FFA content from 11.65% to 2.04% with FFA conversion of 83%. FFA content was successfully reduced indicating that photo-catalytic esterification is a viable option in order to produce FAME. Biodiesel analysis using Gas Chromatography Mass Spectrometry (GCMS) is used to calculate yield and methyl ester content according to international biodiesel standard European (EN14103).

Abstrak

Foto-esterifikasi sisa minyak masak (WCO) dengan foto-mangkin TiO_2/EFBA500 sebagai mangkin foto heterogen telah dikaji dalam kajian ini. WCO ialah minyak tidak boleh dimakan dengan kandungan asid lemak bebas (FFA) yang tinggi, memerlukan pengesteran untuk mengurang kandungan FFA diikuti dengan transesterifikasi untuk menghasilkan asid lemak metil ester (FAME). WCO telah diesterkan dengan metanol melalui proses fotokatalitik dan penyinaran cahaya UV sebagai sumber cahaya. Foto-pemangkin TiO_2/EFBA500 telah disintesis menggunakan kaedah impregnasi basah yang biasa. Sampel dicirikan dengan Pembelauan Sinar-X (XRD), Mikroskopi Imbasan Elektron (SEM), Serakan Tenaga Sinar (EDX) dan Spektroskopi Pemantulan Resap UV-vis (UV-Vis DRS) analisis. Keputusan perincian mendedahkan bahawa tenaga jurang jalur TiO_2/EFBA500 berjaya dikurangkan daripada 3.0 eV kepada 2.88 eV yang sesuai dalam penyinaran cahaya UV dan tenaga yang rendah diperlukan dalam proses tersebut. Komposit semikonduktor TiO_2 yang digabungkankan dengan abu tandan buah kelapa sawit kosong (EFBA) menunjukkan aktiviti pemangkinan yang sangat tinggi untuk pengesteran foto FFAs. Keputusan eksperimen menunjukkan keadaan optimum foto-esterifikasi dengan muatan mangkin nisbah kepada minyak ialah 4 wt.%, 20:1 metanol kepada nisbah molar minyak dan 2 jam masa tindak balas mencapai pengurangan kandungan FFA daripada 11.65% kepada 2.04% dengan penukaran FFA sebanyak 83%. Kandungan FFA telah berjaya dikurangkan menunjukkan bahawa pengesteran foto-mangkin adalah pilihan yang terbaik untuk menghasilkan FAME. Biodiesel dianalisis dengan Kromatografi Gas-Spektroskopi Jisim (GC-MS) analisis untuk mengira hasil dan kandungan metil ester mengikut piawaian biodiesel antarabangsa Eropah (EN14103).

Introduction

The depletion of fossil fuels has brought about the development of a renewable and sustainable alternative energy which is environmentally friendly for the benefit of the future [1]. Fatty acid alkyl ester, also named as biodiesel, has almost the same properties as petroleum fuel which is a good replacement for conventional petroleum product especially in the transportation sector. Besides that, it produces low emission of carbon monoxide, sulfur dioxide and un-combusted hydrocarbon [2]. This alternative energy is claimed to be as clean as the biofuels produced via catalytic transesterification of triglycerides (TG) with alcohol e.g. methanol converted to fatty acid alkyl ester (biodiesel) and glycerol as by-product [3]. TG is the main component of fat and oil in vegetable oils and animal fats. Examples of vegetable oils are such as soybean oil, sunflower, cottonseed etc., [4]. Reported by Volli et al. in order to reduce the cost of biodiesel and to avoid ecological imbalance due to the use of this edible sources, non-edible sources have become a new target feedstock for the biodiesel production [5]. The examples of non-edible oil are waste cooking oil, jatropha curcas oil, greased oil and etc. [6]. The usage of non-edible oil can solve the waste management problem. It is also sustainable and is able to reduce the production cost. This type of non-edible feedstock consists of high FFA content (>1% FFA) and therefore requires a pretreatment step to reduce it [7].

Reported by Razak et al. the homogeneous catalyst has been widely used over generations [8]. However, this catalyst can harm our environment and there are many disadvantages in using this catalyst. Homogeneous catalyst cannot be reused because the reactant and the product are inseparable, and this process also triggers waste water problem during the purification process [9]. Moreover, it can reduce the yield of biodiesel production. Several types of heterogeneous catalysts have been introduced by many researchers that can solve the separation problem. The use of catalyst that can be recycled is an advantage and it will also reduce the operational cost. The example of heterogeneous catalyst includes sulfated zirconia [10], heteropoly acid [11], carbon nanotubes [12], biomass carbon based [13] and more. However, these types of thermal catalytic processes cannot outdo heterogeneous photocatalyst as it is performed at room temperature under either solar energy or artificial light sources, thus reducing the operation cost as it can save the energy [3]. As reported by Guo et al., using photocatalyst in the production of biodiesel can convert more than 90% of FFA [14]. Examples of nanomaterials are cerium oxide [15], zinc oxide [16], titanium dioxide [17], chromium (IV) [18] and metal oxide which are highly stable, very effective, and requires a low cost with high availability [19].

Photocatalyst is a light induced catalytic process that involves oxidization and/or reduction of organic molecules via redox reactions. This process generated electron-hole pair on the surface of semiconductors upon light irradiation [3]. This photocatalyst has been widely used in the applications of wastewater treatment [20], bacteria disinfection [21], hydrogen production [22] and carbon dioxide removal [23]. Photocatalyst in the photo-esterification reaction takes place when alcohol e.g., methanol reacts with positive holes (h^+), generating methanol radicals ($CH_3O^{\cdot}$) and releasing electron (e^-) which is generated under solar irradiation react with FFA formed radical of fatty acid (R-$COOH^{\cdot}$) on the surface of photocatalyst. From the intermediates of $CH_3O^{\cdot}$, R-$COOH^{\cdot}$ and H^+, then formed final products of methyl ester and water [5]. Reported by Citra Dewi & Slamet, they applied TiO_2P_{25} in the photo-esterification and successfully converted 45.2% of FFA in waste cooking oil [24]. Ghani et al., reported that they synthesized bismuth vanadate with reduced graphene oxide bismuth vanadate for photo-esterification of soap nut oil and achieved maximum conversion of FFA at 88% [6, 25]. Thus, photocatalyst is suitable and capable in the reaction process with methanol and FFA under light irradiation. Not only that, it is environmentally friendly, reusable, and produced high yield which assured the successfulness in the production for new alternative energy.

Titanium dioxide nanoparticles (TiO_2) is among high photocatalytic activity consisting of three main crystallographic phases, which are anatase, rutile and brookite [26]. It is nontoxic, easily available, superior redox ability, and photostability. It has become the main focus in bioenergy field as promising heterogeneous catalyst in the esterification process. The photocatalytic activity of TiO_2 depends on the recombination rate of the photogenerated electron hole pair (e^-/h^+). However, it is usually limited by its large bandgap (~ 3.2 eV for anatase) that increases the recombination rate [27]. In order to reduce the e^-/h^+ pair recombination rate, combining techniques with high surface area supported by materials such as zeolite [28], carbon nanotube [29], graphitic carbon nitride [30] and active carbon [31] is the best option. Besides that, it can improve reactivity and kinetic of the catalyst as they formed crystal with high specific surface area. In recent work by Corro et al. they used ZnO/SiO_2 in the photo-esterification of Jatropha Curcas Crude Oil (JCCO) which achieved 96% FFA conversion [32]. Redjeki et al. used CuO/TiO_2 by conversion FFA of Kemiri Sunan Oil around 59%. Therefore, by combining technique with other supported material can prevent the recombination rate of e^-/h^+ pair and enhanced the photocatalytic activity [33].

Recently, some researcher use ash as dopant with TiO_2 semiconductor. Ash is the industrial waste byproduct resulting from the burning of solid fuels. The constituents of ash are mostly unburned carbon, metal oxides (Si, Al, K, Fe, Ca) and other inorganic substances [34]. Reported by Suliman et al., they doped palm oil fiber ash (POFA) with TiO_2 and reduced almost 50% of chemical oxygen demand (COD) in wastewater [35]. Shi et al. also claimed that they had also doped fly ash (FA) with TiO_2 and successfully degraded 95% of phenol in aqueous solution. The concentration of metal oxide of ash materials might be an excellent opportunity when dope with TiO_2 that can enhanced the photocatalytic activity in the reaction [36]. Empty fruit bunches ash (EFBA) from palm oil mill has recently suggested as supported material in the synthesized of photocatalyst. EFBA does not only work to enhance the efficiency of the interfacial charge transfer in the photocatalytic process but also function as a major non-toxic waste sources which is low-cost adsorbent and easily available. It is safe to state that EFBA is the outcome of the thermal power generation plant. Besides that, EFBA can reduce the cost of waste management and environmental problem. In this study, the photocatalytic activity of TiO_2 alone and TiO_2 doped with EFBA is compared in removal of FFA in WCO and further utilized in transesterification for biodiesel production.

Materials and Methods

Materials

Empty fruit bunches ash (EFBA) was obtained from FTJ Bio Power Sdn. Bhd. The feedstock of waste cooking oil (WCO) was obtained from the local restaurant in Bandar Jengka Pusat, Pahang. 1.5 L of WCO is collected, filtered, and saved for analysis. Titanium Dioxide (Degussa P25), n-hexane, methanol, methyl

heptadecanoate, sodium hydroxide, potassium hydroxide, phenolphthalein is all purity > 99%, hydrochloric acid (HCl, purity >32%) were obtained from QReC. All reagent will be directly purchased with analytical grade and used without further purification.

Preparation of catalyst

EFBA was dried in the oven at 120 °C then sieved through 100 mesh screening. TiO_2-Degussa P25 (1.0 g) was mixed with EFBA (1.0 g) in 100 ml distilled water (1:1). The new nanocomposite photocatalyst was obtained from the slurry under stirring (300 rpm) for 1 h, at room temperature, on a thermoset heating plate. After filtration, the slurry was further washed with deionized water followed by drying in oven at 120 °C overnight. Finally, dried material was calcined at 500˚C for 3 h in a tube furnace with a heating rate of 5˚C/min. The sample obtained is 1.8 ± 0.3 g and denoted as TiO_2/EFBA500.

Characterization of catalyst

The catalysts were analyzed using X-Ray Diffraction (XRD) to identify the composition of samples. The diffractograms were measured in the 2θ mode, within the range of 20° to 90° at the speed of 6.0°/min. Scanning Electron Microscopy and Energy-Dispersive X-ray spectroscopy (SEM-EDX) is used to study the morphology of samples. It was done with a SEM JEOL JSM-7100F scanning electron microscope at 15.0 kV. UV-Vis Diffuse Reflectance Spectrometer (UV-Vis DRS) as to measure the bandgap of the samples.

Photocatalytic esterification of WCO

The photocatalytic esterification process was conducted in a reactor assisted by a 6 W UV lamp (λ = 365 nm) as the light source. The reaction mixture catalysed by TiO_2 and TiO_2/EFBA500 photocatalyst, stirred continuously under stirring rate of 400 rpm by using an internal magnetic stirrer which generated a strong liquid rotation leading to homogeneous irradiation of the whole reacting mixture. A 10 g of WCO was used with varies parameter of methanol to WCO molar ratio in the range of 12:1, 16:1, 20:1, 24:1, the amount of catalyst is 1 wt.%, 2 wt.%, 3 wt.%, 4 wt.%, 5 wt.%, UV irradiation time is 1 h, 2 h, 3 h, 4 h, 5 h. After esterification, the mixture was centrifuged at 5000 rpm for 15 min. The lower layer consists of unreacted triglycerides (further trans-esterification), and insoluble catalysts. The upper layer consists of unreacted methanol and water from reaction process. The catalyst was first filtered and separated, and the excess methanol was removed by drying in the oven for 15 min at 60 °C to obtain the esterified WCO for use in transesterification reaction. Acid value of the WCO was determined by titration method (in triplicates) using standard isopropanol potassium hydroxide (0.1 N) according to AOCS; Cd 3a-63. The conversion was calculated using equation 2.

Trans-esterification of WCO

Trans-esterification of WCO was performed in a 100 mL three necked flask in an oil bath equipped with magnetic stirring for temperatures up to 65 ˚C using reflux method. 1 wt.% of NaOH catalyst was added to methanol 12:1 methanol to WCO molar ratio, stirred, and addition of 5 g esterified WCO. Transesterification product was separated into two layers using separating funnel. The upper layer is Fatty Acid Methyl Ester (FAME) and the lower layer is glycerol. FAME is the main product or called biodiesel, meanwhile glycerol is the by-product in this experiment. FAME was then washed with hot water (< 90 °C). Biodiesel produced was going through yield calculation and methyl ester content by Gas Chromatography Mass Spectrometry (GCMS) analysis (GC-7860B Agilent). The temperature at injector and detector were programmed at 240 °C. The flow rate of Helium as carrier gas at 19.2 mL min^{-1} and the column temperature was set at 150 °C with ramping rate of 15 °C min^{-1}. Table 1 showed the formula to calculate biodiesel conversion, ester content and biodiesel yield according to international standard European EN14103.

Table 1. Equation to calculate the biodiesel conversion, ester content and biodiesel yield [37]

Formula	Equation
Conversion (%)	$d = \frac{A}{Mass\ of\ WCO} \times 100$
Ester content (%) from EN14103	$c = \frac{TA\ - AEI}{AEI} \times \frac{CEI\ \times VEI}{m} \times 100$
Mass of pure biodiesel from biodiesel conversion (g)	$Y\ = c\ \times A$
Pure biodiesel yield (%)	$FAME\ yield, \% = \frac{Y\ (g)}{mass\ WCO\ (g)} \times 100$

A = Mass of biodiesel collected (g), TA =Total area, AEI = Area of internal standard, CEI = Concentration (mg/mL) of methyl heptadecanoate solution, VEI = Volume of (mL) methyl heptadecanoate solution, and m = Mass of sample

Determination of acid value and FFA conversion

250 ml conical flask was prepared and 0.2 g of WCO. 10 mL toluene: isopropanol KOH (1:1) was added in the conical flask with a few drops of phenolphthalein indicator in the sample solution, titrated with 0.1 mol/L isopropanol KOH standard solution. The solution was observed from colorless to slightly red until it remained unchanged for 30 s, which meant that the titration endpoint was reached. The acid value (AV) was calculated by the following formula Eq. (1):

$$A = \frac{V\ \times C\ \times 56.11}{m} \quad (1)$$

where AV is the acid value of the sample, V is the volume of isopropanol KOH standard solution consumed to reach the titration end point, C is the concentration of KOH standard solution, 56.11 is the molecular weight of KOH, m is the weight of the test sample. The conversion rate of FFA (FFA conversion%) is considered as the fraction of the esterification reaction of FFA and methanol, and the conversion rate of FFA (FFA conversion%) was determined according to the acid value ratio using Eq. (2):

$$FFA\ conversion\ \% = \frac{A_a - A_b}{A_a} \times\ 100 \quad (2)$$

where Aa is the acid value of the WCO. Ab is the acid value of WCO after esterification.

Results and Discussion

Properties of waste cooking oil

The FFA chemical composition analysis was performed physiochemically using titration method. The results shown in Table 2 indicated that WCO has 11.65 % content of FFA with 23.30 mg KOH g^{-1} of acid value.

Table 2. The properties of waste cooking oil

Properties	Waste Cooking Oil
Acid value (mg KOH g^{-1})	23.30
Free Fatty Acid (%)	11.65
Saponification value (mg KOH g^{-1})	184
Molecular weight ($gmol^{-1}$)	915

Characterization of photo-catalyst

The diffraction pattern of raw EFBA, dry EFBA and TiO_2/EFBA500, are presented in the Figure 1. The peaks of the raw and dry EFBA showed all the cellulose materials from 2θ = 29˚ to 90˚. Dry materials that had been dried in the oven at 120 ˚C showed graphite

structure at 2θ = 27˚, 80˚ and 88˚. Also, the intensity of dry EFBA was a bit higher than raw EFBA. This was due to the drying process of EFBA at 120 ˚C which developed the crystallite size and produced the graphite structure [38]. As for TiO_2/EFBA500, it showed that dry EFBA had well embedded to the anatase and rutile phase of TiO_2. The peaks of rutile, anatase and cellulose of the EFBA were dispersed throughout the surface of the catalyst. This promoted active photocatalytic activity in the esterification. As reported by Berrones-Hernández et al. the impregnation technique promoted a deposition element of one element on another [36]. Therefore, the catalyst will have improvement in stability and efficiency in the photo esterification process due to deposition of TiO_2 on EFBA. As proven, the conversion of FFA catalyzed by TiO_2EFBA500 achieved 83% after 2 h reaction time under UV light irradiation.

