All the data obtained from the application of FTIR was subjected to chemometrics data analysis. Principal component analysis (PCA), hierarchical cluster analysis (HCA) and discriminate analysis (DA) were used to discriminate samples from different origins. XLSTAT software was used to perform chemometric analysis of FTIR and GC-MS data of *C. citratus* and *C. nardus* essential oils and commercial samples. The scattering pattern of authentic and commercial samples was displayed using two-dimensional PCA plots. HCA is a method of cluster analysis that aims to create a hierarchy of groups. The HCA dendrogram indicated significant differences and similarities. For analysis of FTIR data, the spectral ranges of 1000-3300 cm^{-1} were employed.

Results and Discussion

Identification of volatile compounds in *C. citratus* and *C. nardus*

Cymbopogon essential oils (n = 6) and commercial samples (n = 6) were analysed utilising GC-MS techniques in the current research investigation. Samples of *Cymbopogon* essential oils included a total of 111 constituents. Monoterpenes, sesquiterpenes, aldehydes, ketones, alcohol hydrocarbons, alkanes, oxygenated monoterpenes, and oxygenated sesquiterpenes comprise the volatile constituent profile of *C. citratus* essential oil Overall, the main compound identified in essential oil and commercial samples of *C. citratus* were citral and linalool (Table 1). The major volatile compound in *C. citratus* essential oil was citral, which is present almost in all the analysed samples. Prior study indicated that citral plays a crucial role in the development of the plant's taste and other food recipes [8]. Citral exhibits various important therapeutic properties like antimicrobial, antioxidant, anticancer, anti-diabetic and anti-inflammatory [9].

The frequently identified compounds of *C. nardus* samples (Table 2) were citronellal, citronellol, and D-limonene. The main constituents of the essential oil in *C. nardus*, commonly known as citronellal, and citronellol are also found in this study [10]. The absence of citronellal from Origin 3 and citronellol from Origin 1 is due to various factors related to the plant, interaction with the environment (soil type and climate, etc.), the maturity of the plant concerned, even at harvest time during the day and related to the extraction method [11]. *C. nardus* and *C. citratus* essential oils were considered important products in the food and cosmetic industry. Consumer safety greatly depends on the ability to trace the quality of *C. nardus* and *C. citratus* essential oils. The development of new analytical techniques that are robust, dependable, effective, and affordable is crucial for determining the authenticity of essential oils. There

is currently interest in chemometrics and innovative analytical techniques.

The current research uses FTIR and GC–MS techniques for the characterization of *C. nardus* and *C. citratus* essential oils. The findings demonstrate that the authenticity of *C. nardus* and *C. citratus* essential oils can be determined by FTIR and chemometrics (HCA & PCA). It takes little sample preparation to distinguish both essential oils from commercial samples. As far as we are aware, this is the first example in which the FTIR technique and chemometrics have been employed to assess the authenticity of *C. nardus* and *C. citratus* essential oils. Additionally, recent research has demonstrated the significant potential of vibrational spectroscopy in conjunction with chemometrics to deliver precise and trustworthy results for determining the authenticity of essential oils. Based on the data collected using HCA and PCA, all samples could be unambiguously identified with 100% accuracy.

Analysis of FTIR spectra of *C. citratus* and *C. nardus*

The typical FTIR spectrum of *C. citratus* and C. *nardus* essential oils obtained by hydro distillation and commercial samples are presented in Figures 1(a) and (b), respectively. In the infrared (IR) region, molecular vibrations matching a specific vibration frequency show the functional group of each sample including its molecular identification [8]. In this analysis, the differences between the samples were determined based on the wavenumber of the absorption band in the IR.

The absorption bands in Figure 1(a) at 1672 to 1612 cm^{-1} were assigned to C=C stretching vibrations of the alkenes functional group. Citral has conjugated double bonds (C=C-CHO), which are frequent in acyclic monoterpenes, as evidenced by the intense peak seen at 1672 -1612 cm^{-1} caused by vibrations of C=C (*cis* and *trans*). As can be seen in the spectrum, the intensity of the essential oil *C. citratus* peak at 1672-1612 cm^{-1} was higher than those in commercial samples. The result might be useful for faster determination of the quality of commercial products *C. citratus* essential oil. The intensity difference might due to the low content of marker compounds in *C. citratus* which was citral. The peak around 1442 to 1377 cm^{-1} could be assigned to the C-H bending vibrations of the alkanes functional group. Bands at 1194, 1154, 1153, 1120 and 1121 cm^{-1} resulted from the C-O stretching vibrations of phenolics. The peak at 1043 cm^{-1} was attributed to the stretching vibrations of C-O. The peak at 984 cm^{-1} is assigned to the C-H bending absorption of the alkenes functional group. The peak at 864, 842, 820, 747 and 748 cm^{-1} are assigned to aromatic rings =CH vibration absorption [12]

The main constituents of *C. nardus* essential oil were citronellal, citronellol and geraniol [13]. The characteristic bands of citronellal and citronellol which were the major compounds in *C. nardus* dominated by the C=O stretching of the aldehyde group ascribed by the band between 1740-1700 cm^{-1}. Within the range of 2970–2850 cm^{1}, typical asymmetric and symmetric stretching vibration bands of methyl and methylene groups were found. Figure 1(b) shows low intensities of the peak at 1740-1700 cm^{-1} and 2970-2850 cm^{-1} of commercial samples compared to essential oils of *C. nardus*. Furthermore, around 1670 cm^{-1}, the olefinic unsaturation C=C stretching of conjugated double bonds emerged [14]. Sharp and medium peaks were also seen for the bending of methylene CH_2 (1450-1440 cm^{-1}) and the symmetric bending of methyl CH_3 (1377 cm^{-1}). There were also some small vibrations of functional groups (910–740 cm^{-1}) and C-O stretching (1030-1000 cm^{-1}) [9].

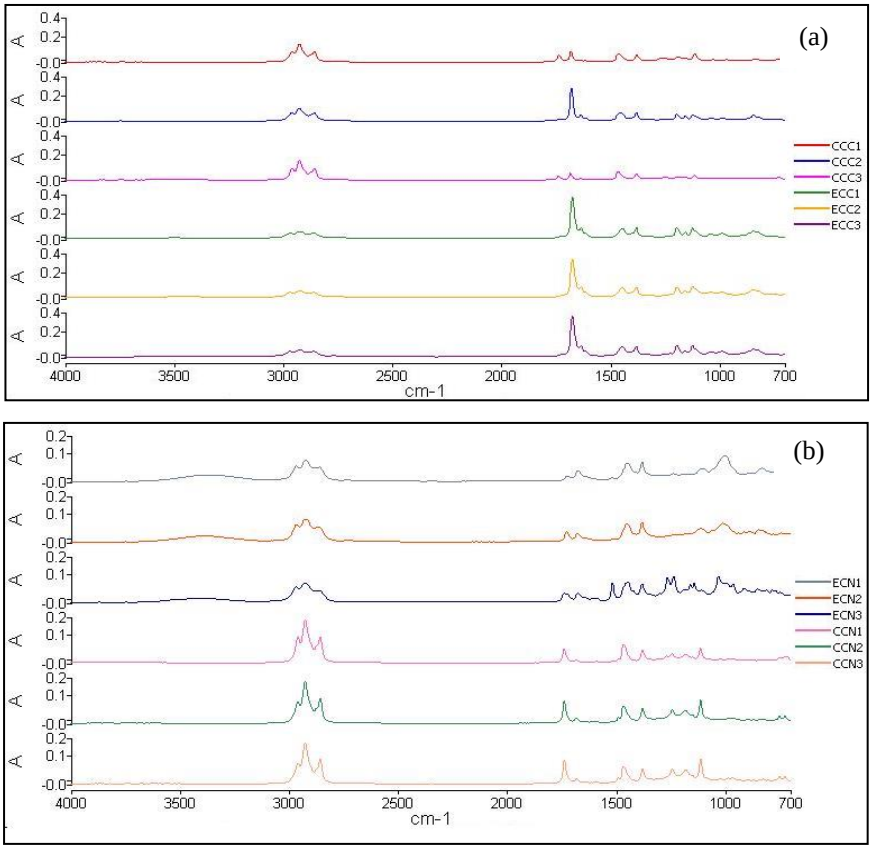

Figure 1. (a) FTIR spectra for essential oils and commercial samples of *C. citratus* (b) FTIR spectra for essential oils and commercial samples of *C. nardus*

Discrimination of samples based on FTIR data

The primary sources of variability in a dataset and the relationships between samples and variables are found using PCA analysis. The unsupervised method known as PCA provides pattern recognition data that is used to categorise and differentiate samples based on experimental data. FTIR spectroscopy is a simple, quick, and accurate method for classifying various plant species. Knowing the spectrum information rapidly could be highly important for the authentication of plant products in the market. In the present research study, FTIR data of *Cymbopogo*n essential oils (n=6) and commercial samples (n=6) were used to be distinguished by PCA analysis. The PCA showed two principal components (PCs) with 1400 variables totalling 80.37% of the total variance. PC1 encountered the most

explained variance with 61.70%. The PCA model of FTIR data showed good predictive ability as the total variance value was more than 50% [15]. The PCA analyses were performed to observe classification patterns of essential oils and commercial samples on the basis of their FTIR.

Based on the PCA plot in Figure 2(a), three clusters represented twelve samples. The cluster of ECN1, ECN2 and ECN3 appeared in the second quadrant. Meanwhile, CCN2 and CCN3 were found in the first quadrant where PC1 was negative. In addition, ECC1 and ECC2 had the largest distance from other sample clusters. Essential oils of *C. citratus* must have more distinctive functional groups compared to other samples. The findings are consistent with [16] who agreed that well-separated clusters are determined by distinctive compounds. This proved that the IR spectral characteristics of *C. citratus* essential oil samples were considerably different from those of other samples. Commercial samples of *C. citratus* clusters were located in the third quadrant. Nevertheless, it was found that commercial samples of *C. citratus* and *C. nardus* were unable to be differentiated. Therefore, it seemed quite challenging to observe the FTIR PCA score plot as FTIR can only identify the functional groups of the samples' essential oils, for which almost all samples have close similarities in terms of functional groups.

The PCA variable plot showed the discrimination of *C. citratus* and *C. nardus* essential oils attributed to a different absorbance of wave number present in the sample which was revealed by the fingerprinting FTIR spectroscopy. Based on the variables plot in Figure 2(b), the wavenumber of functional groups for samples of essential oils and commercial samples of *C. nardus* and *C. citratus* were difficult to deduce because they are overlapping each other. The loading plot unravels spectral differences responsible and have a strong impact on their clustering in the respective PC. The result of this observation indicated that the largest distance between *C. citratus* and *C. nardus* were caused by several wavenumbers representing certain functional groups listed in Table 3. Those responsible wavenumbers were determined by comparing the position of observation points in the loading plot with the PCA score plot and had variable influences on the projection (VIP) values in the range of 0.7 to 1.0. In general, variables with VIP values higher than 0.7 are considered significant for the separation of samples [17].

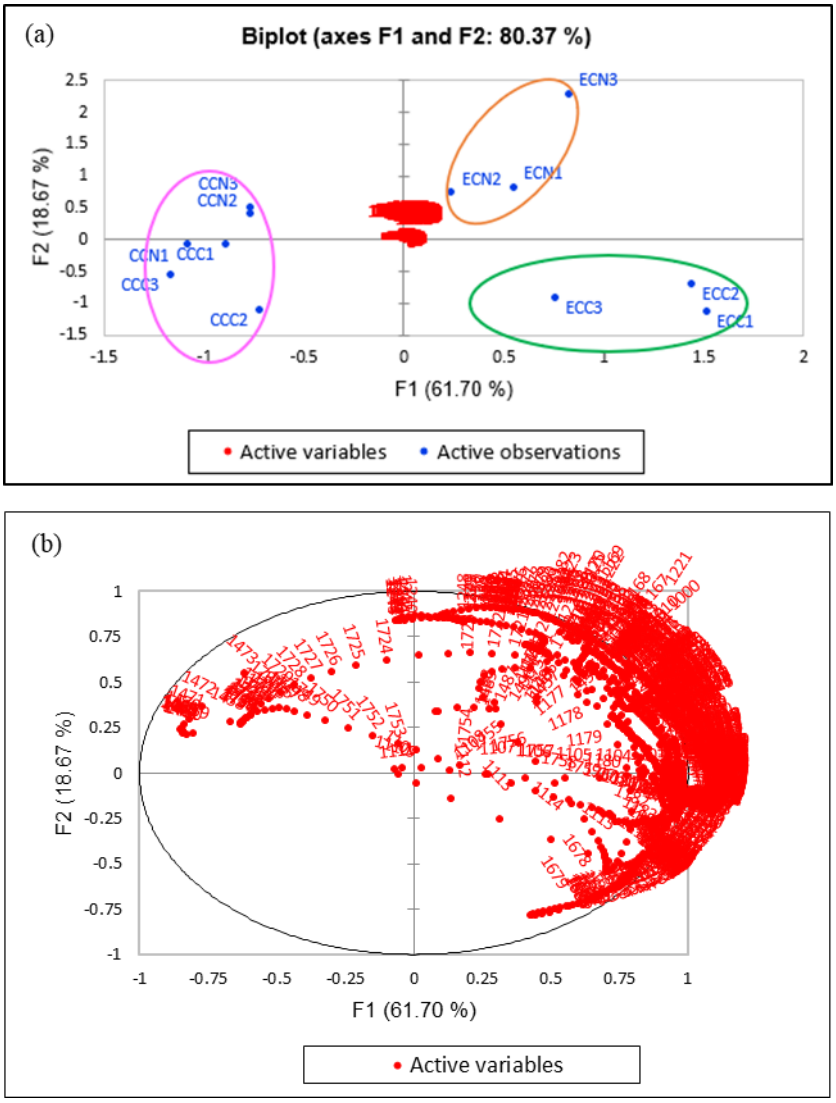

Table 3. Wavenumber responsible for the separation of *C. citratus* and *C. nardus* from PCA analysis on the loading plot

Wavenumber (cm^{-1})	**Band Assignment**	**Variable Influences on the Projection (VIP)**
1794	C=O from citronellal /citronellol	0.866
1710	C=O from citronellal /citronellol	0.941
1651	C=C from citral	0.800
1607	C=C from citral	0.812

These responsible wavenumbers are useful and could be used as a marker to discriminate *C. citratus* and *C. nardus*. In conclusion, although the distances of some clusters were very close, different sample species could still be discriminated by PCA. Overall, FTIR-PCA was able to discriminate the sample by visualizing the data on the score plot in contrast to FTIR spectra solely. This combination method could be applied as a non-destructive method for the discrimination of different species of herbs. The results revealed clear discrimination between essential oil of *C. citratus*, *C. nardus* samples and commercial samples. The result of PCA was further confirmed with HCA.