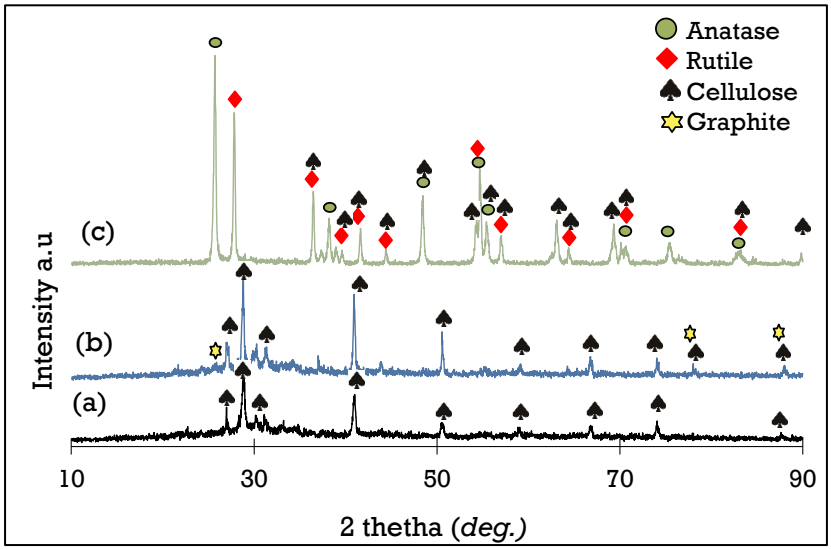

Figure 1. The XRD pattern of (a) Raw EFBA, (b) Dry EFBA and (c) TIO$_2$/EFBA500

Figure 2 showed SEM image of the dry EFBA, TiO_2, TIO$_2$/EFBA before and after being calcined at 500˚C. A micrograph showed rough appearance for all the catalyst. Raw and Dry EFBA appeared granular and spherical in shape whereas TiO_2 exhibited agglomerated nanoparticles, spherical and irregular shapes [38]. Naeem et al., reported that doping technique can prevent the agglomeration of TiO_2 nanoparticles during the reaction process [40]. From the micrograph, it showed that TiO_2 was well deposited on the surface of EFBA which successfully doped between TiO_2 and EFBA. The effect of calcination temperature at 500˚C showed ordered and homogeneous distribution of the TiO_2 nanoparticles on the EFBA composite [36]. The result from experimental data of XRD confirmed that EFBA was successfully coordinated with TiO_2 metal as TiO_2 has cubic and spherical crystal that can promote larger cluster formation on the EFBA particles [41]. The reactive species suggested favorable reduction of FFA content and active photocatalytic esterification of WCO. Furthermore, the presence of elemental composition of this catalyst was confirmed by EDX analysis in the Table 3.

Figure 3 showed the UV–vis diffuse reflectance spectra of Dry EFBA, TiO_2, TiO_2/EFBA and TiO_2/EFBA500 respectively, and the band gap energy was estimated to be about 4.0, 3.0, 2.95 and 2.88 eV, respectively using Tauc plot equation. This showed that the band gap energy of the EFBA-doped TiO_2 samples monotonically became narrower after doping and calcination at 500˚C.

Catalytic activity of the TiO_2 and TiO_2/EFBA photocatalyst

To determine the optimal conditions of FFA esterification reaction photocatalyzed by TiO_2 and TiO_2/EFBA500, we examined the effects of the reaction time under UV irradiation, methanol to WCO molar

ratio and photocatalyst/WCO mass ratio. Figure 4 and Figure 5 show the FFA content after photo esterification process using TiO_2 and TiO_2/EFBA500 respectively. There is a comparison of FFA reduction using TiO_2 and TiO_2/EFBA500 photocatalyst as TiO_2/EFBA500 photocatalyst reduced more FFA content than TiO_2 photocatalyst. As reported by Klubnuan et al. ash can modify the semiconductor material and control the bandgap energy [42]. Therefore, doping EFBA with TiO_2 can increase the crystallite size and reduce the bandgap energy from 3.0 eV to 2.88 eV confirmed by XRD and UV-Vis-DRS results which improve the photocatalytic reaction. From the results, the optimized value reduction of FFA content using TiO_2 catalyst only achieved 4.88% from 11.65% FFA content with 4 h reaction time under UV light, 20:1 methanol to WCO molar ratio and 4 wt.% TiO_2 catalyst. Same condition with different optimized parameter for TiO_2/EFBA500 photocatalyst achieved 2.04% of FFA reduction from 11.65% FFA content by 2 h reaction time, 20:1 molar ratio and 4 wt.% catalyst loading. These results suggested that TiO_2/EFBA500 photocatalyst was more active and efficient during the photo-esterification compared to TiO_2. TiO_2/EFBA500 only needed 2 h reaction time to convert 83% FFA rather than using TiO_2 that needed 4 h reaction time to convert only 58% FFA.

Table 3. Elemental composition of photo-catalyst

	Elemental Composition (%)									
	C	**O**	**Ti**	**Si**	**K**	**Ca**	**Mg**	**S**	**P**	**Al**
Dry EFBA		53.86		10.85	23.80	5.39	0.71	2.50	2.45	0.16
TiO_2		48.39	51.61							
TiO_2EFBA	28.54	65.96	1.59	2.19	0.53	0.33	0.34			
TiO_2EFBA500	24.21	65.75	5.37	2.51	1.17	0.48	0.52			

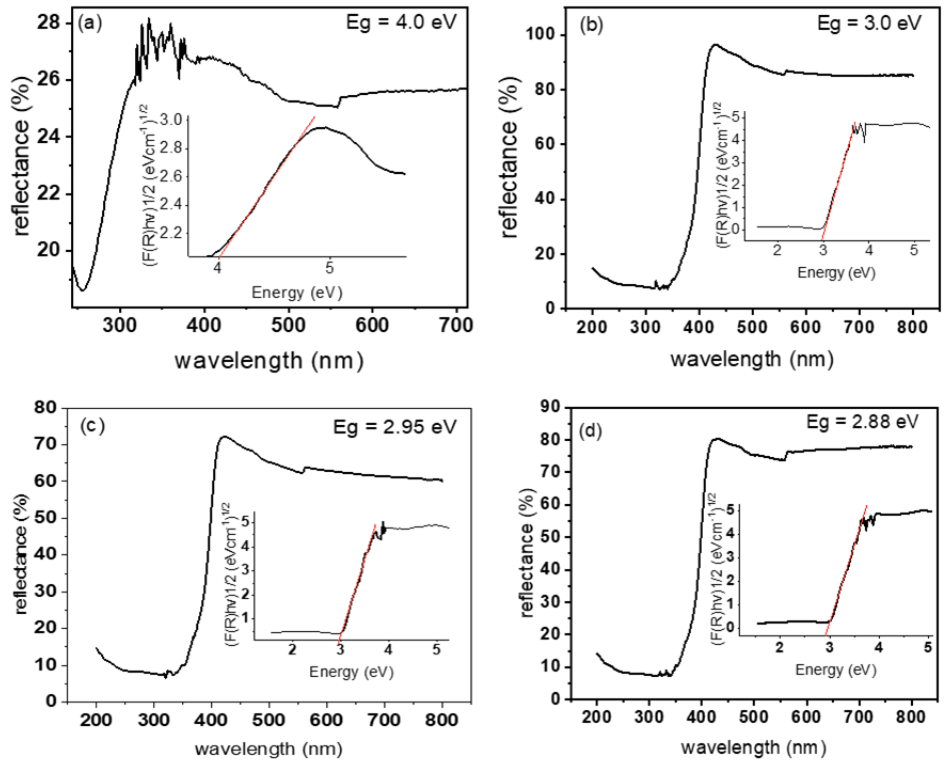

Figure 3. UV Vis DRS of (a) Dry EFBA, (b) TiO_2, (c) TiO_2/EFBA and (d) TiO_2/EFBA500

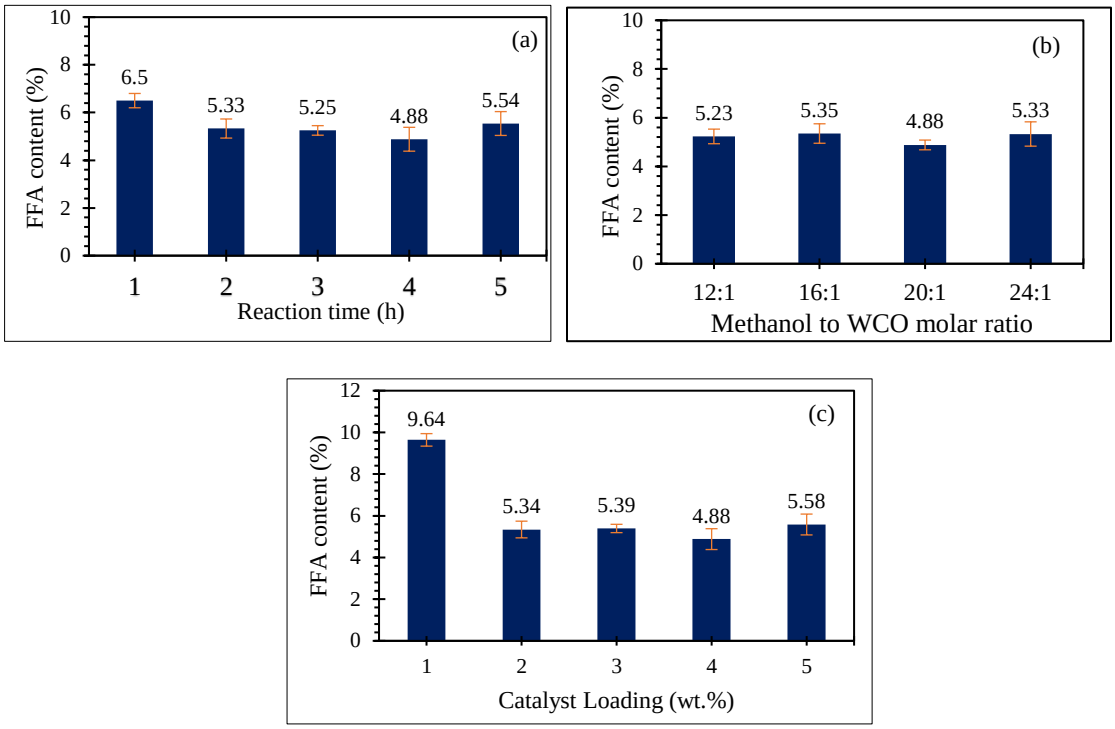

Figure 4. Photocatalytic esterification of WCO using TiO_2 photocatalyst (a) reaction time with (4 wt.% catalyst loading and 20:1 methanol to WCO ratio), (b) methanol to WCO molar ratio with (4 wt.% catalyst loading and 2 h reaction time) and (c) catalyst loading with (20:1 methanol to WCO molar ratio and 2 h reaction time).

From the FFA content results in Figure 4 and Figure 5, different parameters were studied to determine the optimized parameter for reduction of FFA content in WCO which were reaction time from 1 to 5 h, methanol to WCO molar ratio from 12:1 to 24:1 and catalyst loading from 1 wt.% until 5 wt.%. The reaction was conducted for three replications in each level. Photo-esterification of WCO contained 11.65% FFA catalyzed by TiO_2 photocatalyst showed in Figure 4 from 1 to 4 h, the FFA content decreased slowly from 6.5% until 4.88 %. Then the FFA increased again at 5 h as it faced reversible esterification reaction due to longer reaction time. Guo et al., reported that, reaction time under UV light more than 3 h will inhibit the reaction process [14]. The reason is because increasing reaction time will also increase the temperature of UV irradiation in the reactor that can cause saponification reaction. For the methanol to WCO molar ratio, the best ratio was at 20:1 as it achieved the maximum reduction of FFA content. It was the same for catalyst dosage, as the catalyst increased from 1 wt.% to 4 wt.%, the percentage of FFA content decreased from 9.64% to 4.88%. When exceeding 4 wt.%, the FFA content increased again which reduced the conversion of FFA. Adequate catalyst dosage can reduce the FFA content. However, excessive catalyst dosage can inhibit the reaction due to high viscosity in the reaction process. The maximum conversion of FFA catalyzed by TiO_2 photocatalyst reached only 58% under 4h reaction time, 20:1 methanol to WCO molar ratio and 4wt.% catalyst loading. This basis was also applied for photo-esterification in Figure 5. Photo-esterification reaction catalyzed by TiO_2EFBA500 in Figure 5 showed that the optimized parameter at 2 h reaction time, 20:1 methanol to WCO molar ratio and 4 wt.% catalyst loading reduced the FFA content from 11.65% to 2.04% in which the conversion of FFA was up to 83%.

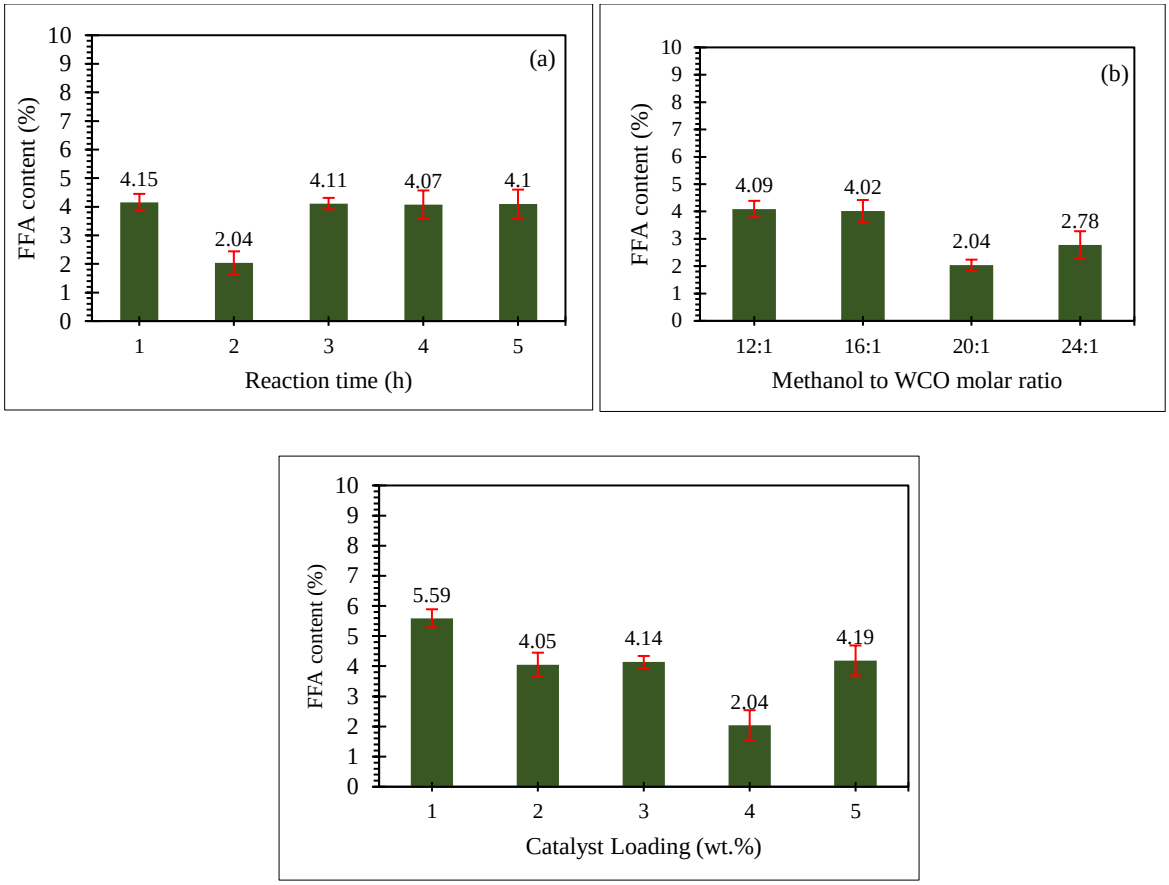

Figure 5. Photocatalytic esterification of WCO using TiO_2/EFBA500 photocatalyst (a) reaction time with (4 wt.% catalyst loading and 20:1 methanol to WCO ratio), (b) methanol to WCO molar ratio with (4 wt.% catalyst loading and 2 h reaction time) and (c) catalyst loading with (20:1 methanol to WCO molar ratio and 2 h reaction time)

After the photo-esterification process, the esterified WCO will be trans esterify for a second step reaction. The process conducted using reflux method and catalyzed by NaOH under 1 h reaction time; 12:1 methanol to oil molar ratio, 1 wt.% catalyst loading and 65 ℃. The WCO Biodiesel was analyzed using the GC-MS analysis to determine the chemical composition of the product. Each peak of the WCO Biodiesel product chromatogram was identified by comparing to published data and GC libraries. The largest peak in Figure 6 and detailed compound of fatty acid in Table 4 showed the presence of high amount of esters of oleic acid 34.84% followed by palmitic acid 29.01%, linoleic acid 9.99% along with stearic acid 4.86%, linolenic acid 1.74%, palmitoleic acid 1.42% and myristic acid 1.11% in alkali catalyzed process. As reported by Mekonnen & Sendekie, homogenous base catalyst using non-edible feedstock oil produces high yield of biodiesel that can achieve the limit set by international standard D6751 [43]. From the results, triglycerides of esterified WCO oil were successfully converted to FAME product only using a minimum range reaction parameter producing 65.5% FAME product and calculated using the equation in Table 1 [44].

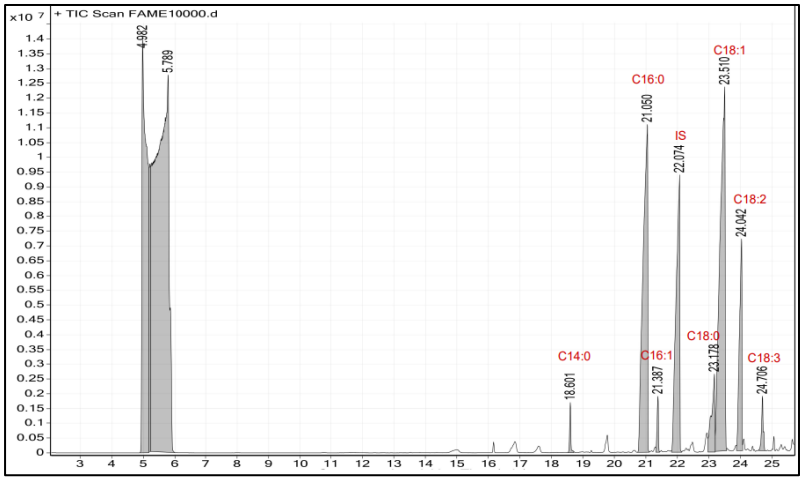

Figure 6. GCMS chromatogram of WCO Biodiesel produced by transesterification in the presence of 1 wt.% NaOH catalyst, 12:1 methanol, 65 ˚C at 1 h reaction time

Table 4. Composition of Fatty acid methyl ester in the WCO Biodiesel

Fatty Acid Compound	**Retention Time (min)**	**C N:U**	**Composition (wt.%)**
Myristic acid	18.60	C14:0	1.11
Palmitic acid	21.05	C16:0	29.01
Palmitoleic acid	21.39	C16:1	1.42
Stearic acid	23.18	C18:0	4.86
Oleic acid	23.51	C18:1	34.84
Linoleic acid	24.04	C18:2	9.99
Linolenic acid	24.71	C18:3	1.74

Conclusion

TiO_2/EFBA500 photocatalyst was prepared via simple impregnation method and used in the photo-esterification of waste cooking oil for biodiesel synthesis. Under optimum reaction conditions of 2 h reaction time with UV light irradiation, 20:1 methanol to WCO molar ratio and 4 wt.% catalyst loading achieved 83% FFA conversion and reduced from 11.65% to 2.04 FFA% content. Thus, TiO_2/EFBA500 photocatalyst is a promising catalyst for photo-esterification of waste cooking oil. TiO_2 alone can convert FFA up to 58% and doping with metal oxide compound from EFBA can enhance the effectiveness of photocatalytic activity which successfully achieved 83% FFA conversion. Therefore, photo-esterification process can increase the yield of biodiesel using high catalytic activity of semiconductor nanomaterial. It also has a low production cost as it can be carried out at room temperature and uses low quality feedstock oil. For future study, TiO_2 will be compared with other type of nanomaterials to determine the properties and mechanism of semiconductor nanomaterials doped with EFBA and also using different doping techniques.

Abstract

In-syringe dispersive solid-phase microextraction with activated carbon as adsorbent was successfully developed to determine organophosphorus pesticide (OPP) residues in vegetable samples and the analytes were detected using gas chromatography-flame photometric detector (GC-FPD). Under optimized conditions (6 mg of activated carbon in 10 mL sample volume with 3 min extraction time and desorption with 300 µL of acetone), activated carbon was proven to be an effective adsorbent for the organophosphorus pesticide residues in vegetable samples with a satisfactory percentage recovery achieved from 81.46 to 108.93%. All the studied analytes showed good linearity in the range of 10 to 500 µg kg^{-1} and the correlation of determination (R^2) was from 0.9962 to 0.9985. The LODs obtained were from 0.39 to 0.84 µg kg^{-1}, and LOQs were from 1.18 to 2.56 µg kg^{-1}. This method gives precision values for both intra- and inter-day within accepted variable limits (<15 % of RSD). The in-syringe dispersive solid-phase microextraction managed to eliminate the centrifugation process, reduce chemical consumption during extraction, and additionally speed up the extraction process, making it more efficient. This developed method can be applied to real samples such as vegetables and fruit juices as well as tap, river, or ground water analysis for the determination of OPPs.

Keywords: organophosphorus pesticide, in-syringe dispersive solid phase microextraction, gas chromatography-flame photometric detector

Abstrak

Pengekstrakan mikro fasa pepejal dalam picagari dengan menggunakan karbon aktif sebagai penyerap telah berjaya dibangunkan untuk menentukan sisa racun perosak jenis organofosforus (OPP) dalam sampel sayur-sayuran dan analisis telah dikesan dengan menggunakan peralatan analisis kromatografi gas – pengesan fotometrik nyalaan (GC-FPD). Di bawah keadaan yang dioptimumkan (6 mg karbon aktif dalam isipadu sampel 10 mL dengan masa pengekstrakan selama 3 minit dan diserap dengan 300 µL aseton), karbon aktif terbukti sebagai penyerap berkesan bagi sisa racun perosak organofosforus dalam sampel sayur-sayuran berdasarkan peratusan pengesanan semula yang dicapai dari 81.5 hingga 108.9%. Semua analit yang dikaji menunjukkan garis lurus yang baik dalam julat 10 hingga 500 µg kg^{-1} dan memberikan korelasi penentuan (R^2) dari 0.9962 hingga 0.9985. Had pengesanan yang di dapati adalah dari 0.39 hingga 0.84 µg kg^{-1}, dan had pengkuantitian adalah dari 1.18 hingga 2.56 µg kg^{-1}. Kaedah ini memberi nilai ketepatan pada kedua-dua intra dan antara hari dalam sisihan piawai relatif (RSD) yang diterima (<15% daripada RSD). Pengestrakan mikro fasa pepejal secara penyerakan dalam picagari berjaya mengelakkan proses pengemparan, mengurangkan penggunaan bahan kimia dalam proses pengekstrakan dan juga proses pengekstrakan menjadi lebih pantas dan lebih cekap. Kaedah yang dibangunkan ini boleh digunakan untuk sampel sebenar seperti sayur-sayuran, jus buah-buahan dan juga sesuai untuk analisis air paip, air sungai dan air tanah untuk penentuan sisa racun perosak organofosforus.

Kata kunci: perosak jenis organofosforus, pengekstrakan mikro fasa pepejal dalam picagari, kromatografi gas – pengesan fotometrik nyalaan

Introduction

The presence of a significant amount of nutrients and minerals in fresh vegetables, fruits, and pulses makes them important healthy diet food. Unfortunately, they too can turn out to be the source of toxic substances such as pesticides [1]. Pesticides are toxic substances with mixtures of chemical or biological ingredients designed to kill, reduce, or repel insects, weeds, rodents, fungi, and other organisms that threaten public health and the economy. They have numerous beneficial effects but risks as well. Pesticides are used by farmers to protect their fruits and vegetables from diseases and pests while at the same time providing high yields [2]. More than 1100 pesticides are currently registered, according to the status list of all active pesticide chemicals on the European Union market [3]. Pesticides are also commonly utilized in agricultural activities because of their low cost and high effectiveness in controlling pests, weeds, and illnesses.

The increased manufacturing of pesticides for agricultural and non-agricultural applications has resulted in pollution of soil, air, surface, and groundwater posing a major threat to the environment and human health through direct exposure or residues in food and drinking water [4]. Table 1 lists common pesticides group based on their controlling pests. Organophosphorus pesticides (OPPs) are a class of phosphate or phosphorothioate molecules that is one of the world's ten most well-known pesticides [4]. OPPs, on the other hand, are very toxic even at low levels, and can be transmitted to humans, birds, and mammals through contaminated water, air, and food. They are usually absorbed by the lungs, mouth, or skin, and accumulate in the salivary glands, kidneys, fat, and liver [5]. Trace-level OPPs in various types of sample matrices are difficult to detect due to interference such as sugar, plant pigments, and fats.

Vegetables and fruits, which are good sources of minerals, vitamins, antioxidants, and fiber, make up 30% of a consumer's diet, according to a 2003 report by the World Health Organization (WHO). Since Cameron Highlands is one of Malaysia's major vegetable producers, it is important to examine the risk of pesticide residues in these extensively produced vegetables that are grown there for human consumption. According to studies, certain fruits, and vegetables with greater pesticide residue levels and over the maximum residue limit (MRL) may be harmful to consumers' health. Maximum Residue Limits (MRLs), which limit the concentration level of commodities, promote food safety measures as they should not exceed 0.01-0.05 mg kg^{-1}. Unfortunately, as proven by previous research, among all the vegetables, cabbage has a higher contaminant value compared to others such as spinach, tomato, and celery. While mustard show the lowest one that has been contaminated by OPPs. The observed trend in the concentration of studied OPPs was dimethoate (36.8%) > diazinon (14.3%) > parathion methyl (12.3%) >parathion ethyl (20.3%) > chlorpyriphos (14.0%) >

malathion (9.9%). The EU order of percentages of OPPs above MRLs is as; cabbage (24.8%) > cauliflower (13.6%) > broccoli (11%) 17 > cauliflower (13.6%) > lettuce (4.0%) > spinach (3.7%) > celery (1.8%) > mustard (1.8%) [6, 7].

Table 1. Common pesticide groups based on their controlling pests

Insecticides	Fungicides	Herbicides	Rodenticides	Fumigants	Insect repellents
Pyrethroids	Thiocarbamates	Bipyridyls	Warfarines	Aluminium and zinc phosphate	Diethyltoluamide
Organophosphorus	Dithiocarbamates	Chlorophenoxy	Indanodiones	Methyl bromide	
Carbamates	Cupric salts	Glyphosate		Ethylene dibromide	
Organochlorine	Tiabendazoles	Acetanilides			
Manganese compounds	Triazoles	Triazines			

The determination of OPPs in complex matrices, such as environmental, food, and biological samples, usually requires extensive sample pre-treatment [8]. Preconcentration procedures must be included in the sample preparation steps because of the high sensitivity needed for OPP testing . OPP residues persist in environmental waters, fruits, and vegetables because of inappropriate and widespread OPP application [9]. Their broad applications in agriculture or insect control in public spaces result in OPPs and their metabolites being frequently detected in vegetables, fruits, water, soil, and other environmental matrices [10]. Regular sample clean-up to pre-concentrate the OPPs uses evaporation which may cause the OPPs to degrade thus lowering the detection or recovery of OPPs.

The common extraction technique used for the analysis of pesticides is conventional liquid-liquid extraction (LLE), solid-phase extraction (SPE), and solid-phase microextraction (SPME). Lately, many researchers have modified common extraction methods such as magnetic dispersive solid phase extraction (MD-SPE), reverse micelle-supramolecular solvent micro-extraction framework with dispersive solid phase extraction (MOF-DSPE), and magnetic solvent bar-liquid phase microextraction (MSB-LPME). However, these procedures have downsides, such as using a lot of toxic and expensive organic solvents, being tedious, and taking a long time [9, 11-14]. Dispersive solid phase microextraction (DSPME) is a technique that has been recently used for the extraction, clean-up, and pre-concentration of different analytes in real samples. DSPME is an easy, fast, and cost-effective SPME procedure that can be applied to complex matrices with high extraction efficiency, high enrichment factor, and reduced usage of sample solution and chemical solvents [15].

Thus, in this study, our focus is to develop a new, simple, and rapid method for the analysis of OPPs residues in vegetables and fruits by in-syringe DSPME using activated charcoal as an adsorbent to enhance the sensitivity of the method, to eliminate the centrifugation process and to reduce the use of chemicals in the extraction.

Materials and Methods

Chemicals and reagents

The selected OPPs used in this research namely Parathion-methyl (98.5%), Fenchlorphos (99.0%), and Chlorpyrifos (99.8%) purchased from Dr. Ehrenstorfer GmbH (Germany) as shown in Figure 1. Activated charcoal was purchased from Merck (Germany). Acetonitrile and methanol were purchased from Fisher Scientific (Korea). Acetone was purchased from Friendemann Schmidt Chemical (Australia). Ultrapure

deionized water (resistivity, 18.2 MΩ cm^{-1}) was produced by a Sartorius Milli-Q system (Germany) and was used during this study for the preparation of the solution.

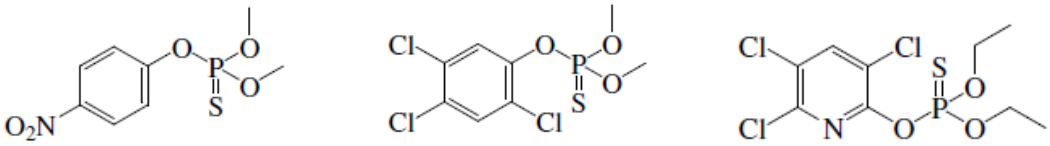

Figure 1. Structures of selected organophosphorus pesticides

GC-FPD conditions

All analysis was done using a GC-2010 Plus gas chromatography-flame photometric detector (GC-FPD) (Shimadzu, Japan) and this GC was equipped with auto-injector AOC-20i. The capillary column SGE-BP1 (30 m 0.25 mm I.D. 0.25 µm film thickness) was used to quantify OPPs. Helium gas was used as the carrier gas with a linear velocity flow mode. The pressure was 100 kPa with the total flow and column flow at 50.00 and 1.0 mL/min, respectively. The temperature of the injector and FPD detector was maintained at 260 ºC and 300 ºC, respectively. The injection was performed using splitless mode and the injection volume was set at 1 µL. The column temperature was programmed as follows: initial temperature of 100 ºC and held for 1 min, then increased to 200 ºC at the rate of 20 ºC min^{-1} and held for 8 min. The final temperature was increased to 220 ºC at the rate of 15 ºC min^{-1} and held for 2 min. The total run time for the GC analysis was 17.33 min.

In-syringe DSPME procedure

The schematic of the in-syringe DSPME procedure is shown in Figure 2. The prepared sample solution was added with 6 mg of activated charcoal and was vortexed for 3 min. Then, the mixed solution was transferred into a 10 mL syringe with a 0.45 µm syringe filter. At this time, OPPs were bonded with activated charcoal and remained inside the syringe filter. Then, the OPPs were desorbed using 300 µL acetone and the extracted OPPs were injected into GC-FPD for the quantitative analysis.

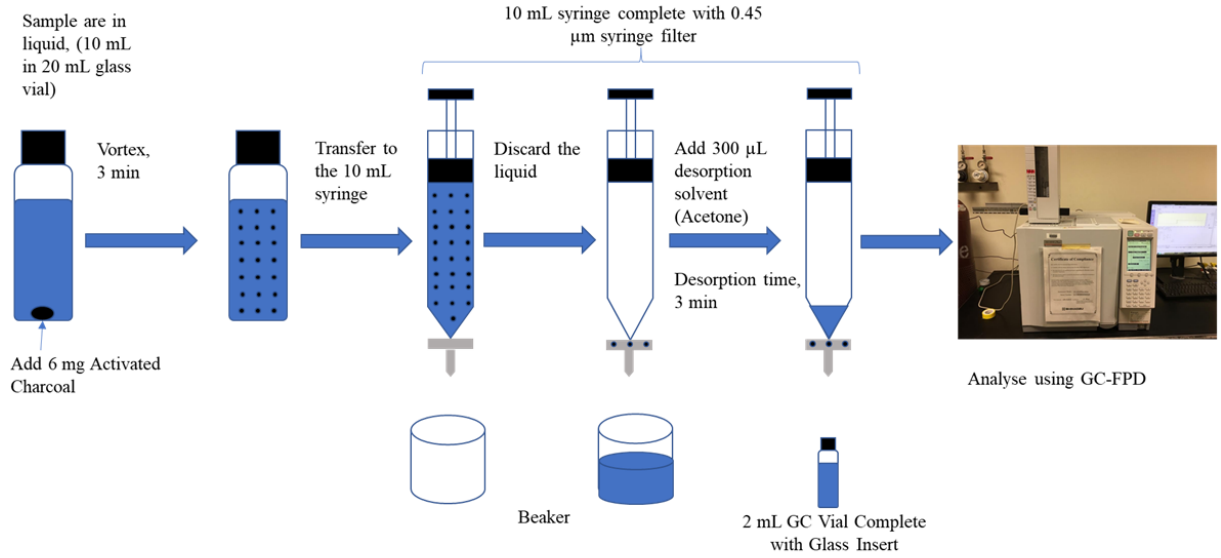

Figure 2. Schematic of in-syringe DSPME procedure

Sample collection and pre-treatment

Mustard, kale, cabbage, tomato, and strawberry were purchased from three different markets in Cameron Highland, Pahang. The representative sample (500 g) was chopped, and the sample was homogenized using the food processor. Then, sample juice was extracted using a juice extractor. The sample solution was filtered, and the suspended solid was discarded. Then, 10 mL of filtered solution was put in the 20 mL glass vial and kept in the refrigerator at 40°C till the extraction using the DSPME procedure.

Optimization of extraction conditions

To optimize the DLLME of OPPs from water samples, analytical factors that potentially affect the sample were studied. The parameters involved were tabulated in Table 2 below.

Table 2. Optimization condition

Parameters	Level
Mass of Activated carbon (mg)	2, 4, 6, 8 and 10
Extraction time (min)	1, 3, 5, 7 and 10
Desorption Solvent	Acetone, Acetonitrile and Methanol
Desorption volume (μL)	100, 300, 500, 700 and 1000
Desorption time (min)	0, 3, 5, 7 and 10
pH	5, 6, 7, 8 and 9

Method validation

Method validation (linearity, limits of detection (LOD) and quantitation (LOQ), pre-concentration factor, and recovery was performed using the proposed in-syringe DSPME method. Linearity was investigated over the range of 10 to 500 μg kg^{-1}. The LOD and LOQ values were calculated based on the standard deviation of the response of the standard blank and the slope of the calibration curve. The pre-concentration factor was calculated from the spiked peak. While recovery studies were carried out using spikes at three concentration levels (30, 50, and 100 μg kg^{-1}). All spiked samples were extracted in triplicates. All the formula is shown below;

$$\text{RSD} = \frac{\text{standard deviation}}{\text{mean}} \times 100\% \quad (1)$$

$$\text{LOD} = \frac{\text{standard deviation}}{\text{slope}} \times 3.3 \quad (2)$$

$$\text{LOQ} = \frac{\text{standard deviation}}{\text{slope}} \times 10 \quad (3)$$

$$\% \text{ Recovery} = \frac{C_{ext}}{C_{int}} \times 100 \quad (4)$$

where C_{ext} is the concentration of analyte in extractant phase; while C_{int} is the initial concentration of OPPs.