Samples of *C. citratus* and *C. nardus* essential oils and commercial samples were shown to be discriminated by the HCA dendrogram in Figure 2(c). A similar group is represented by the cluster of samples on the HCA dendrogram, as shown in the PCA plot. Commercial samples and essential oil samples were grouped into

three primary categories. On the right branch were two groups of *C. citratus* and *C. nardus* essential oil samples, and on the left branch were commercial samples. As can be observed, the commercial samples were assumed to be low-content of major chemical compounds or mixtures with other chemical substances. The clustering pattern of the examined samples was easily observed by the HCA dendrogram, and the outcomes were completely consistent with those of the PCA.

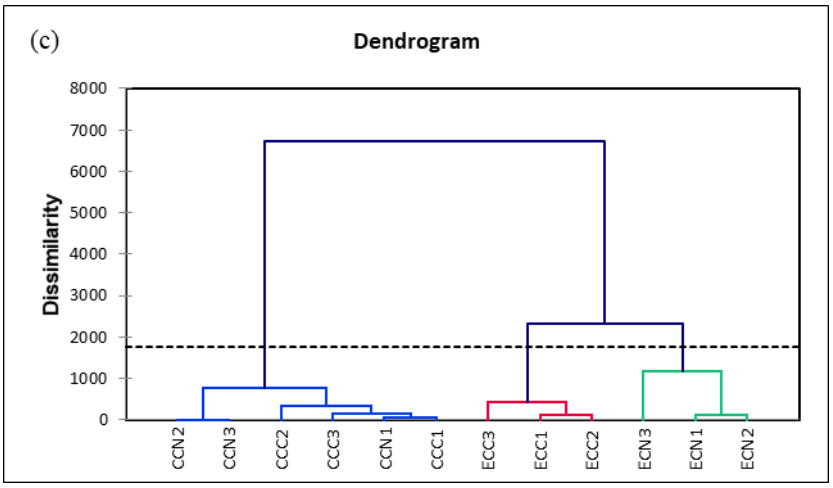

Figure 2. (a) Biplot PCA (b) variables plot and (c) HCA dendrogram of FTIR data of essential oils (n=6) and commercial samples (n=6) of *Cymbopogon* essential oils

This PCA plot was able to discriminate between *C. citratus* and *C. nardus* natural essential oils but not the commercial ones. The discriminant analysis (DA) model was built using the same pre-processed data to classify the samples based on natural essential oils and commercial samples by maximizing the covariance between the data matrix (X) (variables) and samples (Y) (origin of samples). DA is used to discriminate samples using the classification technique. Figure 3 shows the classification pattern of the samples using the DA model with variance explanation 10% and 0% of component 1 and component 2, respectively. The DA score plot showed clearer discrimination of commercial samples from *C. nardus* and *C. citratus* compared to PCA.

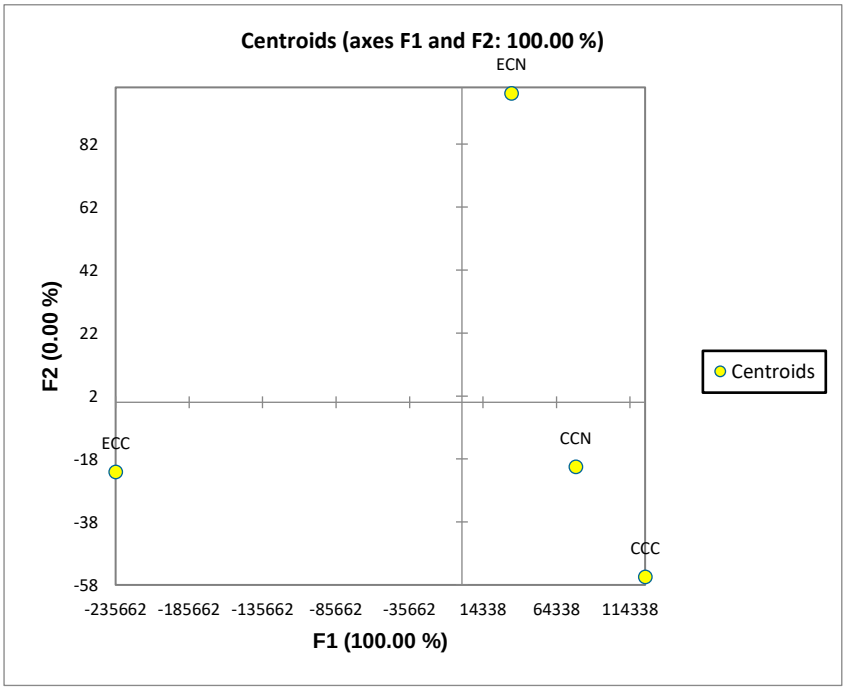

Figure 3. Discriminant analysis plot

A unidimensional test of the quality of the means of the classes identifies the significant variables in the study. Variables with p-value < 0.05 indicate significant variable that plays role in the discriminating model. The Fisher distances test at α 0.05 between the groupings is significantly different. The p-value < 0.01 indicates the natural essential oils of *C. citratus* and *C. nardus* are significantly different but there is no difference between commercial samples of *C. citratus* and *C. nardus* (Table 4). The results obtained revealed the commercial samples were either low-quality or mixtures with other chemical substances.

Table 4. The *p*-values for Fisher distances

Sample	CCC	CCN	ECC	ECN
CCC	1	0.000	< 0.0001	< 0.0001
CCN	0.000	1	< 0.0001	0.000
ECC	< 0.0001	< 0.0001	1	< 0.0001
ECN	< 0.0001	0.000	< 0.0001	1

Conclusion

C. nardus and *C. citratus* essential oils were considered important products in the food and cosmetic industry. Consumer safety greatly depends on the ability to trace the quality of *C. nardus* and *C. citratus* essential oils. The development of new analytical techniques that are robust, dependable, effective, and affordable is crucial for determining the authenticity of essential oils. There is currently interest in chemometrics and innovative analytical techniques. The current research uses FTIR techniques for the characterization of *C. nardus* and *C. citratus* essential oils. The findings demonstrate that the authenticity of *C. nardus* and *C. citratus* essential oils can be successfully determined by FTIR and chemometrics (HCA & PCA). It takes little sample preparation to distinguish both essential oils from commercial samples. As far as we are aware, this is the first example in which the FTIR technique and chemometrics have been employed to assess the authenticity of *C. nardus* and *C. citratus* essential oils.

In summary, it was successful to distinguish the essential oils of *C. citratus* and *C. nardus* from commercial samples using FTIR, and chemometrics. Through HCA and PCA analysis, the classification patterns of different samples may be readily revealed. To the best of our knowledge, this study has been the first to use chemometrics along with FTIR to assess the discrimination of *C. citratus* and *C. nardus* essential oils with commercial samples. This study has the benefit of being a thorough application of simple and easy well-known analytical methods. Nevertheless, the GCMS data obtained complements and confirms the chemical compounds in *C. citratus* and *C. nardus,* particularly the identification of citral and citronellal as major component in each species, respectively. Chemometric analysis through PCA and HCA is a fast, economic, reliable, simple and non-destructive analysis for quality control and authenticity of *C. citratus* and *C. nardus* essential oils. The findings of this study may be used to give a thorough assessment of the quality of *C. citratus* and *C. nardus* commercial products, as well as an optimal evaluation technique for medicinal herb quality management.

STUDY OF SOLVOTHERMAL SYNTHESIS OF MAGNESIUM-BASED METAL-ORGANIC FRAMEWORKS

(Kajian Sintesis Solvoterma Kerangka Logam-Organik Berasaskan Magnesium)

Abstract

Metal-organic frameworks (MOFs) are a class of reticular materials consisting of metal ions coordinated to organic ligands. Theoretically, magnesium metal of the s-block has low electronegativity due to their large ionic radii and low ionic charges. The coordination number of magnesium immensely varies depending on the electrostatic interactions with the ligands. Therefore, designing strategic synthesis of Mg-based MOFs becomes a challenge hence its scarcity in literature. This study aims to investigate the different procedure of synthesizing Mg-MOFs using both flexible and rigid organic linkers in organic solvents at high temperature; termed solvothermal method. Magnesium nitrate hexahydrate ($Mg(NO_3)_2.6H_2O$) are used as the metal source and mixed with naturally occurring plant acids as the organic linkers; malic acid and tartaric acid. Rigidity was introduced by addition of aromatic organic ligands of benzene-1,4-dicarboxylic acid (BDC) and benzene-1,3,5-tricarboxylic acid (BTC). By varying precursor ratios and organic solvents, we hope to improve the reaction condition for the previously reported synthesis of Mg-MOFs. Single crystal X-ray diffraction (SCXRD) and powder X-ray diffraction (PXRD) analysis showed that the same quality crystals and high crystallinity powder have been produced under improved reaction conditions. The coordination of s-block metal ions has also been found to be most suited in a solvent mixture of H_2O and *N*,*N*-dimethylformamide (DMF).

Keywords: metal-organic framework, nanomaterial, solvothermal synthesis, s-block, green chemistry

Abstrak

Kerangka logam-organik (MOFs) adalah satu kelas bahan retikulasi yang terbentuk dari ion logam dikoordinasikan ke ligan organik. Secara teori, logam blok-s magnesium mempunyai nilai keelektronegatifan yang rendah kerana radius ion yang besar dan cas ion yang rendah. Nombor koordinatan antara logam magnesium berbeza-beza bergantung kepada interaksi elektrostatik dengan ligan yang berkaitan. Justeru, perancangan sintesis MOF berasaskan magnesium secara strategik adalah satu cabaran berikutan kekurangan perbincangan mengenainya dalam tinjauan literatur. Kajian ini bertujuan untuk meneliti pelbagai prosedur sintesis Mg-MOF menggunakan penghubung organik samada fleksibel mahupun tegar pada suhu yang tinggi; iaitu kaedah solvoterma. Magnesium nitrat heksahidrat ($Mg(NO_3)_2.6H_2O$) digunakan sebagai sumber logam dan dicampurkan dengan asid tumbuh-tumbuhan sebagai ligan organik semula jadi; asid malik dan asid tartarik. Ketegaran dalam kerangka dimasukkan melalui penambahan ligan aromatik organik iaitu asid benzena-1,4-dikarboksilik (BDC) dan asid benzena-1,3,5-trikarboksilik (BTC). Dengan mempelbagaikan nisbah pendahulu dan pelarut organik, kami berharap dapat menambah baik keadaan tindak balas yang

telah dilaporkan bagi sintesis Mg-MOF. Analisa pembelauan hablur tunggal sinar-X (SCXRD) dan pembelauan serbuk sinar-X (PXRD) menunjukkan bahawa hablur yang sama kualiti dan serbuk dengan kehabluran yang tinggi telah berjaya disintesis dengan penambahbaikan terhadap keadaan tindak balas. Campuran pelarut H_2O dan *N*,*N*-dimetilformamida (DMF) pula merupakan keadaan yang paling sesuai untuk pengkoordinatan logam blok-s.

Kata kunci: kerangka logam-organik, bahan nano, sintesis solvotermal, blok-s, kimia hijau

Introduction

Metal-organic frameworks (MOFs) are reticular materials composed of metal ions linked by organic ligands with specific functional groups such as carboxylate that can coordinate to the metal nodes [1]. The most dominant choices for the metals are from the p- and d-block elements due to the pronounced characteristics of transition metals such as visible light absorption, multiple oxidation states and predictable coordination geometries. On the other hand, MOFs based on s-block elements are relatively less studied. One of the main factors for the lack of interest is the unpredictable MOF structure due to having little control over the metals' coordinative behaviour. Large difference in electronegativity between s-block metal and carboxylate oxygen atom leads to a mainly ionic interaction. Thus, the coordinative nature of the metal centre throughout the network is instead determined primarily by the orientation of the functional groups, directly influenced by steric considerations [2]. Despite the setbacks, s-block MOFs can provide distinctive and intriguing properties inherited from their respective s-block elements; inexpensive and non-toxic [3]. The unpredictable coordination behaviour of the ionic metal nodes may result in interesting characteristics such as low density, flexible networks and water-soluble MOFs [4]. Therefore, s-block MOFs have the potential of a wide range of applications. Biocompatible MOFs can be designed from s-block metals such as Na^+, K^+, Mg^{2+} and Ca^{2+} which are already involved naturally in biological processes. Apart from amino acids which have been extensively studied as linkers, plant acids on the other hand have been largely under the radar and investigating their potential in biocompatible MOFs synthesis will be significant.

It is useful to study the previously reported synthesis as part of the ongoing effort to improve the methodologies of synthesizing s-block metal MOFs. While s-block metals generally have the same behaviour, ions with different properties will contribute to variations in reactivity. Mg^{2+} provides more control to the connections of metal-linker to form the framework. A larger Ca^{2+} ion compared with Mg^{2+} resulted in higher coordination number [2]. Furthermore, since s-block metals ions are hard metals, they preferably form ionic bonds with hard-heteroatom based organic ligands. Carboxylates consequently are the most used linkers. Some reports of using soft bases require modification of the heteroatom onto the organic linkers such as N-based carboxylates to yield a stable structure [5]. For the reaction condition, solvothermal synthesis has been the most widely used method with few variations on the parameters. For example, group 1 metals are best dissolved in polar solvents like ether due to the ability to coordinate to the metals [3]. Therefore, the main objective of this study is to identify the ideal method that has been used to synthesize Mg-based MOFs and make improvements on them.