Results and Discussion

Assignment and identification of OPPs peak

The mixed OPPs standard solution (1 mg L^{-1}) was injected into GC-FPD in a splitless mode where the technical parameter such as injection volume, gas flow, and temperature gradient were optimized to get a better resolution. The peak was assigned and identified by retention time based on molecular weight and OPPs

structure as shown in Figure 3. The first peak at 12.312 min is parathion-methyl (PM), followed by fenchlorphos (FE) at 13.154 min and chlorpyrifos (CH) at 14.583 min.

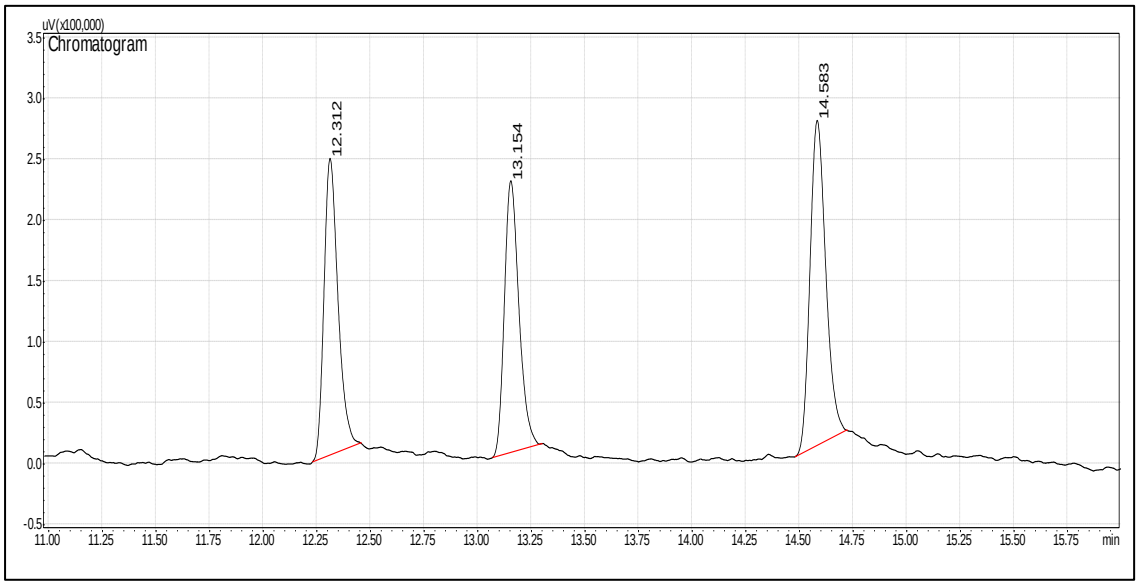

Figure 3. Chromatogram of OPPs a) parathion-methyl b) fenchlorphos c) chlorpyrifos

Optimization of extraction conditions

In this study, the effects of six critical parameters such as the mass of activated carbon, extraction times, volume, time, pH, and solvent were investigated. The optimization process is the process of changing one parameter while at the same time, keeping all other parameters of the same condition to monitor the responses. The optimization was carried out in triplicates using water as a sample matrix with a concentration of 250 µg L^{-1} each.

Effect of mass of activated carbon

The mass of adsorbent used in the extraction has a significant effect on the extraction efficiency. In this study, commercially available activated carbon was used as an adsorbent and the mass of activated carbon was studied in the range of 2-10 mg. Based on Figure 4(a), 6 mg of activated carbon gave a higher peak area as compared to below 6 mg and there is no obvious increase observed in the peak area when the mass of activated carbon is more than 6 mg. The reduced reaction could be because the saturation of active sites on the adsorbent has been exceeding. Hence, 6 mg of activated carbon was selected as the optimal adsorbent amount [9].

Effect of extraction time

Extraction time is an important factor that can influence extraction efficiency because there is a need for a short period for the binding of target compounds with the adsorbent. The effect of extraction time was studied in the range of 1-10 min. It was observed that the peak area for all OPPs increased as the extraction time increased up to 3 min and dropped thereafter when it reached more than 5 min maybe because of the desorption of analyte from the adsorbent [16]. Thus, 3 min was chosen as an optimal time for the extraction of vegetable samples as shown in Figure 4(b).

Effect of desorption solvent

Types of solvent used also play a vital role and give a significant effect on the extraction efficiency to ensure high recovery and sensitivity toward the performance [17]. Referring to Figure 4(f), acetone gave a higher peak area than methanol. To produce a very high quantity of contact area and quick migration of analytes from the aqueous sample into the extraction phase, the

extractant solvent must be disseminated into the aqueous sample as very small droplets. In comparison to the other two solvents, acetone has the lowest viscosity. The reaction decreases as the desorption solvent's viscosity rises (acetone, acetonitrile, and methanol respectively, 0.32, 0.37, and 0.55 centipoise at 20 °C). The likelihood that a reaction will occur increases with polar solvent viscosity. As a result, acetone was selected as an optimal solvent and this result was agreed with another researcher. As a result, acetone was selected as an optimal solvent and this result was agreed with another researcher [18].

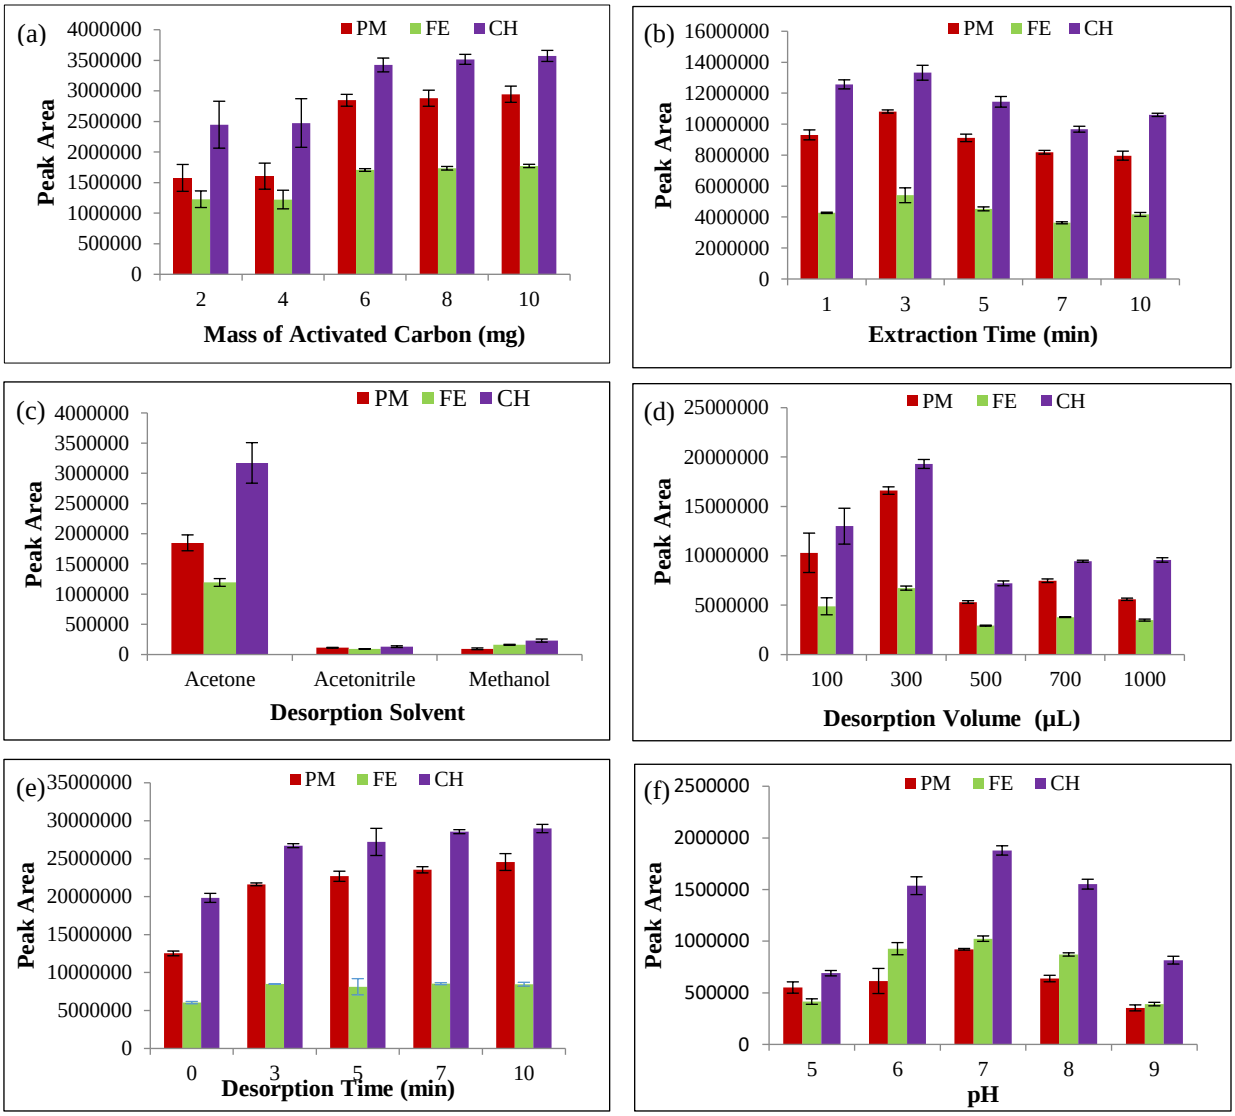

Figure 4. (a) Effect of mass of activated carbon (Extraction condition: extraction time, 5 min; desorption volume, 500 µL of acetone; desorption time, 3 min and without pH adjustment (b) Extraction time (Extraction conditions: mass activated carbon, 6 mg; desorption volume, 500 µL acetone; desorption time, 3 min); (c) Desorption volume (Extraction conditions: mass activated carbon, 6 mg; extraction time, 3 min; desorption time, 3 min); (d) Desorption time (Extraction conditions: mass activated carbon, 6 mg; extraction time, 3 min; desorption volume, 300 µL acetone); (e) pH (Extraction conditions: mass activated carbon, 6 mg; extraction time, 3 min; desorption time, 3 min; desorption volume, 300 µL acetone); (f) Desorption solvent: (Extraction conditions: mass activated carbon, 6 mg; extraction time, 5 min; desorption time, 3 min; desorption volume, 300 µL acetone) on the extraction efficiency.

Effect of desorption volume

In Figure 4(c) effect of desorption volume was studied in the range of 100 to 1000 µL. Among the studied volumes, 300 µL gives the highest peak area and this low volume fits the title micro-extraction. It was observed, that when the volume increases more than 300 µL, the peak area becomes smaller compared to those of 100 µL and 300 µL. This is probably due to the increasing dilution factor and the solubility of analytes in the aqueous phase the extraction step was increased which will lead to a decrease in the extraction efficiency. Thus, the smaller the volume is, the more concentrated the solvent becomes. Hence, an eluent volume of 300 µL was selected for further analysis as it gave the highest peak area ratio response for all four OPPs [19].

Effect of desorption time

The effect of time in the range of 0-10 min on the extraction efficiency of the targeted OPPs was investigated using acetone as the solvent. Figure 4(d) shows the peak area increases significantly between 0-3 min before decreasing when increasing the desorption time to 10 min [20]. Increase in peak area due to the response of analyte from sorbent to solution while the constant result after 5 min because of re-adsorption of analyte onto the sorbent. Hence, 3 min was selected as the optimal time in the subsequent extractions.

Effect of pH

Solution pH plays an imperative role in separation science as it controls both the degree of ionization of the materials present in the solution and the dissociation of functional groups of the analyte [21]. In this study, the pH of the sample solution was adjusted in the range of pH 5 to 9. The initial pH for the sample solution was between pH 6 to 8. Based on the graph in Figure 4(e), the optimal pH value was around pH 6-8 because of increasing in the OPPs stability between 4.5-7. When approaching pH 9 the peak area was decreasing because of OPPs start to hydrolyze as the higher the pH the faster the hydrolysis process of OPPs will be. Since the obtained pH is like the pKa value of the analyte, no pH adjustment is needed for further experiments.

Method validation

A series of spiked samples that ranged from 10 to 500 µg kg^{-1} were applied to plot the matrix match calibration curves (n=3). The method validation was done under optimized conditions (6 mg of activated carbon in 10 sample volumes with 3 min extraction time and with 300 µL of acetone). The linearity shows the correlation of determination (R^2) ranging from 0.9962 to 0.9985. The optimized method was determined by measuring the (repeatability) and inter-day (intermediate) at a spiking level of 100 µg kg^{-1} in vegetable samples. Precision was determined on the same day with five duplicates while inter-day precision was calculated with five replicates on three different days. Relative standard deviation (RSD) ranged between 0.89% to 2.17% while inter-day ranged between 1.27% to 3.13%. The assessed values on precision were found to be within the known variable limits (<15 %) [12]. Table 3 displays the linear performance, LOD, LOQ, PF, and inter-day results. In-syringe DSPME can detect and quantify the OPPs at concentrations as low as 1.18 µg kg^{-1}. The pre-concentration factor is described as enrichment factor times with theoretical volume. Based on the calculation, it was found that the pre-concentration factor for parathion-methyl, fenchlorphos, and chlorpyrifos are 5548, 1216, and 3833 respectively at the concentration of 250 µg kg^{-1}.

Table 3. Linearity, LOD, LOQ, PF, intra-day and inter-day performance for in-syringe DSPME procedure

Analyte	Linearity Range (µgL^{-1})	R^2	LOD (µgL^{-1})	LOQ (µgL^{-1})	Intra-day RSD%(n=5) at 100 (µgL^{-1})	Inter-day RSD% (n=3) at 100 (µgL^{-1})	Pre-concentration Factor at 250 (µgL^{-1})
Parathion-methyl	10-500	0.9985	0.53	1.60	2.16	0.89	5548
Fenchlorphos	10-500	0.9962	0.39	1.18	3.13	1.61	1216
Chlorpyrifos	10-500	0.9966	0.84	2.56	1.27	2.17	3833

Recovery

The recovery study was done with three different spiked levels (30, 50, and 100 µg kg^{-1}) in blank vegetable samples. Table 4 displays the relative recovery data obtained from the experiment where the recovery for parathion-methyl, fenchlorphos, and chlorpyrifos are within 81.46 to 108.85%, 97.73 to 108.93%, and 92.71 to 106.14% respectively.

Table 4. Relative Recovery for OPPs Extracted by in-syringe DSPME

Analytes	Relative Recovery (%) ± %RSD (n=3)		
	30 µg kg^{-1}	**50 µg kg^{-1}**	**100 µg kg^{-1}**
Parathion-methyl	108.85 ± 1.98	93.31 ± 3.68	81.46 ± 4.66
Fenchlorphos	108.93 ± 4.79	106.04 ± 2.21	97.73 ± 4.72
Chlorpyrifos	105.04 ± 3.59	106.14 ± 3.40	92.71 ± 2.46

Real sample analysis

The developed in-syringe DSPME method was applied to real sample analysis to determine OPPs in vegetable samples of mustard, kale, cabbage, tomato, and strawberry. All 15 vegetable samples were purchased from three different market locations in Cameron Highland, Pahang. This analysis was run in optimized in-syringe DSPME conditions. This indicates that most farmers at Cameron Highland, Pahang are following the rules and regulations set up by the Agricultural Department during farming, harvesting, and preserving the vegetables.

Conclusion

In-syringe solid phase microextraction using activated carbon as an adsorbent was successfully developed to determine the pesticide residues in vegetable samples and then were detected using GC-FPD. Under optimized conditions (6 mg of activated carbon in 10 volumes of the sample with 3 min extraction time and 300 µL of acetone), activated carbon was proven to be an effective adsorbent for pesticide residues in vegetable samples based on higher percentage recoveries achieved from 81.5 to 108.9 %. All the studied parameters showed good linearity in the range of 10 to 500 µg kg^{-1} and gives a correlation of determination (R^2) from 0.9962 to 0.9985. This method gives precision values on both and inter-day within accepted variable limits (<15 % of RSD). The in-syringe solid-phase microextraction method managed to reduce the use of chemicals in the extraction. Additionally, this method proves to be faster and more efficient than other conventional extraction methods. Table 5 shows the comparison between this project with previous studies. This developed method can be applied to real samples such as vegetables and fruit juices as well as tap, river, and groundwater analysis for the determination of OPPs.

Abstract

The current study describes a validated, reliable, simple, and sensitive high-performance liquid chromatographic method with fluorescence detection (HPLC-FL) for the determination of curcumin at the *in vitro* and *in vivo* levels in pure and Self Emulsifying Drug Delivery System (SEDDS). The mean recovery of pure curcumin was 99.1%. The calibration curves were linear over the range from 31.3 to 1000 ng/mL with correlation coefficient of $R^2 \geq 0.9999$. The lower limit of quantification (LLOQ) was 31.3 ng/mL. The validation results confirmed the linearity, accuracy, and precision of the developed method. Furthermore, the curcumin-SEDDS excipients solubility were conducted, and later curcumin loading content (LC) was determined. Moreover, pharmacokinetic parameters, mean peak plasma concentration (C_{max}), time to reach peak concentration (T_{max}), and total area under the plasma concentration-time curve from time zero to the last sampling time, i.e., 1440-minute (AUC0-1440m) were successfully measured with the values of 238.81 ng/mL, 70.83 min and 11249.60 ng.min/mL, respectively. This method is suitable to detect curcumin in pure and SEDDS formulation *in vitro* and *in vivo*.

Keywords: curcumin, plasma, self-emulsifying drug delivery system, pharmacokinetic

Abstrak

Kajian semasa menerangkan kaedah kromatografi cecair (HPLC) berprestasi tinggi yang disahkan, boleh dipercayai, mudah dan sensitif dengan pengesanan pendarfluor untuk penentuan kurkumin pada tahap *in vitro* dan *in vivo* dalam Sistem Penghantaran Ubat Pengemulsi Sendiri (SEDDS) dan tulen. Purata pemulihan kurkumin tulen ialah 99.1%. Keluk penentukuran adalah linear dalam julat dari 31.3 hingga 1000 ng/mL dengan pekali korelasi $R^2 \geq 0.9999$. Had kuantifikasi yang lebih rendah (LLOQ) ialah 31.3 ng/mL. Keputusan pengesahan mengesahkan kelinearan, ketepatan dan ketepatan kaedah yang dibangunkan. Tambahan pula, keterlarutan eksipien kurkumin-SEDDS telah dijalankan, dan kandungan pemuatan kurkumin (LC) kemudiannya ditentukan.

Selain itu, parameter farmakokinetik berjaya diukur dengan kaedah ini termasuk purata kepekatan plasma puncak (C_{max}), masa untuk mencapai kepekatan puncak (T_{max}), dan jumlah kawasan di bawah keluk masa kepekatan plasma dari masa sifar hingga masa pensampelan terakhir, iaitu, nilai 1440-minit (AUC0-1440m) masing-masing 238.81 ng/mL, 70.83 min dan 11249.60 ng.min/mL Kaedah ini sesuai untuk mengesan kurkumin dalam formula tulen dan SEDDS daripada penilaian *in vitro* kepada *in vivo*.

Kata kunci: kurkumin, plasma, sistem penyampaian ubat pengemulsi sendiri, farmakokinetik

Introduction

The dried ground rhizome of the perennial herb *Curcuma longa* Linn , or also known as turmeric, has been used in Asian medicine since the second millennium BC [1]. According to the Food and Agriculture Organization of the United Nations, turmeric has been used as food preservative, coloring and flavoring agents [2]. Turmeric is traditionally used for the treatment of wounds, inflammation and tumors [3-5]. It has been linked with antioxidant, anti-inflammatory, anti-microbial, antiproliferative, angiogenesis, anticancer, antidiabetic, antirheumatic, antiviral effects and low toxicity with promising clinical application [2, 6-9]. Recently, a study showed that curcumin minimize the effect on cognitive functions, reduce fatigue as well as improving resilience to the detrimental effects of psychological stress on mood in elderly [10].

Curcuma spp. contains turmerin (a water-soluble peptide), essential oils (such as turmerones, atlantones and zingiberene) and curcuminoids which are natural polyphenols responsible for the yellow color of turmeric. There are three types of curcuminoids, namely bis-demethoxycurcumin (BDMC), demethoxycurcumin (DMC) and curcumin **[**1,7-bis(4-Hydroxy-3-methoxyphenyl)-1,6-heptadiene-3,5-dione]. Among the three curcuminoids, curcumin which is also known as diferuloylmethane, or diferulylmethane is the most biologically active constituent.

Liu et al. reported the LLOQ of curcumin was 0.5 ng/mL through LC-MS/MS method with high sensitivity and short run time [11]. However, the curcumin extraction from rat plasma adopted by Liu et al. was complicated and time consuming [11]. May et al. used matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF/MS) to study curcumin and its metabolites in mouse serum and lung cell resulting in correlation coefficients of 0.94-0.99 with concentrations of 0.04-10.00 nmol curcumin [12]. Despite high sensitivity and short run time, LC-MS/MS and MALDI-TOF/MS are expensive instruments with hard overcome matrix effects [13].

High performance liquid chromatography (HPLC) also been employed in plasma curcumin quantification with limitation of long analysis run time and tedious extraction methods [14-16]. For instance, Heath et al. extracted curcumin with 95% ethyl acetate/5% methanol [14], and Pak et al. utilized a 3-step extraction which requires large plasma sample volume and uses of chloroform [15]. In another study, Schiborr and colleagues developed a sensitive HPLC-FD with an extremely short retention time at 1.2 minutes which may potentially be interfered by solvent and plasma front peaks [16]. Besides, the extraction step was repeated twice in their developed method [16].

Protein precipitation has been introduced as one of the most common and simple sample pre-treatment methods in removing the protein in plasma sample. It is a simpler method as compared to the extraction process. Ma et al. and Li et al. have developed simpler HPLC assay method using direct protein precipitation method for curcumin extraction with UV and PDA detection, respectively. The HPLC method developed in Li et al. had a relatively shorter run time of 3 minutes and lower LLOQ of 1 ng/mL as compared to Ma et al. [17, 18].

More recently, Anwar et al. modified and developed an analysis method for curcumin using Ultra Performance Liquid Chromatography (UPLC) with Quadrupole-time of flight-mass spectrometry (Q-TOF-MS/MS) [19]. This is a very sensitive chromatographic method which offered short sample retention time at 2.18 minutes; however, the extraction method used a toxic solvent, i.e., chloroform and required a large plasma sample volume of 500 µL. In addition, the technology requires expensive equipment that is not available in most

laboratories. Therefore, the aim of this study was to develop an improved method for the quantification of curcumin in plasma using simple high performance liquid chromatography (HPLC) with rapid sample pretreatment procedure. This method is also used to quantify curcumin in self-emulsifying delivery system include solubility, loading content and formulation studies.

Materials and Methods

Chemicals and reagents

Curcumin (99.8% analytical standard) was purchased from ChromaDex (Irvine, CA). Curcuma extract was purchased from Naturalin (Bio-Resources Co. Ltd, Changsha City, China). Canola oil, corn oil, soyabean oil, sunflower oil, peanut oil, and olive oil were purchased from a local store. Oleic acid, PEG-400, Tween 20®, Tween 80®, Cremophor EL®, Cremophor RH40®, and Labrasol® were sponsored by Hovid R&D, Penang, Malaysia. HPLC grade of acetonitrile (ACN) and acetic acid (100% glacial) were obtained from Merck (Darmstadt, Germany). Water for HPLC was prepared by double glass distillation and filtered through 0.45 μm nylon membrane filter (Millipore, Bedford, MA, USA). Human plasma obtained from Hospital Pulau Pinang, Malaysia.

Method development: Instrumentation and equipment

HPLC system consisted of a Waters e2695 Separations Module auto-sampler with refrigeration unit, Waters 2475 Multi-wavelengths Fluorescence Detector. Data acquisition and analyses were performed using the Empower Software 3 (2010, Waters, US).

Analytical and chromatographic conditions

Chromatographic separation was achieved on a reversed phase Waters Symmetry® C_{18} (5μm x 4.6 mm x 250 mm) column. Column and injection temperatures were both maintained at 25°C. Isocratic solvent with flow rate of 1.2 mL/min was used. The sample was injected through a fixed sample loop of 10 μL. The excitation and emission wavelengths for curcumin were set at 365 nm and 512 nm respectively. The analysis time was 6 minutes per sample.

Preparation of mobile phase

A 1% acetic acid solution was prepared by adding 4 mL of glacial acetic acid into 400 mL of distilled water. This was then eluted together with 600 mL of acetonitrile to make up a mobile phase of acetonitrile and acetic acid 60:40 (% v/v) and adjusted to pH 3.25 with acetic acid. Liquids used for the mobile phase were filtered with 0.45μm filter paper (Millipore, Merck, Germany) and kept in amber glass bottles prior to use. Fresh mobile phase was prepared daily.

Preparation of stock solutions and calibration samples

Stock solution of curcumin was prepared in ACN at a concentration of 1 mg/mL. This curcumin stock solution was diluted 50 times with ACN to a working solution of 20 μg/mL. The calibration standards were created by mixing the appropriate amount of the working standard with human control plasma to obtain a final volume of 1 mL, resulting in six calibration standards ranging - 31.3, 62.5, 125, 250, 500 and 1000 ng/mL. Standard solutions were prepared by adding volumes of 1.565, 3.125, 6.25, 12.5, 25, and 50 μL of a working solution into 998.435, 996.875, 993.75, 987.5, 975, and 950 μL of blank plasma. All solutions were protected from light and stored at 4°C. For each validation and assay run, the calibration curve of curcumin was prepared fresh from the working solution. All the plasma samples were stored at -20°C and brought to room temperature prior to use.

Sample pre-treatment procedure

Plasma samples and working solutions were thawed to room temperature before use. An aliquot (100 μL) of plasma samples were pipetted into 1.5 mL microcentrifuge tube (Eppendorf, Germany). Direct deproteinization procedure was carried out by adding 200 μL of acetonitrile. The mixture was vortex-mixed for 20 seconds and centrifuged at 12800 x g for 15 minutes. A 100 μL aliquot of the supernatant was transferred to the HPLC vials and 10 μL of the mixture was injected into the HPLC system for further analysis.

Assay validation

In order to confirm the suitability of the method for its intended use, it was validated for specificity, linearity,

precision, accuracy, limit of quantification, limit of detection and stability according to the International Conference on Harmonization guidelines [20] and Guideline on bioanalytical method validation [22].

Specificity

For a specific method, there should be no interference of impurities or other compounds in the blank plasma to the detected peak of curcumin [21]. To test specificity, 10 µL of blank plasma pre-treated according to previous section was injected for analysis. The chromatograms of spiked curcumin plasma samples were compared to the blank plasma. The specificity of the method was determined by analyzing 6 human blank plasma samples.

Linearity

Calibration standards were prepared from the curcumin stock solution at 6 concentrations ranging from 31.3 to 1000 ng/mL. Peak area of curcumin from the chromatogram was plotted against the corresponding curcumin concentrations in plasma.

Accuracy and precision

The within-day accuracy and precision of this assay were evaluated by analyzing plasma aliquots of the calibration standards in 6 replicates on the same day. The between-day accuracy and precision were determined by analyzing each calibration sample once for 6-consecutive days. According to USP [22] and FDA[21] guidelines, the acceptance criteria for within- and between-day accuracy was within ± 15% deviation (DEV) from the nominal values and precision was within 15 % relative standard deviation (RSD).

Recovery

The absolute recovery was determined at each of the calibration point. A set of drug solution was prepared at the same concentrations of curcumin and processed using the sample treatment procedure. The absolute recovery was evaluated by comparing the peak area of curcumin in the spiked plasma sample to the corresponding curcumin solution.

Stability

Due to the possibility of delayed injection or reinjection of samples in the HPLC system, the post-operative stability of treated samples in autosampler vials was assessed. In freeze-thaw stability, samples were thawed at room temperature and refrozen at -20°C over three cycles and assayed. Short-term stability was evaluated to ensure stability of curcumin in plasma to cover the sample preparation time. These samples were exposed to ambient laboratory conditions for 8 hours before curcumin assay. Whereas long-term stability of curcumin in plasma stored at -20°C was evaluated by assaying the samples at baseline, 1 month and 2 months. All stability tested samples were analyzed in 6 replicates.

Curcumin self-emulsifying formulation: Solubility study

Briefly, the solubilization capacities of various oils (Table 1) and the cosolvent, Polyethylene glycol 400, were investigated to select excipients that can solubilize the maximum amount of curcumin using the equilibrium method [23]. An excess amount of curcuma extract (2 g) was added to 10 g of the various oils, and the cosolvent separately, allowed to rotator at 10 rpm for one day at approximately 25±2°C. After that, samples were centrifuged at 12800 g for 15 min to remove the undissolved curcumin, and the supernatant was filtered through a 0.2 µm PTFE membrane filter. Later, 0.02 g of each filtrate was first dissolved in the proper volume of ACN, then further diluted with a sufficient volume of the mobile phase. Curcumin concentration in each vehicle was determined, and all measurements were in triplicate.

Evaluation of blank and loaded self-emulsifying formulation

The effectiveness of self-emulsification, also known as dispersibility assessment, is carried out based on the results of the solubility experiments, in which the selected vehicles (oil phase) were further screened with the assigned surfactants (Table 1) for their emulsification capacities by visual assessment [24]. Only formulations that were able to produce a grade A system at room temperature were chosen for curcumin-loading studies (Table 2).

Table 1. Grading system for emulsification behavior exhibited by SEDDS upon dilution

Grading	Description
Grade A	Spontaneous emulsification; demonstrating a clear appearance (60 s)
Grade B	Spontaneous emulsification; demonstrating a bluish appearance (60 s)
Grade C	Emulsion displays fine milky appearance (120 s)
Grade D	Dull, greyish white appearance with an additional oily appearance together with slow emulsification, (>120 s)
Grade E	Poor or minimal emulsification noted with large oil droplets noticed on the surface

S=Second

For the loading content (LC) evaluation; selected oil-vehicle: cosolvent with the combination of different ratios were studied. To perform the experiment, the samples were treated as per the procedure of the curcumin solubility studies, and the LC was measured via HPLC in triplicate.

Pharmacokinetic evaluation: Animals' selection

Twelve adult male Sprague-Dawley rats were selected in this study, weighing 220g to 286g. The ethical has been approved by the Animal Ethics Committee (AEC) of Universiti Sains Malaysia (USM).

Samples preparation

Similar amount of the curcumin in curcuma extracts alone, and in the loaded optimized self-emulsifying drug delivery systems (SEDDS) formulation were dissolved separately in distilled water (pH 5.6-5.8), with an administration dose of 250 mg/kg body weight of the rats through oral intubation. The formulations were well-mixed before each administration, and the dose was flushed with 2 ml of water after completion of oral administration.

***In vivo* study design**

The study was carried out according to a 2-period, 2-sequence crossover design with a one-week washout period. The rats were randomly divided into two groups with six in each. Before administration, the rats were fasted overnight for at least 12 h with free access to water. After formulation administration, the rats were fasted for 4 h, and water was withheld for 2 h. Approximately 0.3 ml blood samples were withdrawn from the tail veins of each rat on sampling intervals at 0-minute (pre-dosing), 20, 40, 60, 90, 120, 180, 240, 360, 600, 960, and 1440 min post-dosing administration [25]. The blood samples were collected into heparinized microcentrifuge tubes and then the tubes were centrifuged at 12800 g for 15 min to separate the plasma. The plasma samples were analyzed using proposed HPLC method.

Pharmacokinetic data analysis

Using C_{max}, T_{max} and AUC0-1440m as pharmacokinetic parameters, the oral bioavailability of curcumin was compared between the optimized loaded SEDDS formula and the isolated extract. The C_{max} and T_{max} were obtained directly from the plasma concentration values, whereas the $AUC_{0\text{-}1440m}$ was calculated using the trapezoidal formula.

Statistical analysis

To test the statistical significance, a one-way analysis of variance (ANOVA) with Tukey's HSD (honest significant difference) tests was used. The difference in all the analyses was considered statistically significant when $p < 0.05$. All the statistical tests were done using (Minitab® statistical software, version 17.2.1.0, Minitab Inc., USA).

Results and Discussion

Method development: HPLC-detector Condition

The excitation and emission wavelengths were set at the characteristic wavelengths of curcumin at 365nm and 512nm [26]. In this study, acetonitrile (ACN) was chosen due to its low viscosity and strong eluting power [27]. The mobile phase was optimized by manipulating the ratio of solvent and acetic acid to achieve good resolution, short run time and symmetric peak shapes. After optimization, mobile phase made up of acetonitrile and 1% acetic acid solution (60:40, v/v; pH 3.25) with a flow rate of 1.2 mL/min and a run time of 6 minutes was

used with Waters Symmetry® C_{18} column (5µm x 4.6 mm x 250 mm) in the current study.

Sample pre-treatment

A pre-treatment procedure is often needed to remove protein and potential interferences from samples prior to HPLC analysis. Various studies suggested the use of liquid-liquid/solid-liquid extraction method [15, 19] which is tedious, time-consuming and involved the use of toxic solvent. Different from liquid-liquid extraction and solid-phase extraction, protein precipitation is commonly used for fast sample clean-up and disrupting protein-drug binding [28-30]. In the current study, addition of 200 µL ACN to the plasma sample was used to deproteinize plasma protein and extract the curcumin content into solvent. This direct single deproteinization step enables us to accomplish pre-treatment step fast and easily.

Method validation

The method was validated according to the guidelines issued by the United States Pharmacopeia (USP) [22] and Food and Drug administration (FDA) [21]. The validation experiments and results obtained are described below.

Specificity

Specificity is described as the ability of a method to discriminate the analyte from all potentially interfering substances [18]. Figure 1(a) shows the sharp peak of 1000 ng/mL curcumin standard solution eluted at 4.9 minutes. Figure 1(b) shows chromatogram of blank plasma while Figure 1(c) shows plasma spiked with 1000 ng/mL curcumin standard solution, the chromatogram indicates that there is no any interference to the peak of interest. Quantitatively, the peak area of the spiked plasma and the curcumin standard solution were found to be equivalent. These results prove that the developed method is specific for curcumin analysis.

Sensitivity and linearity

In regard to the sensitivity, Signal to Noise (S/N) of the retention peak is crucial. For an acceptable detected S/N peak, the height of the corresponding peak and the difference between the largest and smallest noise values should be equal to at least five times the width at the half-height of the peak and, if possible, situated equally around the peak of interest [31]. This is also known as lower limit of detection (LLOD). In this study, the LLOD was 15.6 ng/mL.