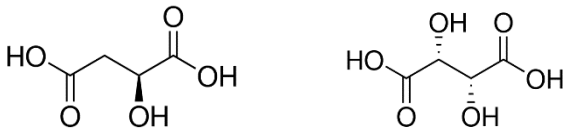

Figure 1. The organic linkers used in this study (A) L-(–)-malic acid and (B) L-(+)-tartaric acid

The solvothermal synthesis of Mg-MOF in this study are done with different combination of solvents to achieve condition than the previously reported methods. We utilize aliphatic linkers from naturally occurring plant acids for possible biocompatible applications. Previously it has been reported the pesticide encapsulation by two porous calcium L-lactate MOFs [6]. However, successful synthesis of MOFs with such properties are rare since the framework of s-block metals tend to be flexible and nonporous [2]. Therefore, we also incorporate rigid aromatic linkers that have shown the ability to form porous and more stable MOFs. Herein the s-block metal used is Mg^{2+} ion. The aliphatic linkers used are plant acids of malic acid and tartaric acid while the aromatic dicarboxylic acids are benzene-1,4-dicarboxylic acid (BDC) and benzene-1,3,5-tricarboxylic acid (BTC).

In this study, we hope to study the pattern in which s-block MOFs are synthesized and improve the established methods that has been used to synthesize Mg-MOFs. The effect of varying the synthesis parameters; solvents, temperature and time are studied. Improvements in term of less use of organic solvents, milder reaction conditions and shorter reaction time are preferred. The resulting compounds were then characterized by powder X-ray diffraction (PXRD) and, when possible, single crystal X-ray diffraction (SCXRD) [1]. Based on the findings, we outline few suggestions in approaching the synthesis of s-block MOFs using various biocompatible linkers.

Materials and Methods

Materials

All reagents and solvents were commercially purchased and used without further purification.

Synthesis of MOFs

All of the reagents were mixed in 6 ml solvents at molar ratio outlined in Table 1 & 2. A molar ratio of 1 equates to 0.4 mmol. The solvents used are *N*,*N*-dimethylformamide (DMF), deionized water (H_2O), ethanol (EtOH), dimethylacetamide (DMA) and tetrahydrofuran (THF). Unless stated, the ratio of solvents used in a mixed system are of equal parts except for triethylamine (TEA) where only 2 drops are added into the glass vial. The solutions were made to reach homogeneity by sonication, before being put into the oven at 120°C until the product is formed. The metal source used are magnesium nitrate hexahydrate ($Mg(NO_3)_2.6H_2O$). The organic ligands used as plant acids used are L-(–)-malic acid (Mal), $(CH_2CHOH)(CO_2H)_2$ and L-(+)-tartaric acid (Tar), $(CHOH)_2(CO_2H)_2$. The aromatic linkers are H_2BDC (benzene-1,4-dicarboxylic acid) and H_3BTC (benzene-1,3,5-tricarboxylic acid).

Characterization

Single crystal X-ray diffraction (SCXRD) are collected by a Gemini E Oxford Diffraction diffractometer with monochromatized Cu Kα radiation. Powder X-ray diffraction (PXRD) data are recorded at ambient temperature on a Shimadzu-600 diffractometer with Cu Kα radiation (λ=15406Å, 30kV, and 40 mA) with a scan speed of 2° min^{-1} and a step size of 0.02° in 2θ. The simulated PXRD patterns and unit cells database are obtained from the Cambridge Crystallographic Data Centre (CCDC). Both methods are used to identify the resulting solids by comparing the unit cells of the crystals with existing data and the X-ray diffraction patterns of the powders with existing spectra of their respective reagents.

Results and Discussion

The reaction conditions are chosen from methods that have been previously used to successfully synthesize MOFs across the periodic table. Polar solvents such as DMF and EtOH are some of the common solvents [7] while addition of H_2O into the mixture has been proven to yield Mg-based MOFs [2]. Where possible, SCXRD has been used to identify the resulting crystals while PXRD was used for the obtained powder.

Table 1. Parameters used for Mg-MOF reactions varying the solvent ratio

Mg-MOF crystals

The method used for crystal **4** yields Mg(Tar)(H_2O), a rectangular MOF crystal (Figure 2A) with refcode CELJOU (Table 3). The MOF was previously synthesized by a better method in terms of solvent and reaction condition. As opposed to solvothermal synthesis with DMF:H_2O solvent at 120°C (Table 1), the original method uses only water as the medium with warming in silicone oil bath at 60°C for 5 min before being left to sit for 16 hrs. While the original method is the preferred green synthesis route, the method for crystal **4** establishes that the solvothermal synthesis with DMF as its base can act as a universal template capable to synthesize a myriad of MOF crystals. This is also observed by others whereby the decomposition of DMF to its respective formic acid and dimethylamine (base) provides the desired linker deprotonation rate capable of slowly forming high quality crystals of a lot of MOFs [7].

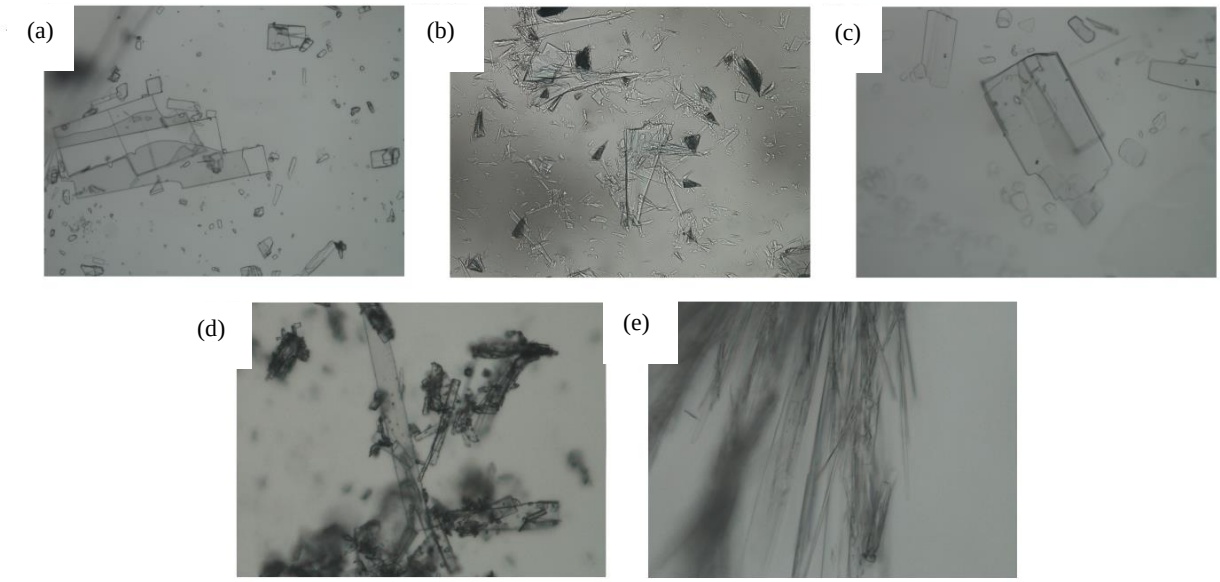

Figure 2. Microscopic view at ×20 magnification for crystals of (a) **4**; (b) **9**; (c) **24**; ×40 magnification for microcrystalline powder of (d) **21**; (e) **22**

The method used for crystal **24** synthesized Mg(Tar)(H_2O) MOF with refcode JIFXIG (Table 3) having similar morphology (Figure 2B) to crystal **4**. The original reported method uses PTFE lined autoclave at 100°C while the crystal **24** can be obtained in a normal glass vial at 120°C (Table 2). This allows for bulk synthesis to be possible since pressure resistance autoclave synthesis can only be done in small batches. Similar to the method used for crystal **4**, the use of DMF increases the control on the reaction. The deprotonation rate is highly tuneable by controlling the amount of formic acid or dimethylamine by adding them manually before the solvothermal reaction begins.

Table 3. Unit cell parameters of Mg-MOF crystals

Crystal	CCDC Refcode	Space Group	*a* / Å	*b* / Å	*c* / Å	*α* / °	*β* / °	*γ* / °	V / Å^3
4	CELJOU [8]	$P2_12_12_1$	7.904	11.119	18.213	90.0	90.0	90.0	1601
9	JIFXIG [9]	$P2_12_12_1$	7.878	11.100	18.157	90.0	90.0	90.0	1587
24	DOHDOU [10]	$R\bar{3}c$	8.148	8.148	22.788	90.0	90.0	120.0	1310

The method used for crystal **9** produces plate-like Mg($OOCH)_2$(HOOCH) MOF crystal (Figure 2C) with refcode DOHDOU (Table 3). The solvent used for crystal **9** is an equal mixture of DMF:H_2O (Table 1), while the reported previous method is DMF:EtOH:H_2O with ratio 10:0.5:0.5. This means the amount of DMF has been reduced significantly. Moreover, the previous method requires an addition of 0.1 ml of formic acid. The successful synthesis of crystal **9** shows that enough formic acid can be obtained from the disintegration of DMF at high temperature. In addition, the temperature and reaction vessel needed is also not as demanding. While the previous method is carried out in a Teflon lined autoclave at a temperature of 140°C, crystal **9** can be synthesised in a glass vial at 120°C. It is important to note that for the original method, substituting the metal precursor for other metal salts such as Mg(ClO_4)·$6H_2O$ gives the same result. Thus, it can be inferred that the same observation is true for crystal **9**.

Mg-MOF powder

There are two powder MOFs identified by their PXRD in comparison with the simulated pattern from the database. Powder **21** (Figure 2D) is the $Mg_3(BDC)_3(EtOH)_2$ MOF (Figure 3) with refcode KIFKAM [11] incorporating the BDC linker and the solvent EtOH in the framework. The reaction condition of this MOF is the same as the original reported method, except for the solvent. The use of fully EtOH instead of EtOH:H_2O mixture may be the reason for the formation of powder **21**. It has been understood that water is ineffective in synthesizing some MOFs [12], making it a suitable modulator in MOF synthesis. Thus, modulated-solvent mixture is ideal in controlling the crystallization rate [13], resulting in the preferred crystal size compared to the fast, uncontrolled synthesis of the powder. On the other hand, lowering the temperature or reducing the reaction time does not produce any crystals.

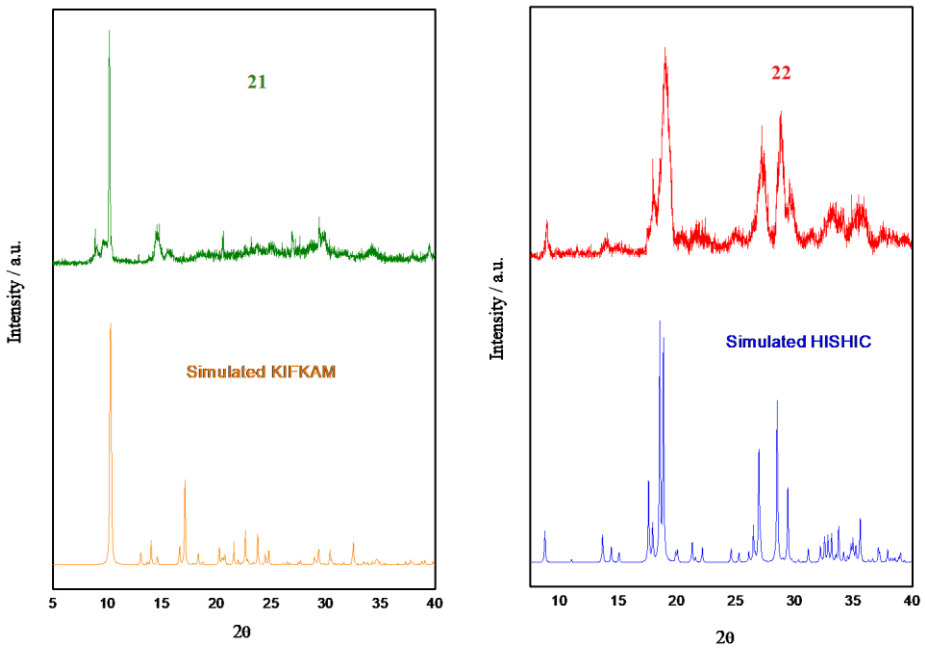

Figure 3. PXRD spectrum of powder **21** and **22** showing high crystallinity of the products. The characteristic peaks of the powder **21** and **22** match with the simulated peaks of an Mg-MOF with refcode KIFKAM and HISHAC respectively

Powder **22** (Figure 2E) is a MOF (Figure 3) with composition $Mg_3(BTC)_2(H_2O)_{12}$ with the refcode HISHIC [14]. The BTC linker and H_2O solvent are incorporated into the framework. Like powder **21**, the original method used the solvent mixture EtOH:H_2O to synthesize the crystals (Table 2). Using only the EtOH produces powder. However, the reaction condition in this case utilises a much lower temperature of 120°C compared to the original optimum temperature of 150°C for the same period of 24 hours. The lowering of the optimum temperature can be used in the bulk synthesis of powder MOF for uses in various applications, where good quality crystals are not necessarily required. For example, the encapsulation of pesticide *cis*-1,3-dichloropropene into a Ca-based MOF-1201 that has been done in its powder form [6].

Conclusion

In this study, we have explored different approaches in solvothermal synthesis of Mg-MOFs. Characterization from SCXRD and PXRD have been used to identify the synthesized compounds. Improvements have been made to certain aspects of the reaction. Lower temperature, shorter time and less use of organic solvents have been utilised. A solvent system of H_2O:DMF shows to be effective in promoting coordination of Mg^{2+} metal ions to the linkers. However, no MOF consisting of both the plant acids and rigid

linkers simultaneously were obtained. Understanding the required parameters and conditions for mixed-linker synthesis are crucial. Further studies can be done to investigate the mechanisms of incorporating mixed-linker into s-block frameworks.