Lower limit of quantification (LLOQ) is defined as the lowest concentration on the standard curve that can be quantified with accuracy within ±15% of nominal and precision not exceeding ±15% C.V. according to the USP [22] and FDA [21] guidelines. In the current study, even though the developed method allowed detection of as low as 15.6 ng/mL of curcumin but it was not precise as the S/N ratio is low. At concentration of 31.3 ng/mL, the accuracy and precision (C.V. %) were 95.2% and 2.1%, respectively, which met the criteria set in the guideline [21, 22]. Hence the LLOQ of the current developed method was determined to be 31.3 ng/mL.

Validation was completed by running the developed system in six independent days; hence data of all the six calibration curves was compiled for summary. Results show that all of our six calibration curves were linear in the range of 31.3-1000 ng/mL with $R^2 \geq 0.9999$.

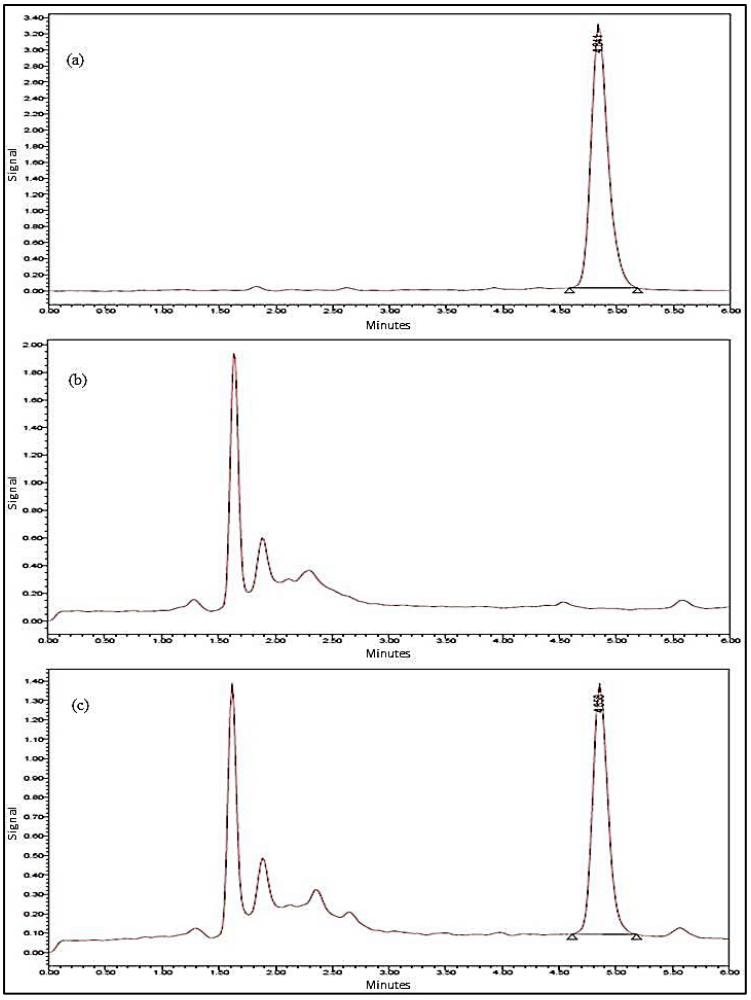

Figure 1. (a) Chromatogram of 1000 ng/mL curcumin standard solution, (b) chromatogram of blank plasma, and (c) chromatogram of plasma spiked with 1000 ng/mL curcumin standard solution. Arrow indicates curcumin retention peak.

Table 2. Regression parameters for calibration curves (n=6) of curcumin plasma assay method

Calibration Curve (Day)	**Correlation Coefficient (R^2)**	**Slope**	**Intercept**
1	0.9999	0.0086	7.2605
2	1.0000	0.0097	2.0608
3	0.9999	0.0096	-0.0870

5	1.0000	0.0096	-2.0267
6	1.0000	0.0095	0.1690
Mean	1.0000	0.0094	1.2778
S.D.	0	0	3.2

S.D. = Standard Deviation

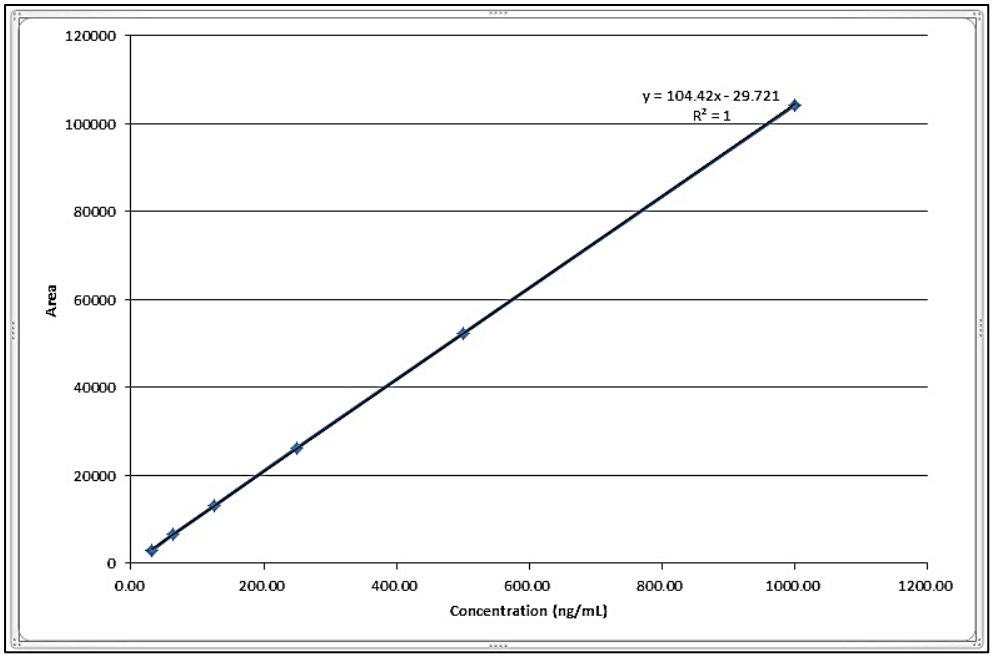

Figure 2. Example of calibration curve for curcumin plasma assay method from concentration of 31.3-1000 ng/mL

Accuracy and precision

Table 3 presents the within- and between-day accuracy and precision for each of the sample. The within-day accuracy and precision from 31.3-1000 ng/mL was in the range of 93.7-105.4 and 0.4-2.4%, respectively (Table 3 (a)). The between-day accuracy and precision from 31.3-1000 ng/mL was in the range of 96.8-100.3 and 0.4-2.3%, respectively (Table 3 (b)). In the current study, our assay successfully met the criteria for good accuracy and precision.

Recovery

A summary of the absolute recovery of curcumin was shown in Table 4. The absolute recovery of curcumin at concentrations of 31.3-1000 ng/mL was in the range of 97.9±2.1%-99.9±0.5% (Table 4). A study carried by Ma and colleagues in 2007 shown that the recovery of curcumin was 97.08% at concentration of 50 ng/mL, 95.69% at concentration of 200 ng/mL and 94.90% at concentration of 1000 ng/mL respectively [17]. Whereas the recovery of curcumin was 95.70±5.60% at concentration of 2 ng/mL, 97.70±5.80% at concentration of 20 ng/mL, 95.60±5.00% at concentration of 400 ng/mL and 96.60±8.40% at concentration of 400 ng/mL respectively in a research investigated by Li and co-workers in 2009 [18]. The absolute recovery shown in the current study was relatively high and precise as compared to the reported literature [17, 18].

Stability

Stability study is necessary in order to rule out the degradation of the investigated compound, i.e., curcumin in plasma samples. Table 5 displays the stability results of curcumin in plasma of the current study. According to Table 5, all the accuracy and precision are within 85%-115% and ≤ 15%, respectively. Post-operative stability in autosampler and short-term stability of curcumin at ambient temperature were satisfactory, with no significant degradation of curcumin being observed for up to 8 hours (Table 5(a) and (b)). Table 5(c) shows that curcumin was stable in plasma at both low and high concentration over three cycles of freeze-thaw. Although sample storage at -20°C is recommended for long term storage, the long-term stability was necessary to be evaluated at the zero-time point, 1-month and 2-months at least. Curcumin in plasma was stable for up to 2-months at -20°C (Table 5(d) and Table 5(e)). These results indicate that curcumin has an acceptable stability under all the tested conditions.

Comparison of recent method with reported method

The comparison of the recent study with the reported methods in Table 6 reveals that the optimized HPLC method developed in the recent study offers a significant advantage in terms of shorter running time. The reduced analysis time is achieved through optimized chromatographic conditions, resulting in faster elution and separation of curcumin. This not only improves the efficiency of the analysis process, but also saves valuable time in the laboratory. Despite the shorter running time, the recent method maintains comparable accuracy, and recovery in detecting curcumin levels in human plasma, making it a promising alternative for efficient and reliable curcumin analysis in clinical research and pharmaceutical applications.

Table 3. Within- and between-day accuracy and precision of curcumin plasma assay method (n=6)

QC Sample	Curcumin Concentration (ng/mL)	Mean Determined Concentration (ng/mL)	Accuracy (%)	Precision (C.V. %)
(a) Within-day	31.3	29.8	95.2	2.1
	62.5	58.6	93.7	1.7

Self-emulsifying curcumin formulation: Solubility

Among the excipients studied, the solubility of curcumin in PEG-400 was significantly higher, 194.28±9.92 mg/g and the highest solubility of curcumin was observed in soyabean and corn oils at 0.71 ±4.22 mg/g and 0.71 ±5.63 mg/g ($p < 0.05$), respectively as shown in Table 7.

Table 7. Solubility study of curcumin in oil phase and co-solvent, n = 3

Potential Vehicle	Concentration of Curcumin (mg/g)	Standard Deviation
Canola oil	0.60	4.27
Corn oil	0.71	5.63
Soyabean oil	0.71	4.22
Sunflower oil	0.66	5.67
Peanut oil	0.68	2.58
Olive oil	0.61	4.67
Oleic acid	0.63	9.92
PEG-400	194.28	9.92

Evaluation of blank and loaded self-emulsifying formulation

Results revealed that the highest number of the rapidly formed (within 1 min) dispersions of "grade A" with the lowest surfactant concentrations was obtained with Cremophor EL® (50%) in soyabean oil out of the 45 formulations (from ration 1:9 to 9:1). Moreover, the curcumin loading in the curcuma extract SEDDS was the highest ($p < 0.05$) at soyabean oil: PEG-400 ratio of 3:2; thus, it was selected and combined with Cremophor EL® at a ratio of 5:5 to produce the optimized loaded SEDDS formulation (grade A).

Pre-clinical pharmacokinetic study

The concentrations of curcumin in the group of rats fed with curcuma extract loaded SEDDS formulation were significantly increased, with mean C_{max}, T_{max}, and $AUC_{0\text{-}1440m}$ values of 238.81 ng/mL, 70.83 min, and 11249.60 ng.min/mL, respectively; however, curcumin from curcuma extract alone was undetectable (below the HPLC LOQ of 31.25 ng/mL), implied that the bioavailability of this purely bioactive form was very low. Mean plasma concentrations versus time profile of curcumin are shown in Figure 3; such impact probably linked to the synergistic enhancement of curcumin absorption by PEGs and Cremophor EL® [34]. The designed SEDDS was able to offer dramatic improvements in bioavailability. Hypothetically, considering the HPLC LOQ value, the AUC was calculated for curcumin from curcuma extract alone over the time of detection for curcumin from curcuma extract loaded in SEDDS formulation. Comparing the AUC for curcumin from curcuma extract loaded in SEDDS formulation, and the hypothetical AUC for curcumin from curcuma extract alone, resulted in value of 1107.10 ng.min/mL, with 15-folds increment in the bioavailability using the developed curcuma extract-SEDD in this work. As a result, the developed curcuma extract-SEDDS formulation offered higher curcumin plasma concentration in compared to the curcumin loaded in solid lipid nanoparticles (C_{max} of 20.85 µm equal to ~7.7ng/ml) with an oral dose of 400 mg/kg [35], as well as curcumin loaded in self-micro emulsifying drug delivery system (SMEDDS) (C_{max} of 0.15 µm equal to ~0.056 ng/mL) with an oral dose of 100 mg/kg [36].

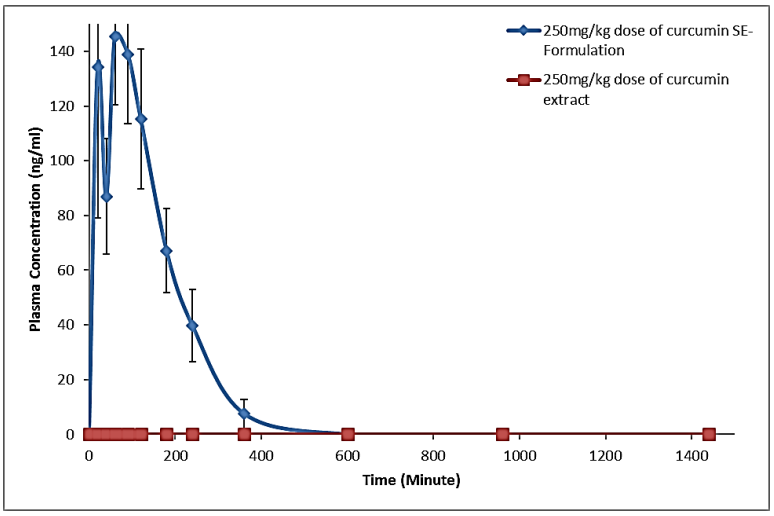

Figure 3. Mean plasma concentration-time profiles (Mean ±S.E.M., n = 6) of curcumin after oral administration of 250 mg/kg curcumin suspension and curcumin loaded in SEDDS formulation

Conclusion

A reliable, simple and sensitive high-performance liquid chromatographic (HPLC) method has been developed and validated as per the ICH guidelines for the determination of curcumin in plasma. This method offers adequate, accuracy, precision, appropriate retention time, moderate pressure and good peak shape. Curcumin remained stable for up to eight hours in the stability test, and did not degrade even after three freeze-thaw cycles. The stable long-term storage period was up to two months. The method application in quantifying the SEDDS formulation in the *in vitro* (solubility and loading content) and *in vivo* level was successfully achieved. The current method is easy and fast to perform, hence, can be applied in pharmacokinetic studies of curcumin alone, or in SEDDS formulation.

Abstract

Rubberwood was favored for the production of medium density fibreboard (MDF). However, with the increasing demand for MDF, the limited supply of rubberwood and the need for biomass conservation, fibre boards made from agricultural residue are under investigation, though their dimensional stability is a challenge. Several researchers have used various methods and techniques for the improvement of MDF mechanical and physical properties. This article reviews the current process of MDF manufacturing and performance indexes that help find the optimum criteria for board fabrication. It was discovered that oil palm fibre has its own chemical composition and thus impacts the properties of board when used as an alternative raw material for MDF production. Thus, the mechanical and physical properties of fibreboard made from oil palm-based fibre were discussed in various hybridization ratios with different types of fibre and compared with rubberwood board. Furthermore, chemical treatments, such as alkaline treatment, acetylation or soaking, and washing with boiling water or removing parenchyma cells were also studied. It was found that the dimensions of the fibre affected the mechanical properties, such as modulus of rupture (MOR), modulus of elasticity (MOE) and internal bonding (IB). The chemical changes in fibre that occur when oil palm fibre is chemically modified were also discussed and summarized.

Keywords: chemical composition, oil palm fibre, medium density fibreboard

Abstrak

Kayu getah digemari bagi pembuatan papan gentian kepadatan sederhana (MDF). Walau bagaimanapun, peningkatan permintaan bagi penghasilan MDF, bekalan kayu getah yang terhad, dan keperluan untuk pemuliharaan biojisim, papan gentian yang diperbuat daripada sisa pertanian sedang dikaji, walaupun terdapat cabaran terhadap kestabilan dimensinya. Beberapa penyelidik telah menggunakan pelbagai kaedah dan teknik bagi penambahbaikan sifat mekanikal dan fizikal MDF. Artikel ini mengkaji proses semasa dalam penghasilan MDF dan indeks prestasinya bagi membantu mengetahui kriteria optimum dalam pembuatan fabrikasi papan. Hasil kajian mendapati gentian kelapa sawit mempunyai komposisi kimianya sendiri dan seterusnya mempengaruhi sifat papan apabila digunakan sebagai bahan mentah alternatif bagi pembuatan MDF. Oleh itu, sifat mekanikal dan fizikal papan gentian yang diperbuat daripada gentian berasaskan kelapa sawit dalam pelbagai nisbah penghibridan bersama gentian yang berbeza jenis telah dibincangkan dan dibandingkan dengan papan kayu getah. Selain itu, rawatan kimia seperti rawatan alkali, asetilasi atau rendaman, dan mencuci dengan air mendidih atau mengeluarkan sel parenchyma juga turut dikaji. Kajian mendapati bahawa dimensi gentian mempengaruhi sifat mekanikal seperti modulus kepecahan (MOR), modulus kekenyalan (MOE), dan ikatan dalaman (IB). Perubahan kimia yang berlaku dalam gentian apabila gentian kelapa sawit diubah suai secara kimia turut dibincangkan dan diringkaskan.