Abstract

Piper betle L. is a well-known medicinal plant that originates from the Asian region. This crop was used daily by the older generation as natural medicine to cure certain types of diseases. A series of phytochemical screening procedures proved that the extract of *Piper betle* contains essential phytochemicals, such as tannin, saponin, flavonoid, and alkaloid, which possess the insecticidal activity potential towards a wide range of insects. Previous studies have led to the implementation of betel extract in the agriculture sector as a pesticide or a major constituent in the production of novel insecticides. The effectiveness of betel extract as a pesticide is quite promising and it can be used as a better alternative to replace the use of harmful, chemical pesticides. Similar to betel extract, hypochlorous acid shows antimicrobial and insecticidal effects, but its true potential has not been studied thoroughly because its current usage is mainly focused on the healthcare sector as disinfectants or to aid wound healing. Both betel extract and hypochlorous acid can be beneficial to the agriculture sector, especially in pest management procedures, if its true potential is studied thoroughly to validate its mechanism or mode of action towards insects.

Abstrak

Piper betle L. ialah sejenis tumbuhan ubatan yang berasal dari Asia. Generasi terdahulu telah menggunakan tumbuhan ini secara harian sebagai ubatan semula jadi untuk merawat penyakit tertentu. Beberapa siri analisis fitokimia telah membuktikan bahawa ekstrak *Piper betle* mengandungi beberapa jenis fitokimia penting termasuk tannin, saponin, flavonoid, dan alkaloid, yang memiliki ciri anti-serangga terhadap pelbagai jenis serangga. Kajian yang telah dijalankan telah membawa kepada penggunaan ekstrak sireh sebagai racun perosak atau bahan utama dalam penghasilan racun serangga yang baharu. Keberkesanan ekstrak sireh sebagai racun perosak menunjukkan hasil yang meyakinkan dan boleh digunakan sebagai alternatif yang lebih baik untuk menggantikan penggunaan racun kimia yang berbahaya. Asid hipoklorus juga menunjukkan kesan antimikrob dan anti-serangga seperti ekstrak

sireh, tetapi keupayaannya yang sebenar tidak dikaji secara mendalam kerana penggunannya lebih tertumpu dalam bidang kesihatan sebagai disinfeksi atau membantu dalam penyembuhan luka. Kedua-dua ekstrak sireh dan asid hipoklorus boleh menjadi bahan yang bermanfaat dalam sektor pertanian, terutamanya dalam kawalan makhluk perosak jika potensi sebenarnya dikaji dengan lebih mendalam bagi mengesahkan mekanisma atau cara tindakannya terhadap serangga.

Kata kunci: *Piper betle* L., fitokimia, ciri anti-serangga, asid hipoklorus

Introduction

Betel (*Piper betle* L.) from the Piperaceae family is a traditional medicinal plant that is widely used in Malaysia and Asia for various purposes [1]. It has its own common names in different regions worldwide, such as *Paan* in India and *Sireh* in Malaysia. It normally appears at the beginning originated from Malaysia, but there are also studies that have proven that this crop might have originated from Thailand since 5500 BC, Indonesia since 3000 BC, and Philippines in 2600 BC. It is estimated that around 100 varieties of betel exist worldwide and 40 of them can be found in India. Betel plants can be directly consumed through chewing or as additives to other types of plant to form a mixture. Aside from human health, betel is also used in the agricultural sector to aid in efficient plant growth.

Figure 1. Betel plant (*Piper betle* L.)

Pest management in agriculture will become more challenging due to the increasing pest resistance to chemical pesticides. The arising problems forced farmers to seek alternatives to controlling pests to avoid yield loss in the future. It is undeniable that the use of chemical pesticides was efficient initially, but it has led to undesirable side effects, such as environmental pollution. Researchers are moving forward in providing farmers with a better alternative that is more environment-friendly, effective at low cost, and able to cater to the main objective of pest control. Plants were proven to contain certain compounds that can largely ward off the insecticidal activity potential [2]. Certain regions in the country have started to use such crops in pest management.

Phytochemical screening of crops is carried out to identify the presence of a chemical or bioactive compound in a certain plant. This procedure is done in the laboratory because it involves the use of chemicals and requires specific conditions. The presence of a certain chemical compound in the plant can be clearly observed. Examples of tests conducted in the phytochemical screening are the froth test for saponin, the ferric chloride test for tannins, and test for anthraquinones. The plant extract is used as the main material for the screening procedure. Some tests require extract in powder form while others require extract in alcoholic form.

Botany of *Piper betle* L.

The Piperaceae family consists of approximately 1000 species of plants and shrubs, including *Piper betle L*. which is also known as betel vine parts. It is a well-known traditional plant due to its many medicinal benefits and can be used for many purposes. Its leaves are the most used plant parts. It has a pungent odour and requires another plant or support for the growth of its vine [3]. These plants can be classified and differentiated based on their leaves, sizes, and colour. Table 1 shows the taxonomy of *Piper betle* L. This type of medicinal plant can be widely found across the world, and most originate from Southeast Asian countries, such as Malaysia, Indonesia, Myanmar, Thailand, and the Philippines. Its name varies depending on the local community because the betel crops were named according to their local language and beliefs. India is one of the most significant countries that relate to the origin of betel. According to their beliefs, betel plant is known as Paan from the Sanskrit word “parn”, which means snake hood as the leaves resemble the shape of snakehead [3].

Table 1. Taxonomy of *Piper betle* L.

Kingdom	Plantae
Subkingdom	Viridiplantae
Infrakingdom	Stretophyta
Superdivision	Embryophyta
Division	Tracheophyta
Subdivision	Spermatophytina
Class	Magnoliopsida
Superorder	Magnolianae
Order	Piperales
Family	Piperaceae
Genus	*Piper* L.
Species	*Piper betle* L.

This crop can be planted in two types of cropping systems, i.e., open cropping system and the controlled cropping system. Under the open or natural cropping system, betels are grown attached to a supporting crop, such as *Cocos nucifera* and *Areca catechu*, which provides support to allow the betel crop to grow up to 15 meters in height.

Biological activity of *Piper betle* extract: Antibacterial Activity

Betel extracts show significant effects in terms of antibacterial properties towards various ranges of microbes that could be very useful not only in the pharmaceutical sector but also related to the agriculture sector. Generally, the antibacterial properties of a compound were studied to be implemented in the treatment of disease-causing bacteria. Some of the pathogens were also founded in food. Betel leaves have been employed as an antibacterial agent in India and other Southeast Asian countries since ancient times, and they are mentioned in various historical manuscripts dating back to the Vedic period (3,000 BC). The extracts of betel leaves, stalks, and stems, as well as the oil obtained from the plants, have all been investigated and proven to be effective against a variety of harmful bacteria [3].

The presence of several strong chemicals such as alkaloids, tannins, phenolic molecules, and glycosides might explain the considerable antibacterial action. Antibacterial properties were discovered in betel leaf extract with ethanol, ethyl acetate, and methanol as solvents, particularly in betel leaf extract [4]. Although generally the studies conducted on the antibacterial properties of betel extract were mainly focused on disease-causing bacteria in humans and animals, some of the bacterial strains were plant-associated. More research and studies should be conducted to study the antibacterial properties of betel extract against disease causing bacterial strains on plants instead of focusing on humans and animals. There are only a few studies reported that validates the effectiveness against plant pathogenic bacteria. According to Nagu [5], betel extract can be a great alternative to be treated against several phytopathogenic bacteria such as *Xanthomonas oryzae, Xanthomonas axonopodis pv. vesicatoria* and *Agrobacterium tumefaciens*. In the study, *Xanthomonas axonopodis pv. vesicatoria* was proven to be the most susceptible bacteria against all type of betel extract. The reported antibacterial properties against several bacterial species were summarized in Table 2 below.

Antilarval activity

The extract of *Piper betle* was studied and proven to contain antilarval activity against the larvae of several species. Among the studied insect species are *Chrysomya megacephala* and *Chrysomya bezziana* [3]. However, there is a significant difference in the effectiveness of different types of extract against the studied insects. Among the extracts, betel essential oil is ranked as the most effective as compared to aqueous extract and ethanol extract. In another study by [12], betel extract was also proven to have a similar effect when treated to the larvae of *Aedes aegypti*. These studies have demonstrated that betel extracts possess the antilarval activity potential that could be used as a major component in the anti-larval agent to curb the insect population.

Antifungal activity

Aside from antibacterial and antilarval properties, betel extract was also found to have antifungal properties, which were caused by several constituents in the extract, including chavicol, chavibetol, chavibetol acetate, and hydroxychavicol [3]. The tested fungi were *Aspergillus*

parasiticus, Trichophyton mentagrophyte, and *Candida albicans*. Once again, the effectiveness of each type of extract varies with chloroform extract, showing the most promising result [13].

Table 2. Bacterial strains studied against betel extract

Bacterial strain	Disease Caused by Bacteria	Isolated	Ref.
Xanthomonas oryzae	Bacterial blight	*Oryza sativa* (rice)	[6]
Xanthomonas axonopodis pv. vesicatoria	Bacterial spot	*Solanum lycopersicum* (tomato) and *Capsicum anuum* Group (pepper)	[7]
Agrobacterium tumefaciens	Crown gall disease	Soil and crown gall	[8, 9]
Xanthomonas campestris p.v. campestris	Black rot	*Brassica oleracea var. capitata* (cabbage)	[10]
Erwinia carotovorum sub sp *carotovora*	Soft rot disease	*Solanum tuberosum* (potato)	[2]
Pseudomonas syringae	Bacterial canker	*Prunus spp.*	[11]

Extraction and phytochemical screening of *Piper betle*

Betel leaf extracts that are commonly studied are aqueous, methanol, ethanol and essential oil extracts. These extracts yield different results because certain active components are only present in a certain type of extract. The percentage of each compound depends mainly on the variety of the betel and environmental factor. Essential oil (EO) extracted from betel leaves contains more than 60 active compounds, each of which has unique characteristics, that are very beneficial. Phytochemical screening is done to determine the retain extract. It is a process to detect the presence of chemical components produced by plants. The detection of phytochemicals is done mainly to determine the presence of major chemicals, such as alkaloids and saponins, but further research has proven that it could also be used to detect the presence of tannins, saponins, essential oil, and other phytochemicals produced naturally by plants [14]. *Piper betle* L. was studied for its phytochemical and was found to contain flavonoids, saponins, isoeugenol, terpenoids, alkaloids, protein, and other naturally occurring beneficial chemicals [15]. There are several methods reported for the detection of phytochemicals in an extract, including for betel extract (Table 3).

According to Mazumder [18], betel crops were one of the most highly produced crops, averaging at Rs 9000 million worth of production yearly, but it is mostly wasted or sold at a very low price [19] introduced the oil extraction method. The first oil extraction method uses the clavenger apparatus, but was unsuccessful due to the rapid formation of an emulsion. Guha introduced a series of improvements that made the extraction process more efficient. The main consideration for the oil extraction process in India is in terms of technology availability and suitable chemicals that can be easily retrieved for the extraction process to be conducted on a large scale [19]. In general, different types of extracts will yield different types of phytochemicals in the extract. In a study conducted by Saini et al. [20], ethanol extract and aqueous extract of betel crops yield the highest quantity of phytochemical that can be traced by a series of phytochemical screening procedures. It recorded a total of six phytochemicals in the extract, which are proteins, saponins, carbohydrates, alkaloids, tannins, and phenol. In contrast, in a study by [21], chloroform extract of the same species of crop yields a

high number of essential phytochemicals, including chavibetol acetate, chavicol, allylpyrocatechol, and chavibetol. It is very crucial to select a suitable extraction procedure to enable the presence of targeted phytochemicals to be studied. Phytochemicals are present in different parts, such as root, bark, stem, flower, and leaf, but their concentration varies depending on the crop variety. The Sri Lankan variety of *Piper betel* L. was studied and proven to contain safrole as the highest concentration of phytochemical with an average of 53%, followed by allylpyrocatechol acetate and eugenol with 15% and 6% concentration, respectively [22]. In contrast, the essential oil extracted from betel crops of the Malaysian variety contains a high amount of chavibetol, in approximately 70% concentration. These differences were proven to be caused by the geographical location as an environmental factor significantly affect the growth phase, as well as the physical and chemical properties of the variety.

Table 3. Series of tests conducted in phytochemical screening of betel extract

Test / Procedure	Observation (indicates presence of targeted phytochemical)	Ref.
Test for alkaloids		
Dragendraff's test	Orange-brown or reddish - brown precipitate	[16, 17]
Mayer's test	Cream precipitate	[17]
Test for glycosides		
Legal's test	Changes of color from pink to red	[17]
Keller-Killani test	Reddish-brown color	[17]
Test for saponins		
Haemolysis test	Changes of red blood cell structure observed under microscope	[17]
Foam test	Stable foam appeared	[17]
Shaking vigorously with distilled water	Lather formed	[16]
Test for flavonoids		
Shinoda test	Orange color formed	[17]
Test with concentrated sulphuric acid	Yellowish orange color formed	[16]
Test for carbohydrates		
Molisch's test	Violet color appeared	[17]
Fehling's test	Reddish-orange precipitate formed	[17]
Test for phytosterols		
Libermann-Buchard's test	Emerald green color appeared	[16, 17]
Salkowski's test	Brown color appeared	[16, 17]
Test for protein		
Biuret test	Violet color formed	[17]
Ninhydrin's test	Purple color formed	[17]
Test for phenolic compound		
Phenolic compound test	Blue color appeared	[17]
Test for tannins		
Addition of 1% gelatine and 10% sodium chloride	White precipitate formed	[17]
Test with Bramer's reagent	Brown precipitate formed	[17]
Ferric chloride test	Greenish black color appeared	[16]
Lead acetate test	White precipitate formed	[16]

Among the phytochemicals present in the betel leaf extract, the phenolic compound recorded the highest concentration compared to other groups of compounds [15]. Phenolic compounds, such as flavonoids, tannin, and carotenoids, are found in most plants. Phenolic compounds are the main compound that helps in UV protection, defence mechanism, and antioxidant properties [23]. The phenolic compounds in betel crops possess antioxidant properties. Researchers have proven and identified phenolic compounds as the most functional metabolite that can be extracted from *Piper betle* L. and it has potentials in many fields of study. These essential phytochemicals were also found in other plants that were studied for similar reasons, including antioxidant and antibacterial potential that provide better alternatives to replace harmful artificial chemicals used widely in the industry. Table 4 shows the phytochemicals present in different types of betel extracts.