Kata kunci: komposisi kimia, fibre kelapa sawit, papan gentian kepadatan sederhana

Introduction

Medium density fibreboard (MDF) is a composite wood product that is traditionally made by breaking down softwood into wood fibre in a defibrator. Then, it is mixed with wax and a synthetic resin binder, such as urea formaldehyde (UF) resin and forming board by using high temperature and pressure. Additives may be added during the manufacturing process to impart additional qualities. However, not all MDF are identical, such as texture, density, color and other characteristics that vary depending on the material used.

MDF has several characteristics that make it a good substitute for plywood or particle board. The material is dense, flat, sturdy, free of knots and machine-friendly. It is made up of small particles and gives dimensional stability without the presence of a noticeable grain, as wood does. MDF, unlike most plywood, has no gaps and produces sharp edges with no tear-out. Besides, MDF panels are available in a wide range of physical properties and dimensions, allowing to construct a finished product with the exact MDF features and density required. It is also an environmentally friendly product that uses renewable resources, such as kenaf, wheat straw, radiata pine, bamboo and non-wood fibres.

Rubberwood is also one of the most preferred raw materials for MDF production as compared to other renewable resources. According to Md. Rowson et al. [1], rubberwood possesses all of the necessary characteristics and its abundance makes it successful in the wood-panel industry. However, at present, rubber plantations are cultivated for the production of latex rather than wood manufacturing [1]. Therefore, rubberwood supply has recently become limited in the wood processing industry because of climatic (extended wet periods) circumstances that made rubberwood harvesting inefficient, especially on higher slopes. In addition, the resource is not available in larger, more desirable blocks, which has an impact on economies of scale. Finally, the demand outstrips supply, making rubberwood a finite (at least in short to medium term) resource.

Oil palm plantations, which are progressively replacing rubber plantations in Southeast Asia, have lately been introduced as popular fibres for new materials in MDF production. It is an under-utilized material, similar to rubber, with potential applications in a variety of industries. Oil palm fibres are now being researched for usage in various wood-based boards, pulp and paper, mushroom cultivation, and animal feed. Empty fruit bunches (EFB) are used as mulch, boiler fuel, fertilizer and for the manufacture of automobile cushions and mattresses [2]. Oil palm trunk (OPT) and oil palm frond (OPF) fibrous threads can be used to produce pulp, paper and chipboard [3]. Fruit bunch fibres can be used to make laminated isotropic fibreboard, cement board and pulp. Therefore, in addition to the research as previously mentioned, oil palm fibre also has a significant potential for converting low-value raw materials into high-quality wood panels that may be utilized as raw materials for the production of MDF.

This study aimed to review and summarize the current process of MDF production by using various agricultural biomasses. In this review, developments in MDF production from various oil palm-based fibres and factors influencing the properties of MDF will be discussed. These studies also identified the properties of MDF made from oil palm-based fibre with the greatest potential, considering their availability and the quality of boards they produce.

Medium density fibreboard raw materials

In general, the wood processing industry is undergoing significant structural changes, with a steady shift away from large-diameter trees and towards smaller-diameter second-cut trees, as well as a shift towards plantations and the estate sector. The latest developments in the MDF sector are strikingly comparable to those in the plywood industry. The main difference is that the latter arose as a result of government policies promoting domestic wood-based industries. However, MDF manufacturing plants arose as a result of raw material shortages that have become increasingly apparent in recent years, as well as the opportunity to use previously untapped resources.

Mixed tropical species, bagasse, radiant pine, rubberwood and cotton stalks, wheat straw, bamboo and rice straw are all important raw materials for MDF [4]. In Malaysia, rubberwood is the only raw material used, as opposed to particleboard or cement-bonded products, which rely on a mix of species and wood waste. Rubberwood has a light color and consistent texture; thus, making it an attractive fibre source for MDF manufacture [1].

Debarking and chipping are the first processes in the MDF manufacturing process. In a digester, cleaned chips are boiled and refined into wood fibres, which are then combined with resin and wax. Before being formed into a continuous mat, the wet fibre, resin and wax combination are dried and delivered to the mat forming. It is trimmed, sanded and cut to desired specifications in the final processing stage.

Current process for manufacturing MDF

MDF is a nonstructural fibre-based panel made out of wood fibres that have been glued together with resin under heat and pressure. Before being mixed with resin and wax, the fibres are refined in a defibrator or refiner. The surface of the fibres is coated with a bonding agent or resin. The resonant fibres are dried, then molded into mats, which are subsequently hot pressed to make a uniform board. The density ranges between 660 kg/m^3 and 850 kg/m^3 [5].

The utilization of various wood or fibrous materials in the production of MDF is shown in Table 1. Table 1 compares the mechanical and physical characteristics of various fibres with those of rubberwood. The qualities of the board were affected by both the manufacturing process and the chemical composition of the fibre. The mechanical and physical characteristics of the board are affected by the resin type, resin level, pressing time, pressing temperature, and refining parameters. Most materials use UF as a resin as compared to PF resin. In addition, it can be seen that, regardless of the type of fibre employed, higher resin content will increase MOR and MOE. However, higher pressing temperatures increase the internal bonding (IB) and lead to decrease WA and TS. Nevertheless, the mechanical (MOR and MOE) and IB of the board improve after increase refining parameters thus low WA and TS were obtained.

Figure 1 depicts the entire manufacturing process, including material preparation (chipping), fibre formation, fibre treatment, mat forming and hot pressing and board treatment. First, the wood is chipped using a chipper machine. After that, the chips are screened to separate the fibre different sizes [6]. A belt conveyor with an iron remover built over it transports the confirming chips to the chip's washer. The chips are then washed to increase their quality. After that, the chips are moved to the fibre separation section. To soften the chips, they are heated at 160°C–180°C or 6–8 bar pressure for 3 min–5 min.

To make the softened chips less prone to swelling, around 1 wt.%-2 wt.% paraffin wax is applied [7]. After that, the softened chips are transferred to the grinding chamber. The materials are mechanically decomposed in the grinding chamber with the help of water and heat. UF resin is added to pulp as it passes through the blow valve. The pulp, in the form of fibre, is placed in the dryer [8]. Moisture vaporizes in fibre and is controlled within the appropriate range. The fibre final moisture content is kept within 8%–13% (wt.). The fibre is evenly distributed into the matting conveyor belt and the preset thickness is made by using the air blow function. Hot pressing is used to get the desired thickness.

The prepress removes the air from the mat and strengthens it [18]. Fibreboard is typically categorized by density and can be produced using either the dry or wet methods. Dry method can be used on both high-density (hardboard) and medium-density (medium-density) boards (MDF). Both high-density hardboard and low-density insulation boards can be processed by using the wet method.

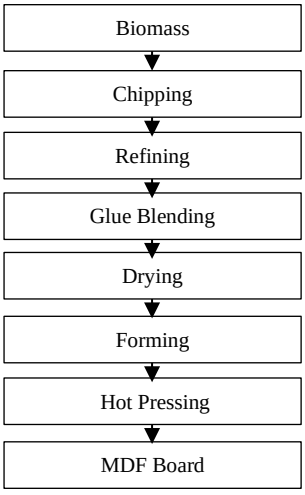

Figure 1. Flow chart for the production of MDF

Dry process fibreboard

Particleboards and dry process fibreboards are created in the same way. Resins such as UF and phenol formaldehyde (PF), as well as other additives can be sprayed on the fibres or added as the wet fibres are fed from the refiner into a blow line drier. On the other hand, some fibreboard plants add the resin to the refiner. The adhesive-coated fibres are then air-laid into a mat for pressing, similar to how particleboard mats are formed. Dry-process fibreboard pressing differs from particleboard pressing in a few ways. The fibre mat is normally pre-pressed in a band press once it is created. Next, the densified mat is trimmed with disc cutters and transferred to caul plates for hardboard pressing; in the case of MDF, the trimmed mat is directly transported to the press. All dry-formed boards are pressed in multi-opening presses at temperatures ranging from 140°C to 165°C for UF-bonded goods and 190°C for PF-bonded products [19].

Wet process hardboard

Hardboards made with a wet process differ from fibreboards made with a dry process in various ways. The fibres are first formed into a mat by using water as the distribution medium. Secondly, some wet process boards are manufactured without the use of extra binders. If there is sufficient lignin in the lignocellulosic material and it is kept after the refining process, lignin can be used as a binder. Lignin will flow and act as a thermosetting adhesive when exposed to heat and pressure, increasing the naturally occurring hydrogen bonds. In wet process hardboards, refining is a critical stage in creating strength. The refining process must also produce fibre with a high freeness or the ability to remove water from the fibrous mat easily. The soupy pulp runs quickly and easily onto a continually moving mesh screen in the wet process. Water is drained through the screen and then through a series of press rolls that wring out any remaining moisture. Wet process hardboards are pressed in steam-heated multi-opening presses. The press cycle is divided into three sections and lasts between 6 min and 15 min. The first phase, which is carried out under high pressure, eliminates the majority of the water while getting the board to the necessary thickness. The second phase major goal is to eliminate water vapor. The third phase is relatively brief and leads to the completion of the cure. The maximum pressure employed is at 5 MPa. To induce fibre-to-fibre bonding, heat is required while pressing [19].

MDF Performance Index

MDF performance index is divided into three categories: physical, mechanical and biological performance [20]. The most important physical properties are density, moisture content (MC), water absorption (WA) and thickness swelling (TS). Internal bonding (IB), modulus of elasticity (MOE), modulus of rupture (MOR) and screw holding force (face and side) are the primary mechanical characteristics, whereas the emission of formaldehyde is a major part of biological performance [20].

Physical performance

The swelling that can occur in a board is known as TS, which is inversely proportional to IB values. When the IB value is high, the TS value is usually low. This property is determined by how well the interparticle connection resists moisture absorption. The TS is affected by the MC of the mixture, pressing duration, board moisture, testing conditions and density of board. When the board is exposed to water, the amount of water absorbed into the wood substance is known as WA. It is very dependent on the structure of the wood cell [14]. However, by applying thermal treatment to the fibre, some changes are found, such as degradation of hemicellulose and reduction of hydroxyl group; thus, it reduces the TS value [15].

The drawback of MDF over plywood is that it swells more than plywood when exposed to water and a greater proportion of that expansion may not be recoverable after drying. High internal strains can be caused by in-plane movements as a result of increased or decreased moisture content in the board. These forces may be severe enough to result in buckling board, pushed-out nails and board detachment from the structure. As a result, the fibreboard must be able to swell and expand to control the destructive effect.

Heat treatment enhances the stability of wood, but it can also alter its surface features, hence its wetting properties [21]. Surface inactivation can occur when a

wood surface is exposed to a high-temperature environment [22]. When exposed to high temperatures, the wood surface undergoes a few known changes, including oxidation. Inactivation of wood surfaces, which causes poor bond quality, is a time-dependent process that can be expedited by raising the temperature [23]. Due to interference with adhesive wetting, flow and penetration, as well as the cure and resulting cohesive strength of the adhesive, an inactivated wood surface might produce adhesion issues.

Wood drying at temperatures between 160°C and 180°C causes surface composition changes, as reported by Li et al. [24]. In wood bonding, wettability is critical for good adhesion. To make close contact between wood molecules and adhesive, the adhesive must moisten, flow and penetrate the cellular structure of the wood. There is evidence that wood wettability and adhesion have a favorable relationship. Many tests have demonstrated that high drying temperatures lower the bonding strength of wood adhesives or that high temperatures reduce wood hygroscopicity and impede wettability [25]. Heat treatment causes wood fibres to become hydrophobic; thus, reduces their wetting ability [24]. Contact angle analysis can be used to determine the wettability of wood. The adhesive and coating qualities of wood and wood-based composite surfaces are vital to be determined [26]. Perfect wetting of a surface happens when the contact angle is zero.

The volume of fibre used in MDF has been shown to alter the density of the MDF produced in previous studies. Shorter fibres were well blended with longer fibres by filling the gaps between and amongst the fibres, resulting in a more uniform board with a low density. According to a study [13], the lower-density board had less swelling because it had less wood per unit volume and a low degree of hygroscopic response. Besides, to maintain homogeneous density across the length and width of the board, the fibres are required to be distributed uniformly [14].

Mechanical performance

The MOR is the maximum fibre stress computed in the upper and lower surfaces of the board. It is the material unique breaking stress, given in stress unit per unit area. MOE, on the other hand, is a measure of material stiffness that may be used to calculate the deflection of a product under stress, whereas internal bond measures the fibreboard efficiency and indicates the compatibility of resin adhesive with fibre [27]. Therefore, various factors may contribute to changes in mechanical properties, with some having better mechanical properties, as investigated by researchers. However, it was found that the main factor that affected mechanical properties of board was fibre length [28]. Fibres with a greater length and thickness provided a larger surface area for adhesive contact. According to Wan Daud & Law [29], fibre length had a bigger impact on board dimensional stability than mechanical qualities.

Oil palm biomass *vs* rubberwood

Rubberwood is an environmentally beneficial wood due to its unique characteristics and value that are not found in other materials. According to previous studies, the demand for sawn timber in furniture applications has increased yearly because consumers prefer the unique wood grain and light color of rubberwood, which is easy to work with and furnish with other materials and is durable. Rubberwood has a light-straw to light-brown color and a density of 550 kg/m^3 to 650 kg/m^3. The trunk diameter is usually between 30 cm and 35 cm, while the length is usually between 3 m and 5 m [30].

Oil palm EFB pulp fibres and rubberwood have been identified as two key sources for MDF production. Previous research has shown that oil palm EFB pulp fibres are superior to rubberwood pulp fibres because they contain fibres with higher pH values and buffering capacities. This buffering effect is caused by an acidic reaction agent that converts to a less reactive molecule and obstructs resin flow [31]. MDF made from EFB can be used instead of sawdust MDF, which is known to be less durable.

Most researchers prefer EFB to the currently available resources for manufacturing MDF as the primary raw material. As a result, the qualities of MDF will be affected by changes in the raw material. As previously stated, MDF mechanical properties and stability are greatly influenced by the technique and materials used in MDF manufacturing [32].

Properties of oil palm fibre vs rubberwood

The three main chemical components of a cellulosic fibre of wood are cellulose, hemicellulose and lignin. Cellulose is semi-crystalline polysaccharide with a large amount of hydroxyl group. This hydrophilic nature causes poor resistance to moisture absorption and poor interfacial bond. On the other hand, the physical properties of fibre used affect the mechanical properties of the board produced, such as fibre diameter, length, density, moisture gain, and cell wall. Table 2 compares chemical composition and physical properties of rubberwood and oil palm-based fibre. As listed in Table 2, the chemical composition of oil palm fibre and rubberwood vary in contents.

Generally, MDF manufactured from long fibre length, high density, thick cell wall and small lumen width produces MDF with greater MOR, MOE and IB. However, long fibre increase hydrophilicity; thus, increases their moisture absorption and board swelling. Besides, hydrophilic fibre characteristics can cause poor fibre and resin adhesion because of hydroxyl and polar group present in the component. As aforementioned, a large amount of hydroxyl group present in the fibre reduces their compatibility with resin adhesive because resin is hydrophobic. Therefore, improving adhesion between fibre and resin by reducing hydroxyl group would increase their compatibility by increase the wettability of the fibre surface [33].

EFB fibres are multicellular fibres with a central lacuna that are rigid and strong. The porous surface of EFB provides better mechanical links with resin. However, EFB fibres are coated with residual oil produced during the processing of palm oil. OPF fibre, on the other hand, consists of various sizes of vascular bundles. Vascular files are widely found in thin-walled parenchyma tissues. Each bundle consists of round gloves, vessels, fibres, phloem and parenchyma tissue. Unlike OPF, OPT is filled with relatively smooth and dense parenchyma ground tissues that comprised mainly hemicellulose and cellulose. Parenchyma ground tissues have high hydroxyl bonds which increased water uptake to retain more water as a water-transporting organ in plant trunks [34]. However, only the outer part of oil palm trunk is suitable for use because soft parenchyma tissue is high in the central region [35].

As shown in Table 2, EFB is rich in cellulose as compared to rubberwood, OPT and OPF. However, lignin and hemicellulose content of EFB is smaller if compared to rubberwood. Based on chemical composition, rubberwood is more similar to OPT except for its length, which shows rubberwood has a longest fibre than oil palm-based fibre. However, the biggest drawback of oil palm fibre is its low resistance to fungal attack because of the high carbohydrate (e.g., sugar and starch) deposited in the parenchyma.

Effect of hybridization

Many studies have been reported for enhancing the mechanical properties of MDF produced from oil palm-based fibre. This is because the properties of oil palm-based fibre affect the structural strength of the MDF produced. However, to meet the demand for environmentally friendly MDF, oil palm-based fibre is considered attractive because of their low cost, biodegradability and recyclability. Apart from these benefits, oil palm-based fibre imparts some drawbacks, including short fibre length, thin cell wall and low fibre density. Therefore, hybridization of oil palm-based fibre which is low modulus fibre with high modulus fibre like rubberwood is needed to overcome these disadvantages. This technique aims to produce MDF with better physical and mechanical properties by combining the strengths of both fibres to compensate for the weaknesses of the other. However, there are limited findings on the various blending ratios utilized and the changes of new hybrid on the properties of MDF produced. Table 3 shows the properties of MDF made from oil palm fibre (EFB, OPT and OPF), as well as rubberwood, mix tropical hardwood (MTH) and fibre mixing.