Table 4. Essential phytochemicals in *Piper betle* L. extracts

Phytochemicals	Molecular Formula	Type of Extract	Ref.
Flavonoid	$C_{15}H_{10}O_5$	Ethanol extract	[20]
Alkaloids	$C_{21}H_{20}N_2O_3$	Chloroform, ethanol, and aqueous extract	[20]
Tannin	$C_{76}H_{52}O_{46}$	Aqueous and ethanol extract	[20]
Eugenol	$C_{10}H_{12}O_2$	Methanolic extract	[15]
Safrole	$C_{10}H_{10}O_2$	Methanolic extract	[15]
Chavibetol acetate	$C_{12}H_{14}O_3$	Methanolic extract	[15]
Phytosterols	$C_{29}H_{50}O$	Chloroform, ethanol, and aqueous extract	[20]
Oleic acid	$C_{18}H_{34}O_2$	Methanolic extract	[15]
Trymyristin	$C_{45}H_{86}O_6$	Methanolic extract	[15]

Figure 2 shows a molecular structure for several phytochemicals that are present in betel leaf extract. Although generally all cultivar of *Piper betle* contains similar phytochemicals, its concentration may vary due to several factors, mainly by the environmental factor at the cultivation area. Environmental factors, such as humidity, temperature, shading effect, light intensity, and nutrient availability, play a vital role in crops' growth leading to different chemical concentration for the same species that is collected from different regions and origins. Even though studies have been done to clarify the effect of aging towards the concentration of each phytochemical in the betel extract, it was concluded that the maturity stage of the crop does not largely affect the chemical constituent content of the extract.

Insecticidal activity potential of *Piper betle*

Table 5 shows the current usage of *Piper betle* extracts in pest management as an agent that significantly affects the treated pests. The studies validated the effect of the extract on different stages of insect pest. Some of the extracts acted on several stages and mechanisms, including the larvae and adult stages, affecting the egg-hatching process of insects and showing repellent properties.

Several species of the Piperaceae family, including *Piper betle* L., have been proven to contain insecticidal activity potential toward several species of pests [24]. All the *Piper* species studied were proven to contain similar essential phytochemicals that allow it to possess such potential. Traditionally, betel crops were used directly as a control agent for several insect species that could become vectors for harmful diseases. In modern agriculture, chemical components extracted from various parts of betel crops were studied and applied to produce novel insecticides [25]. Further research and advancement are in progress to produce more efficient insecticides that cause less environmental damage. The essential oil derived from plant species was proven to pose less harm to both humans and environment due to its biodegradable properties [26].

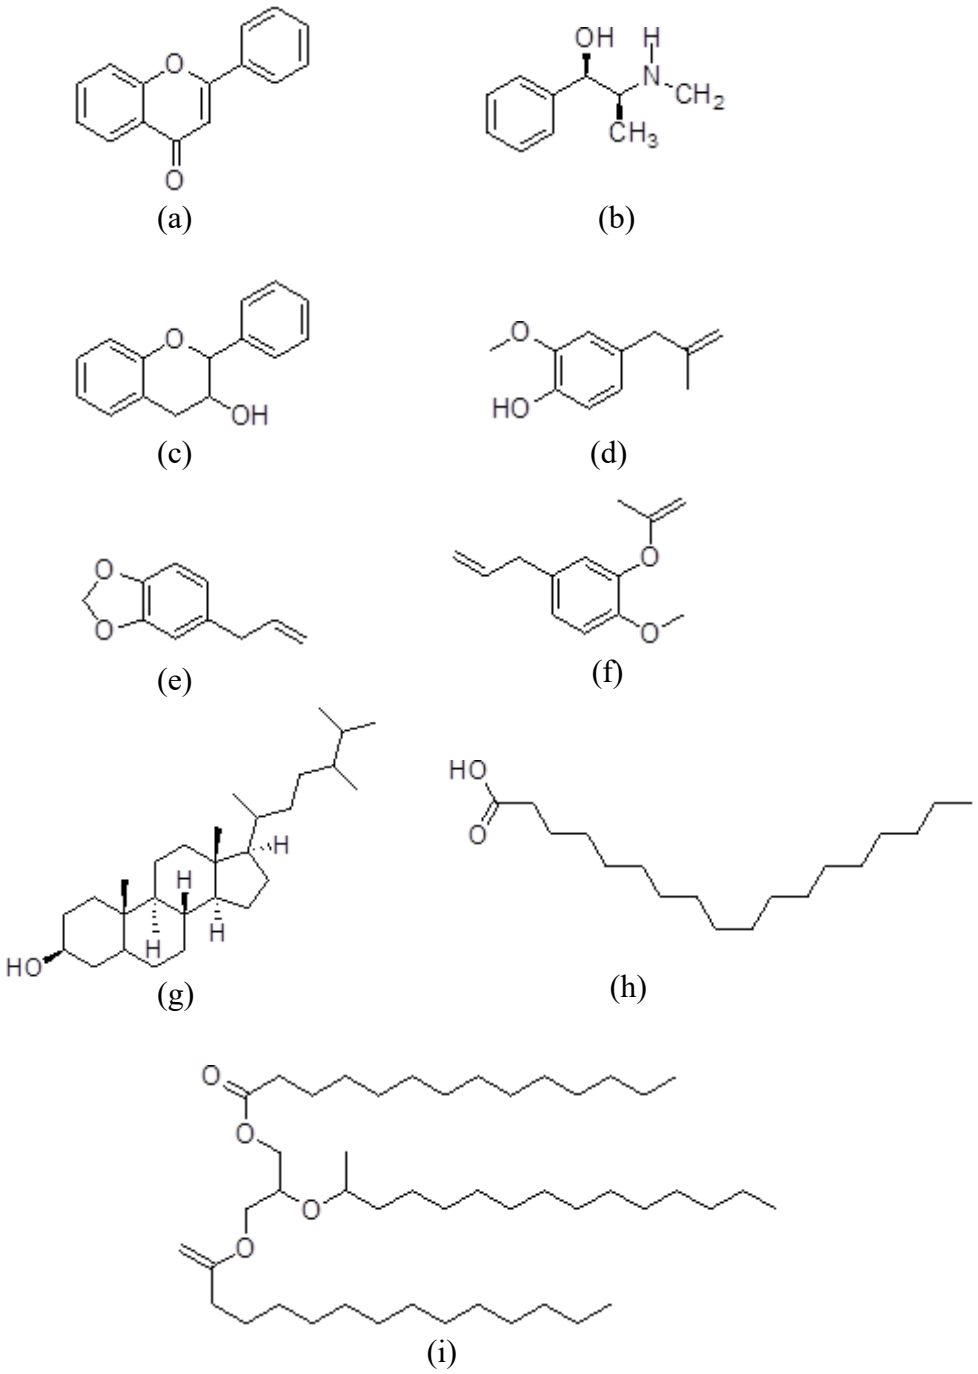

Figure 2. Molecular Structure of Some Phytochemicals Present in Betel Extract. (a) flavonoids (b) alkaloids (c) tannins (d) eugenol (e) safrole (f) chavibetol acetate (g) phytosterols (h) oleic acid (i) trymyristin

Table 5. Usage of *Piper betle* Extract as Pesticide

Insect	Test	Result / Observation	Ref.
Musca domestica	Fumigation toxicity	Provide moderate toxicity to treated insect	[27, 26, 28]
	Contact toxicity	Shows weak properties in topical application but promising result in diet exposure to larvae	
	Ovicidal effect	Shows toxicity effect but lower than eugenol	
	Oviposition repellence	Shows promising oviposition deterrence and increased with increasing concentration	
	Adulticidal bioassay	Betel essential oil with the concentration of 120 µg/cm^3 in ethanol causes 100% knock down effect	
Aedes aegypti	Larvicidal assay	Causes 100% mortality rate at the concentration of 500 ppm after 1 hour of treatment	[27, 12]
Chrysomya bezziana	Larvicidal bioassay	3% betel oil causes 100% mortality rate of 1st instar larvae after 2 hours and 74% mortality rate of 2nd instar larvae after 4 hours 4% betel oil causes 100% mortality rate of 1st instar larvae after 2 hours and 2nd instar larvae after 4 hours	[27]
Chrysomya megacephala	Larvicidal bioassay	2% betel oil causes 97% mortality rate of the larvae after 4 hours 3% and 4% betel oil causes 100% mortality rate of larvae after 3½ hours	[27]
Sitophilus oryzae	Adulticidal bioassay	1% betel oil causes 100% mortality rate of adult *Sitophilus oryzae* after 1½ hour	[27]
Cylas formicarius	Adulticidal assay	Almost all crude solvent extract provides significant effect to the adult *Cylas formicarius* with ethyl acetate recorded the highest mortality rate (100% after 48 hours), followed by crude acetone extract (70% after 48 hours) at the concentration of 20 ppm	[29]
Meloidogyne spp	Applied to tomato plant infested with *Meloidogyne spp*	The highest decrease of *Meloidogyne spp* population in the soil was recorded at 80.06% by 20% of concentration The highest decrease of *Meloidogyne spp* in the tomato root was recorded at 76.14% by 20% of concentration The highest decrease of eggs produced by *Meloidogyne spp* was recorded at 61.73% by 20% of concentration	[30, 31]
	Test on the survival of second stage juveniles (J_2s) *in vitro*	Causes higher mortality compared to control (untreated water)	
	Test on egg hatching – *in vitro*	Causes egg suppression at 100% by 80% of concentration	
Anopheles spp	Repellent test	80% of betel leaf extract shows the highest repellent percentage at 93.75% followed by 40% concentration (68.75%) and 20% concentration (50%)	[32]

Table 5 shows the insecticidal activity of betel extract for different stages of insects. Mohottalage et al. [22] conducted a study to compare the effectiveness of betel essential oil and *Ceylon citronella* oil extracted from *Cymbopogon nardus* towards adult houseflies (*Musa domestica L.*). It was found to be approximately three times more efficient than the *Ceylon citronella* oil. Adult houseflies were treated with both substances at 24 hours and 48 hours of exposure time. Another study conducted by Yushananta and Ahyanti [28] used different concentrations of betel essential oil to treat houseflies and compared the effect of concentration variation on the mortality rate. From the finding, a higher concentration of betel oil led to a higher mortality rate

for houseflies. They proved that the toxicity of betel extract was mainly caused by the presence of eugenol and safrole in high concentrations. The toxicity potential of the active compound makes it more efficient than other naturally occurring chemicals. Commercially, safrole was applied in the production of insecticide as a synergist.

The essential oil of *Piper betle* acted on the larvae and adult stages of the targeted insects with different concentrations [12]. A recent study validated that the betel oil effectively controlled the larvae of *Aedes aegypti* at the concentration of 500 ppm, higher than the concentration of widely used insecticide, known as temephos, which requires only 0.1 mg/L dose in water to control the larvae efficiently. But there is a recent report that the larvae of *Aedes aegypti* tend to become resistant towards temephos in some countries. On the other hand, there is no report of resistance when betel oil is used to control the larvae [12]. A substance that affects different stages of insects has high potential to be developed into novel insecticides as it will help increase its effectiveness towards the targeted pests. Moreover, it is better to control the pests at the early stage to curb the population of infesting pests and simultaneously reduce the total loss done by the pests. As for small-scale or large- scale production, farmers will surely use this alternative to decrease their expenditures in controlling pests and diseases for the agricultural processes. Aside from affecting adults and larvae of pests, betel EO also shows potential in terms of oviposition deterrent activity. The total number of eggs produced in the oviposition assay at the concentration of 100 ppm by using *Piper betel* L. extract yields decreased quantity by five (5) times lower than the control condition [12].

Regarding the mode of action and mechanism, each phytochemical targets and acts differently to the treated insects or pests, but it still yields the same result, causing mortality to the organisms [26] studied the insecticidal activity of betel essential oil and other chemicals, including eugenol acetate, eugenol, and β-caryophyllene, by two modes of action or treatment to the *Musa domestica*, which are contact toxicity and through fumigation. All chemicals used can be traced in the betel essential oil, but the chemicals were tested individually as a comparison to the betel essential oil. Different concentrations of each chemical were prepared by diluting it in acetone and applied to filter paper placed inside a jar. Approximately 20 starved and an anesthetized uniformly sized houseflies were placed into the jar containing the filter paper and the mortality rate was recorded after 3 hours. Another mode of action by betel oil studied by Subaharan et al. [26] is through contact toxicity, which can further be divided into two categories, namely topical application and dietary exposure to larvae.

In conclusion, the studies show promising results for the individual constituent found in betel essential oil. Almost all results for the individual chemicals were superior to the betel essential oil. It can be concluded that the substances play an important role in insecticidal activity against houseflies. Another study conducted by Yushananta and Ahyanti [28] concluded that a higher concentration of betel oil and more prolonged exposure to the betel oil causes a higher mortality rate of *Musa domestica*. The highest concentration used was 25%, which yields about eight houseflies mortalities. The highest mortality was recorded for six houseflies at an exposure time of 20 minutes.

There are several causes of death for the treated insect, either by direct contact or through fumigation that causes the chemical to enter the insect through the respiratory system. Tannins are one of the phytochemicals that is responsible for the death of insects. Tannins' mechanism targets the cell wall and digestive system of pests [28]. The nature of certain pests, e.g., houseflies tend to lick anything in its surrounding, can provide a pathway for the tannins, also known as a contact poison, to enter the inner structure of the pests. After entering the body, it inhibits significant enzyme activity and causes digestive failure, leading to death. Another example of the phytochemical mechanism in insecticidal activity is the inhibition of the respiratory system by flavonoids. This chemical constituent pathway is mainly through the airways by entering the respiratory tracts. It causes paralysis and muscle depletion by acting on the central nervous system of the affected organisms. Chavicol and eugenol, another major component in betel oil, were mainly used

as pesticide synergists due to their antiseptic properties.

Regarding the treatment at the larvae stage of certain insects, betel oil will first target the larvae's midgut epithelium, which then leads to malformed tubules that will then causes larvae mortality. Generally, different types of phytochemicals target different parts of the insect, but further research can be done to clarify which one of the phytochemicals acts, or if all phytochemicals mechanisms occur simultaneously as the mechanism was just stated individually.

Hypochlorous acid: A review

Hypochlorous acid (HOCl) is a substance that is naturally produced primarily by white blood cells, including neutrophils and eosinophils, of most mammals as a response to injury or infection [33]. This chemical is nontoxic and noncorrosive, but is effective and widely used in the pharmaceutical, health and a wide range of other sectors. For instance, this chemical can be easily found at home because it is used as an active compound in cleansers and bleaches [34]. These usages of HOCl have proven its potential, and in the future, more use of this beneficial chemical might be discovered, including in the agriculture sector, to aid the processes. There are also records showing that HOCl has already been used as one of the compounds to produce several types of pesticides. So, the implementation HOCl in the agriculture sector is not new and further development can be done to reduce the dependency on synthetic chemicals.

HOCl can be produced through several chemical processes. As stated earlier, HOCl is naturally produced by white blood cells, such as neutrophils of mammals. HOCl is produced due to oxidative burst, a condition whereby oxygen consumption rises remarkably [35]. During this process, also known as a respiratory burst, cells utilize oxygen (O_2) and, an enzyme called NADPHase, triggers the conversion of O_2 to hydrogen peroxide (H_2O_2). This enzyme is bounded to the membrane of mitochondria. The H_2O_2 then reacts with chlorine ion (Cl^-) from the cellular fluid, catalysed by a leukocyte-derived enzyme, known as myeloperoxidase, to yield HOCl. According to a study by [35], approximately 0.1 μM of HOCl can be produced from every 10^6 in vitro neutrophils that can kill *Escherichia coli* (*E. coli*) within 5 minutes. *E. coli* is a microorganism that can be found in the intestine; it is usually not harmful to health, but certain strains of *E. coli* can cause stomach pain and diarrhoea. Aside from natural production by neutrophils and eosinophils in mammals, HOCl can also be produced artificially or through the reactions of several chemicals.

There are several methods that can be used to produce HOCl. Among reactions that yield HOCl are hydrolysis of chlorine gas, electrolysis of salt solution and acidification of hypochlorite. In commercial industries, mild HOCl is produced by the acidifying of NaOCl with hydrochloric acid (HCl) [37]. Other methods to produce HOCl for industrial purposes depend on the size of the industry and available resources for the production procedures. The most widely known commercialized product containing HOCl in a low concentration as its active compound is disinfectants used in the healthcare sector. Disinfectants are used to neutralize wounds in humans due to their antimicrobial properties. The use of HOCl as the main ingredient for disinfectants is a success because it is effective against a wide range of microorganisms in a short period of time [35], and it does not interrupt the wound healing process [36]. These properties are the major factor that lead to the utilization of HOCl in the healthcare industry as suitable chemicals, especially in crucial medical processes. Each substance used was first proven to have no detrimental effects as it relates mainly to the safety of patients and the person in charge of handling the substance.

Two popular disinfectants sold in the market are Medilox® and Sterilox. The products were tested for their stability, which is a primary concern for products containing HOCl. The concentration of chlorine and the pH were proven to be in decreasing pattern over time [37]. In addition, its shelf life is short, estimated to be four days, when it is directly exposed to sunlight or UV radiation. Further research and development should improve their shelf life to produce better quality and long-lasting effects.

The potential of hypochlorous acid towards insecticidal activity

HOCl is widely known as an agent for wound healing treatment and disinfectants as it contains high potential for antimicrobial activity. This potential is also beneficial in sectors other than pharmaceutical. HOCl has the potential for an antimicrobial activity that helps to hinder and inhibit microorganism growth and population. This might lead to HOCI being used for pest control and result in a novel method to aid several processes of agricultural products for better food security. In general, not many studies have been done to verify the true potential of HOCl in controlling agricultural pests. Only a few studies have proven the benefit of using a compound containing chlorine to curb pest population, but there is evidence that household products, such as bleach, have been used as pesticides for a few varieties of pests. This method can be utilized by small-scale farmers who do not want to spend a large budget on controlling pests and diseases of their agricultural crops.

Table 6 shows the results of a study conducted by [38] to evaluate the effectiveness of commercial bleach towards the control of *Aedes aegypti*, which is the principal vector for the dengue virus. The eggs laid by the mosquitoes tend to stay dormant for a few months after it completes embryogenesis, producing an eggs bank for the mosquito species. This problem largely contributes to the rising cases of dengue fever. The mosquitoes have to be controlled as early as the egg stage. Ovicide has to be applied to kill potential eggs in an area. The main problem when using ovicide is the eggs' resistance to desiccation. The outer layer of the eggs can block the insecticide from penetrating the inner layer, and thus decreasing the effectiveness of insecticide at the larval stage of *Aedes aegypti*. In contrast, the active compound found in regular bleach was proven to be able to breakdown the outer layer, making a pathway for the insecticide to enter the eggs [39]. The active ingredient responsible for this action is sodium hypochlorite (NaOCl). The use of household bleach as an insecticide for *Aedes aegypti* is a cost-effective alternative because the bleach itself is cheap compared to insecticide, and the water applied with the bleach was proven safe for daily consumption if the concentration does not exceed four ppm.

Mackay et al. [38] conducted a study on the efficiency of commercial bleach against *Aedes aegypti.* Two types of solution were tested: bleach, and a mixture of bleach and smectite clay. The solution containing bleach and smectite clay was verified to be almost equally effective against the eggs of *Aedes aegypti* on plastic, rubber, and concrete, while the bleach solution alone was less effective against the eggs on concrete. Longer exposure time to sunlight yields fewer eggs at the end of the experiment, implying that exposure to sunlight plays a vital role in increasing the efficiency of bleach spray on eggs. In light of the discovery of the potential of bleach-containing HOCI for pest control, more studies should be conducted to uncover the true potential of HOCl in the agriculture sector. However, the use of bleach must be handled with care because household bleach is corrosive and, at a certain level of concentration, might harm the skin or cause damage to surfaces, such as plastics, some metals, paint, wood, and fabrics.

Potential pesticide formulation of hypochlorous acid and betel extract

HOCl solution and betel extract were proven to contain insecticidal activity potential towards many pests at different stages, including the egg, larval, and adult stages. Betel extract contains essential phytochemicals that provide its insecticidal activity potential, while HOCl contains antimicrobial and insecticidal activity. Improved formulations containing both HOCl and betel extract can be produced to increase their effectiveness. A pesticide formulation that can act on different mechanisms can be valuable to farmers because it can be a cost-effective alternative in pest management. The primary consideration in producing the formulation is the shelf-life of the pesticide and whether combining the compounds would produce adverse side effects. There are studies where the combination of HOCl and betel extract were tested for its effectiveness on fungi. These studies may lead to discoveries and further studies on the efficacy of formulation that combines the two essential compounds towards insecticidal activity.

Table 6. Insecticidal activity of HOCl

Insecticidal Activity Potential of HOCl	Targeted Insect Stage / Targeted Organism	Results	Ref.
Usage of HOCl in the control of Aedes aegypti	Egg stage of insect	Both solution containing bleach only and the formulation between bleach and smectite clay were proven to be effective against the egg of Aedes aegypti	[38]
Classified under the pesticide category	Adult stage of insect	Hypochlorous acid along with other disinfectants were classified under the pesticide categories by The Environmental Protection Agency (EPA)	[40]
Possess antimicrobial properties	Adult stage of insect	HOCl were proven to provide significant effect towards antimicrobial activity that was also possessed by betel extract that could lead to the production of novel insecticide	[41]; [35]
Used as germicide	Microorganism	A type of HOCl germicide known as warexin were proven to possess sporicidal and bactericidal activity potential against several bacterial strain and its effectiveness were higher compared to bleach.	[43]

Conclusion

Piper betle has considerable potential for insecticidal activity. The essential oil extracted from betel plants contains beneficial phytochemicals that can be used as a major component in novel insecticides and pesticides. Tannins, saponins, and flavonoids are examples of essential phytochemicals in betel crops. It is crucial to seek better alternatives for pest management that does not involve the use of chemicals that are harmful to the environment. Moreover, current artificial insecticides and pesticides tend to increase insect resistance up to a point that chemical insecticides are no longer effective. The formulation of betel extract and hypochlorous acid aimed to increase effectiveness as hypochlorous acid has antimicrobial activity potential. An investigation ought to be conducted for the use of betel extract against a broader range of pests. Betel extracts have been proven to be fatal against certain pest species. Future studies should focus on the extract's mechanism and the insects' taxonomy. A combination of hydroporous *Piper betle* extract and other possible solutions must be examined to increase their effectiveness. Currently, the primary use of HOCI is in the healthcare sector as disinfectant because of its antimicrobial and antifungal properties. These chemicals can be further studied to expand their usage to the agriculture sector. Household bleach that contains HOCl as its constituent has been proven to have the potential towards insecticidal activity that could largely contribute to the production of novel pesticides.

Abstract

Antibiotic residues are being continuously detected in the environmental and food matrices. Though the level of antibiotic residues is typically in minute concentration, adverse effects of these antibiotics on the environment and human health have been observed. Hence, there is a demand for simple, rapid, accurate, reliable, inexpensive, and selective sample preparation with high sensitivity and throughput analysis for antibiotic compounds. Conventional extraction techniques such as liquid-liquid extraction (LLE) and solid phase extraction (SPE) are commonly used for sample preparation. However, most of the LLE and SPE techniques suffer from several major drawbacks such as consuming a large amount of toxic organic solvents, being relatively expensive, involving multi-step, time-consuming, and tedious operation. Thus, to overcome these shortcomings, a number of new-generation materials have been developed for the purification and separation of analytes. Over the past few decades, cyclodextrin-based adsorbents have drawn worldwide attention as new-generation adsorbents for sample preparation and extraction due to their extraordinary physicochemical properties. Cyclodextrin is a family of cyclic oligosaccharides built by the hydrophilic outer wall and hydrophobic cavity. These unique properties are modified with chemical functionalization to enhance their extraction capability. This review outlined the recent application of the cyclodextrin-based adsorbent in the sample preparation techniques of a variety of matrices. These methods represent fast, modern, sensitive, and efficient approaches to detecting antibiotic compounds. In this review, several new sample preparation techniques incorporated with cyclodextrin-based adsorbent developed from 2015 – 2022 is discussed in

terms of their analytical performance which includes their sensitivity and efficiency toward the extraction, preconcentration, and isolation of antibiotic compounds from various type of matrices.

Keywords: cyclodextrin adsorbent, sample preparation, antibiotics, microextraction

Abstrak

Sisa antibiotik telah dikenal pasti di matriks sekitaran dan makanan. Walaupun paras sisa antibiotik ini kebiasaannya dalam kepekatan yang sangat kecil, kesan buruk daripada antibiotik ini terhadap sekitaran dan kesihatan manusia telah dicerap. Justeru, terdapat permintaan terhadap penyediaan sampel yang ringkas, cepat, tepat, boleh diguna pakai, tidak mahal, dan selektif dengan kepekaan dan hasil yang tinggi bagi sebatian antibiotik. Setelah beberapa dekad, penjerap berasaskan siklodekstrin telah mendapat perhatian global sebagai penjerap generasi baharu bagi penyediaan sampel dan pengekstrakan disebabkan sifat fizikokimianya yang luar biasa. Tinjauan ini menggaris kasar aplikasi baharu bagi penjerap berasaskan siklodekstrin dalam teknik penyediaan sampel di dalam pelbagai jenis matriks. Teknik pengekstrakan konvensional seperti pengekstrakan larutan (LLE) dan pengekstrakan fasa pepejal (SPE) selalunya digunakan untuk penyediaan sampel. Walaubagaimanapun, kebanyakan teknik LLE dan SPE ini mempunyai beberapa kelemahan seperti menggunakan jumlah pelarut organik toksik yang banyak, agak mahal, melibatkan banyak kaedah dan mengambil masa yang panjang dan berlarutan. Justeru, bagi mengatasi kelemahan ini, beberapa jenis bahan generasi baharu telah dibangunkan bagi penulenan dan pemisahan analit. Setelah beberapa dekad yang yang lalu, bahan penjerap berasaskan siklodekstrin telah mencetuskan perhatian sebagai penjerap generasi baharu bagi penyediaan sampel dan pengekstrakan oleh kerana sifat-sifat fizikokimia yang luar biasa. Siklodekstrin adalah kumpulan bagi oligosakarida siklik terhasil dengan dinding luar yang hidrofilik dan kaviti yang hidrofobik. Sifat-sifat unik ini telah diubahsui dengan berfungsikan kimia bagi meningkatkan keupayaan pengekstrakan. Tinjauan ini menggaris kasar aplikasi baharu bagi penjerap berasaskan siklodekstrin dalam teknik penyediaan sampel di dalam pelbagai jenis matriks. Teknik-teknik ini menggunakan pendekatan yang cepat, moden, sensitif, dan efisien untuk mengesan sebatian antibiotik. Di dalam tinjauan ini, beberapa teknik penyediaan sampel baharu yang digabungkan bersama penjerap berasaskan siklodekstrin yang dibangunkan dari 2015 – 2022 dibincangkan dari segi prestasi analitikal termasuk kepekaan dan kecekapan terhadap pengekstrakan, prakepekatan, dan pengasingan bagi sebatian antibiotik daripada pelbagai jenis matriks.