Abdul Khalil et al. [32] studied the effects of hybridization of EFB and rubberwood and discovered that MDF made from a 20:80 blend of EFB: rubberwood had better mechanical and physical qualities than MDF made from a 50:50 blend. In a separate study, Mustapha et al. [43] used EFB and kenaf fibre and found that a

50:50 EFB: kenaf resulted in lower mechanical properties as compared to 70:30 EFB:kenaf. This finding occurred because the addition of EFB fibre altered the pH value and buffering capacity; thus, affected UF resin flow which was suitable to be used with rubberwood and kenaf fibre [33]. Moreover, poor distribution of UF resin and EFB fibre resulted in the formation of lumps which released during exposure to water; thus increased the swelling thickness [33].

Table 2. Chemical composition and physical properties of oil palm fibre and rubberwood

Fibre	Density (g/cm^3)	Cellulose (%)	Lignin (%)	Hemi-cellulose (%)	Length (mm)	Diameter (µm)	Cell Wall Thickness (µm)	Lumen Width (µm)	Ref.

	-	-	-	30.4-31.5	-	-	-	-	[42]

In another study, the capabilities of EFB fibre and its effect on mechanical qualities of MDF were demonstrated by Harmaen et al. [14]. Table 3 shows that the MDF panel made entirely of rubberwood fibres had significantly better mechanical properties (MOR, MOE, and IB) than the other ratios of rubberwood: EFB. Generally, boards having less than 50% of oil palm EFB fibre had better strength properties. Therefore, weak mechanical properties were expected, but replacing 50% rubberwood is already considerable in the industry. MDF contains 70% EFB and 30% of rubberwood surpassing the minimum requirements of MOR and MOE based on EN standards, which are 11 N/mm^2 and 1800 N/mm^2, respectively [44].

On the other hand, physical performance (TS and WA) of the panel made from rubberwood mixture decreased, indicating that lack of hydroxyl group from rubberwood fibre made it less able to absorb water. However, the density of MDF was not affected by the mixture ratio. This was because 100% rubberwood board had a higher board density. In comparison to lower density boards, Wan Daud & Law [29] mentioned that high density boards had more intimate particle contact; thus contained more wood to withstand mechanical loads.

In addition, the strength of MDF also contributed by the fibre length. As mentioned in previous study, EFB fibres are shorter than rubberwood fibres, resulting in a lower IB value. Shorter EFB fibres contributed to a higher resin-covered surface area. Based on the study, 9%-12% resin was used to cover all surfaces of rubberwood fibres; however, it was insufficient to cover the larger surface area of EFB fibres. As a result, inadequate bonding between fibres would occur throughout the board, as seen on EFB-fibreboard.

The similar trend was also recorded when blending rubberwood with OPF and MTH. However, blending OPF with rubberwood and MTH recorded a better IB value as compared to other blending ratio reported by other researchers [45]. Another study demonstrated the

use of 100% OPF at different refining parameters was performed [46], however the resin level required to achieve optimum performance much higher as compared to other reported study. As reported by Zawawi et al. [46], unlike OPT and EFB, OPF had better characteristics. OPT had higher amount of parenchyma cell, whereas EFB contained residual oil. Therefore, increment of fine fibre of nonfibrous plant material from OPT such as parenchyma tissue during refining process or fine fibre coated with residual oil from EFB reduced wettability which led to a poor bonding between fibre and resin.

MDF from 100% OPT has also been produced at different refining parameters. The pressing temperature was heated at 200°C and 10% resin level was used [47]. These MDF provided an improved IB and TS behavior. In another study reported by Zawawi et al. [48], the board from OPT offered a good surface appearance, good strength and a light color. In comparison to MDF produced from rubberwood and OPT, MDF from EFB has a darker color because of residual oil presence on the surface of EFB. Other than that, Zawawi et al. [48] also conducted research by removing parenchyma cell from OPT fibre. As expected, removing parenchyma tissue enhanced the properties of MDF by increasing the ratio of fibre; thus, facilitated mechanical interlocking with resin.

Treatment of cellulosic fibre of oil palm

The main problem of cellulosic fibre and resin is their compatibility. The hydrophilic characteristics of the cellulose fibres lead to high moisture uptake which can seriously lower the mechanical properties of board produced. In addition, pectin and waxy substance present on the fibre covers the reactive functional groups of cellulose fibre and act as barrier to interlocking with the resin. The wax in cellulosic fibre act as barrier by reducing wettability; thus, adhesion of resin into the fibre. Based on several researches, studies of the chemical treatment were conducted to enhance the properties of fibres such as improvement of wettability, surface modification, chemical groups and tensile strength of oil palm fibre, as well to improve interfacial bonding of fibre and resin [49].

Asyraf et al. [3] also reported a similar finding on chemical modification to improve mechanical properties of oil palm fibre. Their survey found that chemical modification approaches have been widely reported to overcome oil palm fibre limitation; thus, improved compatibility, hydrophobicity and interfacial bonding. This can be achieved by eliminating the fibre hydrophilic characteristics, which raise hydrophobicity and interfacial bonding between the fibre and resin, thus resulting in a greater compatibility. The reactive functional group on fibre, such as the hydroxyl group, is modified during this process by the interaction with chemical treatment. Therefore, surface impurities such as pectin, wax and hemicellulose can be removed effectively. Chemical treatment approaches that are widely used for natural fibres include alkaline, acidity, silane, acetylation and coupling agents [3, 49].

The most widely used method to treat cellulose fibre of oil palm is alkaline treatment. In this treatment, fibre is immersed in alkali solution with different temperatures for different periods and then the fibre is washed with water and oven dried. This treatment improves fibre wetting by removing of wax, hemicellulose, lignin, pectin and oil substance; thus, fibre and resin compatibility [3]. Removing this substance increased the ratio of cellulose in the material and allowed good penetration of resin into the fibre. It also reduced the fibre diameter and produced rougher surface [50]. Studies of EFB fibre by Norul Izani et al. [51] showed that the surface fibre after treatment with NaOH became smoother compared with that of untreated fibre as proven by SEM analysis. Therefore, that fibre treated with NaOH displayed improvement in mechanical and physical properties [52]. However, amongst the properties mentioned, only TS and IB value recorded the lowest and highest values from other treated fibre.

Besides, esterification of fibre also can be done to improve the fibre surface. Esterification or acetylation causing plasticization of cellulosic fibre. The reaction involves generation of acetic acid as by product. Chemical modification of acetic anhydride substitutes hydroxyl group with acetyl group; thus, allowing the fibre to become hydrophobic. A study by Zawawi et al. [53] found that acetylation processes of EFB contributed

to a reduction of TS value; thus increased the dimensional stability of MDF produce.

A comparative evaluation of MDF mechanical properties produced from EFB treated with alkaline and acetylation treatment also was reported [54]. In contrast with their earlier finding [53], the property of MDF from acetylation treatment revealed that MOR, MOE and IB values were higher as compared to alkaline treatment. Zawawi et al. [55] mentioned that alkaline treatment had successfully removed higher oil from EFB surface as compared to acetylation treatment, unfortunately, higher oil removal was not the major factor of the improvement in mechanical properties of MDF board. Similar findings were reported by Bam et al. [56] using bagasse fibre and David Chukwudi [57] using raffia fibre, whereby the acetylation treatment showed a better compatibility with UF resin than that of alkaline treatment.

As mentioned by Zhang et al. [58], adhesive penetration could be a factor to the adhesion strength of the bonded wood. Therefore, research on adhesion properties, such as wettability and pH values are necessary for a strong bond to improve mechanical properties of board. A study performed by Zawawi et al. [53] reported that adhesives used, such as UF performed a better dimensional stability at an acidic condition was because treatment using acetic acid increased resin curing times during hot pressing [54], thus reducing hydrogen bonding sites for water molecule to attach. The surface modification increased bonding strength by understanding the behavior of adhesives and fibre properties. However, reducing wettability of adhesive allowed over penetration into the fibre, resulting in small portion of adhesive remained at fibre interface. Therefore, provided inefficient mechanical property of adhesive [58].

Problems and research needs

The use of oil palm fibre (EFB/OPT/OPF) to replace rubberwood as a material for producing MDF panels has showed promise as a long-term sustainable resource for the MDF industry. However, this only applies to blending oil palm fibre with rubberwood in a ratio of less than 50%, as opposed to the existing industry technique, which allows 100% rubberwood fibre to be exposed to the MDF process and achieve good quality results. Furthermore, past research has shown that using 100% EFB induces a color shift even after the fibre has been treated. Studies to increase the strength of MDF produced, especially its mechanical properties by using 100% biomass from oil palm without increasing the resin content should also be carried out. Below are potential barriers which occur with the use of palm fibre and possible solutions.

Table 4. Potential barriers with the use of oil palm fibres and possible solutions

Barriers	Solutions
High ash and silica content	• Avoid soil contamination • Thorough separation and washing
High moisture content and bulkiness	• On site processing • Seasoning
Heterogeneity of material	• Improvement in fibre extraction technique
Short fibre length	• Optimization of pulp yield • Blending with softwood fibre
Fibre efficiency	• Process development for the mixed raw material (stems, fronds, bunches & mesocarp)
Dark colour	• Improvement in fibre washing/treatment
High resin use	• Blending with other fibre

Conclusion

MDF produced from oil palm biomass are an important part in developing new strategies and policies that aid in reducing the dependence on rubberwood and other wood sources. Oil palm fibre has their own chemical composition and hence their properties differ from those of rubberwood. By chemically modifying oil palm-based fibre through chemical treatments, such as alkaline treatment, acetylation or soaking and washing with boil water or remove parenchyma cell, their mechanical properties such as MOR, MOE and IB could be improved. Chemically modified oil palm-based fibre exhibits better wettability, surface morphology, acidity and buffering capacity because of removed wax, lignin, pectin and oil from fibre surface. Nonetheless, identifying a MDF that has high dimensional stability would be a challenge. Poor dimensional stability of MDF can be remedied by hybridization with rubberwood or other wood source with a ratio of oil palm based less than 50%.

Abstract

Cymbopogon citratus and *Cymbopogon nardus* essential oil are high-value natural products due to their special qualities and commercial significance. In this work, the volatile compounds of the *C. citratus* and *C. nardus* natural essential oils obtained by hydro distillation and commercial sources using gas chromatography-mass spectrometry (GC-MS), Fourier transformation infrared spectroscopy (FTIR) and chemometrics methods were systematically detected and identified. The GC-MS results indicated that the main compound in the natural essential oil of *C. citratus* is citral while citronellal commercial samples of both *Cymbopogan* species are positively significant. Based on the results of GC-MS, citral was the major component in *C. citratus* while citronellal was the major component in *C. nardus*. Analyzing the FTIR data using principal component analysis (PCA), hierarchical cluster analysis (HCA), and discriminant analysis (DA) further revealed that the chemical composition of natural essential oils *C. citratus* and *C. nardus* samples were significantly different from commercial samples. This study revealed the first insight into metabolite compositional differences among *C. citratus* and *C. nardus* using quick and affordable analytical procedures.

Keywords: Fourier transformation infrared spectroscopy, chemometrics, principal component analysis, hierarchical cluster analysis, *Cymbopogon*

Abstrak

Minyak pati *Cymbopogon citratus* dan *Cymbopogon nardus* ialah produk semula jadi bernilai tinggi kerana kualitinya yang istimewa dan kepentingan komersialnya. Dalam kajian ini, sebatian meruap minyak pati semula jadi *C. citratus* dan *C. nardus* yang diperoleh melalui penyulingan hidro dan sumber komersial dikenalpasti dengan menggunakan kromatografi gas spektrometri jisim (GC-MS), spektroskopi inframerah transformasi Fourier (FTIR) dan kaedah kemometrik. Keputusan GC-MS menunjukkan bahawa sebatian utama dalam sampel komersial bagi kedua-dua spesies *Cymbopogan* secara signifikan berkorelasi positif dengan minyak pati semulajadi. Berdasarkan keputusan GC-MS, sitral adalah komponen utama dalam *C. citratus* manakala sitronelal adalah komponen utama dalam *C. nardus*. Melalui analisis data FTIR menggunakan analisis prinsip komponen (PCA) dan analisis kluster hierarki (HCA) seterusnya mendedahkan bahawa komposisi kimia minyak pati semulajadi *C. citratus* dan *C. nardus* sampel adalah berbeza dengan ketara daripada sampel komersial. Kajian ini memberikan keputusan yang jelas tentang perbezaan komposisi metabolit antara *C. citratus* dan *C. nardus* menggunakan prosedur analisis yang cepat dan berpatutan.

Kata kunci: Spektroskopi inframerah transformasi Fourier, kemometrik, analisis prinsip komponen,analisis kluster hierarki, *Cymbopogon*

Introduction

Essential oils from the *Cymbopogon* species are widely used in the perfumery, cosmetic, food and pharmaceutical industries. The most widely used species in food processing is *C. citratus*. Among aromatic species that are also important are *C. fexuosus* (East Indian *C. citratus*), *C. martini* (palmarosa), and *C. nardus* (*C. nardus* grass) [1]. Essential oils contain different volatile compounds and the most common compounds found in *Cymbopogon* essential oil are nerol, geranial, citronellol, geraniol, and piperitone [2]. Phytochemical studies of different species showed the presence of terpenoids, alkaloids, phenolic acids, tannins, and carotenoids, and the genus *Cymbopogon* was reported as a rich source of C-glycosyl flavonoids [2]. Most of the research done has focused on the species of *C. citratus*, with less emphasis on other species in the genus [3].

Numerous studies have been conducted to see the differences in chemical composition and pharmacological effects on *Cymbopogon* species. Essential oil products from the *Cymbopogon* species are also widely available in the market, but until now the validity of commercial products with natural essential oils has not been well distinguished. Difficulty discriminating between *Cymbopogon* species may also occur due to similar physical and morphological characteristics. To avoid confusion, a rapid and reliable method to discriminate *Cymbopogon* species is urgently needed. This is important for quality control, safety and effectiveness of essential oils from the *Cymbopogon* species.

The combination of spectroscopic and chemometric techniques is gaining attention because of its ability to quickly distinguish various plant species [4]. Infrared spectroscopy provides information about the vibrational of functional groups in the studied molecules and the absorption of infrared radiation by the sample [5]. The chromatographic technique is also a common method used in determining the quality of herbal medicine. Recently, the combination of chromatographic and chemometric techniques in the identification of varieties and the discovery of herbal chemical markers has increased widely [6]. Most researchers focus on establishing GC-MS fingerprints to reveal differences in the composition and chemical content of various botanical and geographical origins of plants [7]. Chemometrics tools have not been widely used in the analysis of volatile compounds for geographic origin differentiation and discrimination.

In this study, a simple and fast method for various identification and selection of chemical markers will be developed. FTIR spectroscopy and GC-MS chromatography coupled with chemometrics were used to discriminate the different botanical origins as well as the authenticity of commercial products. Furthermore, for the first time, the potential of functional groups and volatile compounds that contribute to the differences between *C. Citratus* and *C. nardus* species and commercial samples were determined through PCA and HCA models built from FTIR data.

Materials and Methods

Materials

The samples for *C. citratus* and C. *nardus* were collected from three different origins from the state of Pahang, Malaysia and the natural essential oils obtained by hydro distillation were labelled as ECC1, ECC2, ECC3 for essential oils of *C. citratus* and ECN1, ECN2, ECN3 for essential oils from *C. nardus*. Commercial essential oils purchased from three different companies and were labelled as CCC1, CCC2, CCC3 for commercial samples of *C. citratus* and CCN1, CCN2, CCN3 for commercial samples of *C. nardus*.

Sample preparation and essential oil extraction

The stalks and leaves of *C. citratus* and *C. nardus* are washed with tap water and cut into small pieces before being stored overnight in the oven (50 °C). The dried *C. citratus* and *C. nardus* are ground into small sizes. Thirty grams (30 g) of each of *C. citratus* and *C. nardus* are placed in a 2000 mL distillation flask connected directly to the Clevenger apparatus containing distillation water (1000 mL). The samples are heated at 100 °C for 2 hours. The extracted essential oils are dried

over anhydrous sodium sulphate and filtered. The volatile oils are obtained and kept for further analysis.

GC-MS analysis

A 7890A Agilent Technologies Gas Chromatography with a 5760N Mass Spectrometer equipped with an HP-5 ms (5% phenyl methyl siloxane) fused silica capillary column (30 m 0.25 mm internal diameter, film thickness 0.25 m) was used to conduct the GC-MS analysis of samples of essential oils. The temperature of the injector is fixed at 250 °C. For three minutes, the initial oven temperature of 40 °C was maintained. The temperature was then raised to 100 °C gradually at a rate of 8 °C/min. The temperature increased to 200 °C at a rate of 5 °C/min and to 250 °C at a rate of 10 °C/min. For 10 minutes, the temperature was maintained at 250 °C. At a rate of 1.0 ml/min, helium was used as the carrier gas.

FTIR analysis

The procedure begins with the crystal being wiped and cleaned with acetone to ensure precise detection. Small amounts of samples were placed onto the crystal surface in contact with the ATR at ambient temperature (25 °C). Then, after placing the essential oil on the crystal region, the pressure arm over the crystal/sample area was setup. All spectra were background corrected using an air spectrum, which was renewed after each scan. After each measurement, the ATR base was thoroughly cleaned using acetone and the surface was allowed to dry before measuring the next sample. Spectra were recorded in the range 600-4000 cm^{-1} at a resolution of 4 cm^{-1} and each spectrum consisted of 64 co-added scans. The FTIR spectrum of each sample was measured in triplicate to assess precision and ensure the reproducibility of each sample. The spectra were recorded as absorbance values.