Kata kunci: penjerap siklodekstrin, penyediaan sampel, antibiotik, pengekstrakan mikro

Introduction

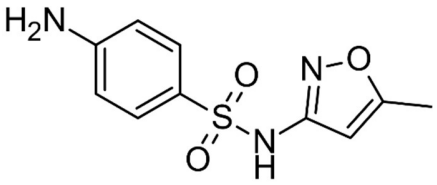
Since their discovery, antibiotics have been widely used for the growth and function disruption of bacteria by targeting certain parts within them [1]. Antibiotics have helped to increase the average life expectancy of men because they are utilized to prevent and treat bacterial infections or as dietary supplements, bringing to heels numerous life-threatening infectious diseases [2,3]. Tetracyclines, amphenicols, macrolides, beta-lactam antibiotics, etc. are natural or semi-synthetic classes of antibiotics that are employed extensively to treat livestock against the activities of the wide variety of gram-positive and gram-negative bacteria, thus promoting healthy living and rapid growth in animal husbandry [4,5]. Antibiotics have been administered to prevent the spread of diseases, antibiotics limit or kill harmful bacteria in order to protect a flock or herd from illnesses. Their use promotes good animal health and helps with food safety, disease prevention, and the livelihood of farmers. In addition, these drugs were commonly used as non-prescription feed additives for the development and growth of farm animals [6].

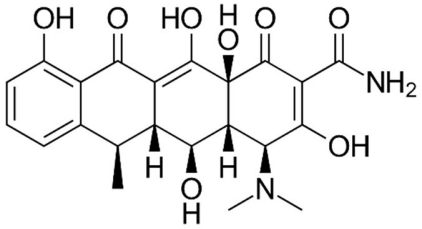
However, the emergence of human antimicrobial resistance from the misuse and overuse of these antibiotics can leave residues in human and dairy products like milk, egg, and meat [3,7]. These sub-therapeutic residues in foods can lead to the occurrence of antibiotic resistance bacteria and cause liver and tissue damage, gastrointestinal and neurological disorders, teratogenesis, carcinogenesis, and allergic reactions in hypersensitive humans [3,8,9]. Hence, the existence of these minute concentrations of antibiotic residue in animal-based food products is a major risk to human health and the ecological environment, thus a public concern. Different groups of antibiotics discussed in this review are presented in Table 1.

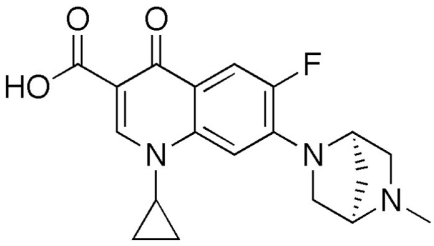
In a bid to curtail the potential threats, and sustain food quality and safety, regulatory bodies like the US Food

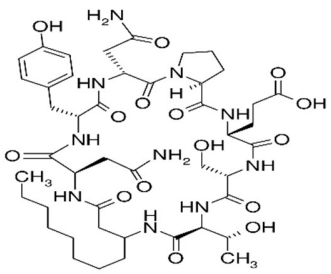
and Drug Administration and European Commission have introduced and adopted the maximum residue limits (MRLs) for antibiotics and veterinary drugs in human and dairy products like milk, egg, and meat [7,10]. The MRLs are legally documented acceptable residue limits in different food matrices without toxicological effects on man. The tolerance levels adopted by China, Brazil, Canada, Codex and European Union ranged from 100 to 600 µg/kg for individual antibiotics and their combinations in dairy products (poultry, cattle, swine, fish, meat, eggs, liver, and muscle) [11–14]. MRLs for selected antibiotics in poultry and milk matrices are listed in Table 2.

Table 1. Different groups of antibiotics are discussed in this review









Antibiotic Groups	Name of Antibiotics	Structure
Sulfonamide	Sulfamethazine, sulfadiazine, sulfamethoxazole, sulfamerazine	
Tetracycline	Oxytetracycline, doxycycline, chlortetracycline, minocycline	
Fluoroquinolone	Danofloxacin, ciprofloxacin, ofloxacin, enrofloxacin	
Lipopeptide	Bacillomycin, daptomycin, surfactin, mycosubtilin	

Table 2. Information on MRL of antibiotics [7,10]

Analyte	MRL (µg/kg)	
	Poultry	Milk
Danofloxacin	300	30
Enrofloxacin	100	100
Ciprofloxacin	30	100
Sulfadimethoxine	100	100
Sulfamethazine	100	100
Sulfonamide	100	100
Oxytetracycline	300	100
Tetracycline	600	100
Chlortetracycline	100	100

The regulatory bodies have devised the means of regularizing the requirements for analytical methodology and result interpretations. Because of this, there is a need to develop an effective, selective, and sensitive analytical method that can detect, preconcentrate, and degrade several antibiotic residues and their derivatives at low concentrations levels from a variety of matrices. The newly developed sample pre-treatment methodology in conjunction with advanced analytical instrumentation must be able to monitor, assess, and quantify low concentrations of antibiotics in complex environmental and food matrices despite the existence of major interferences. These interfering compounds must be removed via the sample pretreatment process before analytical instrumental analysis. The methodology applied for the detection and determination of antibiotic residue falls into two categories. The first category comprises screening steps that are easy to use, cheap, and have high sample through-put, although are considered low in selectivity and sensitivity. They include surface plasmon resonance technology biosensors, magnetic immunoassays (MIAs), rapid test-kit, and enzyme-linked immunosorbent assays (ELISA). The second category includes the confirmatory methods which are specific and provide structural elucidation in conjunction with other detectors when assessing and quantifying target antibiotics [15].

Different analytical instrumentation techniques have been employed for the detection of antibiotics, including high-performance liquid chromatography (HPLC) [16], ELISA, thin-layer chromatography (TLC), gas chromatography [17], and capillary electrophoresis (CE) in conjunction with mass spectrometry, ultraviolet, fluorescence, or tandem mass spectrometry [18]. Despite the advances in technology, especially in instrument development, most analytical instruments cannot handle the samples directly due to high matrix interferences and the conditions of the complex samples. Hence, there is demand for the development of powerful and inexpensive sample preparation techniques that are simple, rapid, reliable, and accurate. Sample preparation step is required in any chemical analysis procedure. It is used to (a) convert the analyte into the instrument-compatible form, (b) eliminate major interferences and reduce matrix effects, (c) enrich the analytes and improve the sensitivity of the method, and (d) improve the precision of the methods. The ideal sample preparation requirements include exhibiting reliable analytical performance in terms of high extraction efficiency and sample clean-up, minimum toxic solvent consumption, being inexpensive, high sensitivity, reusability, high accuracy, and being environmentally friendly.

The conventional sample preparation method, solid phase extraction (SPE) is the most frequently applied method owing to its high enrichment factor, especially with the emergence and use of automated online SPE with direct injection. However, it is a time and solvent-consuming approach, with a potential loss of volatile compounds during the concentration step. Also, the clogging and plugging of the cartridges can affect

consistency in the flow of the automated SPE. These drawbacks can be ameliorated by employing different adsorbents for the preconcentration of antibiotics [19]. To overcome these shortcomings, nanomaterials were usually applied as an adsorbent in sample preparation steps. The advantages of using nanomaterials in various analytical procedures are due to their large surface areas. These can be used to improve the sensitivity and miniaturization of devices by removing interferences species and enhancing analyte concentration. Furthermore, they can be incorporated with different functional groups to improve their affinity for compounds, which makes them particularly useful in the selective extraction of target analytes from complex matrices [21].

One of the best sorption materials ever discovered is cyclodextrin (CD), a series of cyclic oligosaccharides with 6-12 d-glucopyranose units characterized by toroidal (doughnut-shaped) structure. It was first developed in 1881 by Villier from the digestion of starch with *Bacillus amylobacter*; subsequently, Schardinger established its cyclic structure in 1903 [20]. The CDs are natural, eco-friendly, non-reducing, water-soluble, macrocyclic malto-oligosaccharides comprising glucans linked together by α-(1,4) glycosidic bonding. They are produced from the degradation of starch through intramolecular transglycosylation reaction using CD glucanotransferase (CGTase enzyme). Parent CDs are of three types: α-, β- and γ- CD having six, seven, and eight α-(1,4) linked glycosyl units respectively. Moreover, the exterior surface of the CD is hydrophilic while its interior is hydrophobic; these properties entrap biological, organic, and inorganic guest compounds moderately or entirely without covalent bonding to create reversible and noncovalent inclusive complexes.

The CD-based materials has garnered a lot of attention from researchers in recent times because it is nontoxic, economical, readily available, and can be grafted on nanoparticles forming an adsorbent that creates a favorable adsorption site for small organic compounds owing to its unique hydrophobic cavities, high adsorption capacities, and fast adsorption [22]. The supramolecular host-guest interactions exist between the β-CD (host) and organic molecules (guest) which can also be reversed to allow the desorption of the organic molecules from the β-CD (Figure 1). This makes the β-CD sorption material to be reusable, recyclable, efficient, and selective [23]. Also, the outer surface of the β-CD contains hydroxide functionalities which allow metal ions to covalently bond to it; in addition, dehydration, and condensation of β-CD with carboxyl groups will yield complex structure polymers. The tunability properties of the novel β-CD adsorbents allow the efficient and simultaneous removal of different pollutants. In addition, the chemical functionalization of CDs enhances their solubility and stability towards oxygen or light, and also regulates the reactivity of guest molecules [24].

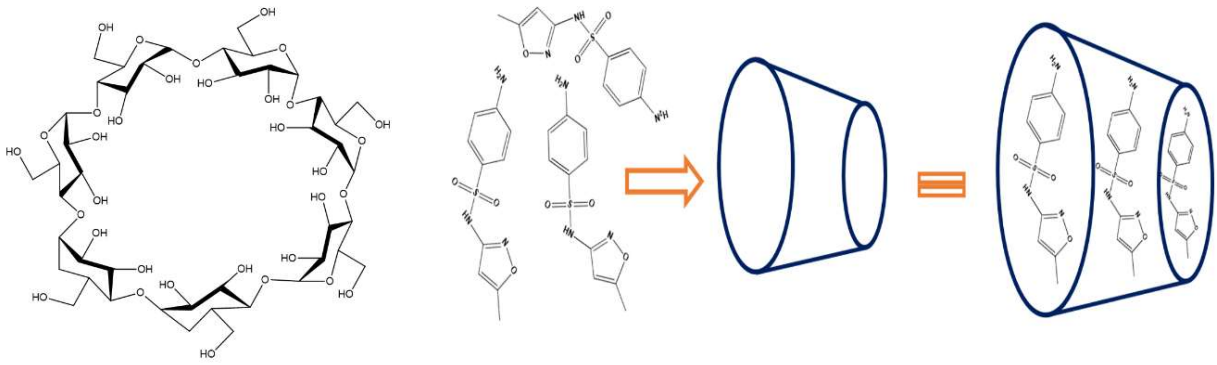


Figure 1. Structure of cyclodextrin (CD) and formation of inclusion complex with antibiotic molecules

This review paper aims to report an overview of sample preparation techniques for the determination of antibiotic compounds using CD-based adsorbents. The review highlights the analytical performances, advantages, limitations, and applications of the adsorbent in extraction techniques to extract antibiotics. Advances from 2015 to 2022 in the sample preparation of antibiotics in variety of matrices are reviewed here. Furthermore, future research of CD-based adsorbents is also elaborated. To the best of our knowledge, the application of CD-based adsorbent in sample preparation of antibiotic compounds has not been reported in an individual review.

Preparation of cyclodextrin-based adsorbents

β-cyclodextrin (β-CD) and their derivatized β-CD-based adsorbent materials have been configured with active sites using various configurations of functional groups to establish unique features which fit for adsorption and extraction performance, touted to be efficient, selective, and reusable adsorbent. As cyclic oligosaccharides makeup of the glucopyranose monomer units interconnected by α(1→4) glycosidic linkages, the presence of hydrophilic exteriors rich hydroxyl (-OH) groups and hydrophobic internal cavity in β-CD has expedited the modification or functionalization strategies with various functional groups [25]. To date, β-CD and its derivatized β-CD have been utilized as adsorbents for lipopeptide antibiotics [26], metronidazole antibiotics [27], tetracycline antibiotics [25,28–32], fluoroquinolone antibiotics [33–36], and sulfonamide antibiotics [37]. Modified CD-based adsorbents for the extraction of antibiotics can be prepared using various strategies. These include chemically modifying cyclodextrins to attach reactive groups, immobilizing them onto solid supports or nanoparticles, and employing techniques like molecular imprinting and supramolecular assembly. These strategies customize the adsorbents, allowing selective capture and extraction of antibiotics from complex samples, thereby enhancing the efficiency and reliability of the sample preparation process.

In order to achieve desired adsorbent properties and evolve as a class of multifunctional adsorbent materials, different chemical modification techniques have been employed to overcome some of the limits experienced by the β-CD, for instance strong inter/intramolecular hydrogen bonding among molecules which result in poor solubility, difficulty to separate, and maximum steric hindrance due to presence of secondary OH groups in the structure [38,39]. Yakout et al. described the formation of Cu-nanoparticles immobilized β-CD functionalized reduced graphene oxide (Cu/β-CD/rGO) via chemical reduction procedures using graphene oxide (GO) and copper nitrate trihydrate ($Cu(NO_3)_2{\cdot}3H_2O$) with sodium borohydride ($NaBH_4$) as an oxidizing agent. The Cu/β-CD/rGO nanocomposite was applied as an adsorbent for efficient extractors of tetracycline antibiotics residues. The morphological analysis revealed that the nanocomposite appeared as a random three-dimensional porous structure with uneven surfaces and the diameter determined by the dynamic light scattering (DLS) technique was found to be in the range of 17.6 to 18.8 nm. Moreover, the successful immobilization of Cu-nanoparticles and β-CD onto rGO was observed at a peak 26.3° for rGO while three peaks at 43.2°, 50.3°, and 74.0° were attributed to Cu nanoparticles which were in good agreement with standard Cu. Four types of interactions were identified which are π-π stacking interactions, cation-π-bonding, inclusion of tetracycline structure in the hydrophobic central cavity of β-CD, and cation-π bonding bridge/and cation-n bonding bridge [25]. Zhao et al. fabricated a microporous structure of monolithic polymer via radical polymerization using allyl-β-CD and methyl methacrylate as co-monomers, triallyl isocyanurate and ethylene glycol dimethacrylate as co-crosslinkers, and azobisisobutyronitrile (AIBN) as an initiator. The microporous structure in the monolithic polymer material was more than 50 nm with a specific surface area of 31.89 $m^2\ g^{-1}$. The lipopeptide antibiotics occupied molecular recognition with the allyl β-CD polymer monolithic column through multiple interactions such as hydrogen bonding, hydrophobic interaction, π-π interaction, and dipole-dipole interaction. The resulting allyl β-CD polymer monolithic column also showed good precision, excellent recovery, good repeatability, and cost-saving which provide advantages for the multi-action separation mechanisms [26].

Ying Zhang et al. reported magnetic mesoporous core-shell structured silicas containing covalently bound CDs (Fe_3O_4@SiO_2@mSiO_2-CD) using facile route by introducing β-CD-silica with core-shell structured mesoporous Fe_3O_4@SiO_2@mSiO_2 microspheres. The presented adsorbent established multiple interactions with doxycycline antibiotic such as inclusion interactions, hydrophobic interactions, electrostatic attractions, and π-π interactions. Moreover, based on the adsorption kinetic study, the maximum adsorption capacity of the adsorbent (83.33 mg g^{-1}) fitted with pseudo-second order with coefficient determination (r^2) and the adsorption process was via chemisorption procedure. The synergistic mechanism in the mesoporous structure and cavity of β-CD has provided good adsorption performance with multiple interactions with the doxycycline antibiotic, as well as the process was spontaneous and exothermic [29]. Similarly, study by Y. Li et al. (2018) found that the prepared CD metal-organic framework (CD-MOF) using γ-CDs and alkali metal cations exhibited excelled selectivity and adsorption capacity against sulfonamide antibiotics with the main force of interaction was due to the hydrogen bonding formed between the antibiotics and OH groups in the CD-MOF adsorbents. The kinetic experiments data showed that the equilibrium adsorption capacity was achieved and fitted pseudo-second-order model with $r^2 > 0.99$ and the process were facilitated by chemisorption [37].

In a study conducted by Sereshti et al., they noted that the addition of β-CD to the hydrophilic/hydrophobic deep eutectic solvent (DES) system improved the extraction efficiency for the tetracycline antibiotics as a result of selective supramolecular host-guest inclusion between the adsorbent and analytes. This was supported by the notorious feature of DES as a disperser and extraction solvent which facilitates and retains the host-guest complexation ability. Moreover, the molecular structure of β-CD which consist of hydrophobic cavity and hydrophilic external surface has made the dissolution in the DES undemanding yet at the same time retaining its ability to establish host-guest complexation [31]. Belenguer-Sapiňa et al. in their study reported that a new adsorbent based on type UMV-7 mesoporous-silica modified with γ-CD has been successfully synthesized for extraction protocol of fluoroquinolones-based veterinary antibiotics. The prepared material exhibited interparticle porosity (0.71 cm^3 g^{-1}) and intraparticle porosity (0.14 cm^3 g^{-1}) with the size of internal cavity of about 0.98 nm enabling more efficient extraction performance as well as more selective towards the targeted veterinary antibiotics [34].

Comparison of sample preparation methods

Numerous sample preparation strategies incorporated with CD-based adsorbents have been developed for the extraction and preconcentration of antibiotic molecules in a variety of matrices. The applications of CD-based adsorbents in sample preparation for the determination of antibiotics in various matrices from recent years are summarized in Table 3. Modified CD-based adsorbents offer several advantages in sample preparation for analytical purposes. They provide selectivity by specifically capturing target compounds, improving isolation from complex samples. These versatile adsorbents can be tailored to capture a wide range of analytes, making them applicable in various fields. By concentrating target analytes, the CD-based adsorbents enhance sensitivity, allowing for the detection of trace-level compounds.

Applications of cyclodextrin-based adsorbents in sample preparation

CD based adsorbents that are applied in extraction as sample treatment involved more than one interaction besides the hydrophobic guest-host inclusion complexes with the target analytes. The interior of CD is hydrophobic while the outer part is hydrophilic and it rarely occurs that the degree of the extraction capacity is much higher, indicating the synergistic interaction based on both structural components [40,41]. Owing to CD's unique structure which include reactive OH groups, it is feasible to chemically modify them to alter their solubility, increase their capacity for inclusion, or produce desirable qualities applied as adsorbent in sample treatment [35,36].

The optimization on extraction parameters in consideration of hydrophobic/hydrophilic structure of CDs as adsorbent involves improving the enrichment

factor of target analytes extracted from diverse types of samples matrices [42,43]. Different types of extraction techniques have been reported which employed CDs in quantification of antibiotics from varied type sample matrices, which include biological fluids, environmental water, and food matrices. Regardless of how simple or complex the sample matrices are, sample preparation is still essential to guarantee that the analytes are successfully isolated, cleaned up, and enriched in the final extract and are in a state that is compatible with the desired analytical technique. Natural CDs has certain solubility in aqueous solution, which limits its application in the field of adsorption due to the steric hindrance and hydrophobicity between CDs and target analytes [44,45]. So, improvement of solubility become the crucial point for CD-based adsorbent/solvent in sample preparation field to improve the target analyte (antibiotic)'s isolation and enrichment factor. The extraction from these sample matrices can be solid phase extraction (SPE) [34,37,46], solid phase microextraction (SPME) [35,47], magnetic solid phase extraction (MSPE) [37,48–51], dispersive solid phase extraction (DSPE) [36,52], and dispersive liquid-liquid microextraction (DLLME) [31,49] which are further discussed on their related CDs adsorbents as well as their application for the selective extraction/clean-up of antibiotic.

Online solid phase extraction and offline solid phase extraction

Since its inception in the early 1990s, solid phase extraction (SPE) has been a common approach for sample preparation. In comparison to the traditional liquid-liquid extraction (LLE), SPE offers simplicity, rapidity, excellent selectivity, and low cost, which have led to its widespread use especially in separation and extraction of antibiotics [53]. In addition, its use in sample preparation is beneficial for extraction, concentration, and sample cleanliness in a short amount of time due to the automation of the extraction procedure and ability to combine with different detection techniques in both on-line and off-line modes [37,53]. To date, various types of SPE adsorbents have been formulated by researchers to obtain high extraction recoveries in different complex traces. In 2018, cyclodextrin metal organic framework (CD-MOF) was developed to preconcentrate sulfonamide (SA) antibiotics and overcome prior SPE adsorbents with poor extraction performance and low hydrophobicity of SA that must be separated and preconcentrated [37]. ɣ-CD with cetyltrimethylammonium bromide (CTAB) were exploited to form a uniform cubic crystal with an average size of 200 – 500 nm and then used as SPE adsorbent for extraction of five selected SA. Elution solvent of acetonitrile/methanol (2:1, v/v) was chosen as it gave the highest recoveries of all SA about 90 – 101.2%. To validate its effectiveness in real samples, four different meats (chicken, pork, fish, and liver) with specific sample preparation were selected and good linear calibration (R^2 = more than 0.9907) were achieved with limit of detections (LODs) varied from 0.32 to 1.7 ng/mL. The prepared CD-MOF was also compared to previous SPE adsorbents [54–57] and successfully applied in SPE for SA preconcentration with high adsorption capacity in less than 10 minutes, high extraction efficiency, and satisfactory recoveries comparable with other methods.

Other than that, the man-made fluoroquinolones (FQs) antibiotic with a functional piperazine group in its structure against Gram-negative and Gram-positive bacteria were also of interest [58]. The widespread use in agricultural and veterinary sectors marked them as an emergent class of pollutant in water [59], and excessive use can cause serious safety and health problems due to their carcinogenicity and antibiotic resistance [60]. Thus, an efficient adsorbent development based on CD in SPE was invented to improve selectivity of targeted FQs. Belenguer-Sepina et al. designed the adsorbent based on porous glycidyl methacrylate (GMA) and ethylene dimethacrylate polymeric material (EDMA) with ɣ-CD as a surface modifier to extract FQs from ground water [46]. The final product of GMA-S-ɣ-CD adsorbent undergone two-step process: functionalization of CD and polymerization of GMA-co-EDMA. Raman spectrometry was used to verify the binding between functionalized CD with GMA-co-EDMA; it revealed the disappearance of thiols stretching (around 2500 cm^{-1}) indicating a good assembling between them, and presence of small peak in GMA-S-ɣ-CD indicating that the presence of small proportion -SH group did not react with modified CD.

The developed GMA-S-ɣ-CD adsorbent was then optimized and compared to previously reported β-CD polymeric material [61]. A significant improvement on recoveries was observed when ɣ-CD was used due to the similar size of targeted analytes with internal cavity of ɣ-CD. The selected optimum conditions for SPE were pH 1 of sample solution, 3 M of NaCl, 1 mL/min flow rate of sample through cartridge, 5:1 (m/v) of adsorbent with respect to sample volume, and 6 mL of methanol as elution solvent. The experimental procedure together with UPLC-MS/MS showed lower LODs between 0.2 – 0.5 µg/L with overall recoveries for five FQs more than 76%, and reusability of adsorbent was tested up to five times according to its constant recoveries. Although the enrichment and selectivity of targeted FQs were improved, the two-step process may be the limitation of this procedure.

A year later, the same group introduced a novel UVM-7 mesoporous silica modified with ɣ-CD as adsorbent for SPE for the isolation of ofloxacin, norfloxacin, and ciprofloxacin in milk samples [34]. UVM-7 material is the nanometric version of MCM-41 that has a macro and meso-pores on its structure. With the addition of CD into the structure, it will produce a truncated cone shape with hydrophilic part in the outside, and hydrophobic in the central part, making it capable to trap the host guest molecules. In this experiment, 10 mL of sample solution at pH 7 and addition of 2 M NaCl into the sample solution was used as the optimum condition for SPE. 100% of water as an efficient washing solvent was applied to remove any impurities clogging in the solid phase and 2 mL of acetonitrile as an elution solvent. Although the recoveries of extraction method were decreased between 60 – 70% due to the analytes losses during the treatment of sample, the result has a good precision to determine analyte under study in milk samples with high degree of confidence. The prepared adsorbent also showed that it is possible to reuse up to six times when dealing with real matrices.

Solid phase micro-extraction

Liu et al. 2019 successfully developed a series of β-CD with varied substituents and applied as supramolecular functional monomers for supramolecularly imprinted polymeric (SMIP) solid phase microextraction (SPME) coatings [47]. Their study showed supramolecular monomer β-CD as the promising adsorbents for the SPME of both nitrophenols and bisphenol A from water samples. The morphology of the prepared SMIP SPME coatings have been characterized by X-ray diffraction analysis (XRD), infrared analysis (IR), scanning electron microscopy (SEM), field emission SEM (FESEM), transmission electron microscopy (TEM) and atomic force microscopy (AFM) demonstrating that the ideal adsorbent has a greater number of pores (0.02 cm^3/g), enhanced intercommunity, and inclusion interaction from β-CD cavities, which boost molecular selectivity recognition. The relative accuracy for the extraction of target analyte from environmental water samples reported was from 88.2 to 90.2% with reusability of SMIP up to 100 cycles. The combination of SMIP technology with inclusion interactions contributed by β-CD cavities such as the hydrogen-bonding interactions, were the main contributions that enhance the extraction efficiency with reported LODs from 1.5 to 3 µg/L.

Another work by Celia-Ruiz et al. reported on β-CD modified nanocellulose (CD-NC) as an adsorbent material where β-CD was covalently bonded to amine-modified nanocellulose through amidation-reaction [35]. Supramolecular self-assembly of CD-modified NC by danofloxacin as guest molecule or target analyte showed excellent extraction efficiency and reusability with improved molecular recognition over its metabolite. These nanocavities with β-CD at its surface has greatly enhanced the SPME selectivity with recovery from 80 to 90% and LOD in milk samples was 2.5 µg/L. The combination of various molecular interactions, including H-bonding, dipolar interactions, and steric interactions between the hydroxyl groups of the CD and the analyte, contributes to the selective recognition of SPME packed mini column. The SPME was carried out using phosphate buffer solution with 12% acetonitrile as the eluent where all encapsulated target analyte was entirely stripped from CD-NC by electrophoretic analysis. The combination of H-bonding and dipolar interactions enabled the analyte to be further separated with higher extraction selectivity and CD-NC reusability, which has been reported to last up to 40 cycles.

Magnetic solid phase extraction and dispersive solid phase extraction

Since its first invention by Anastassiades et al. in 2003, the dispersive solid phase extraction (DSPE) technique has received tremendous attention among researchers due to its improvement on contact surfaces, enhanced adsorbent-analytes interactions, high extraction performance, low organic solvent consumption, and fast approach for extraction [62]. Native CDs such as α-, β- and γ-CD and their modified version have been notably applied in the separation analysis of various analyte compounds due to their explicit features which comprised of hydrophobic cavities and hydrophilic external surfaces as well as readily undergoing modifications. Cui et al. introduced a novel DSPE composite adsorbent prepared from ATP coupled with β-CD using glycidoxypropyltrimethoxysilane as a silane coupling agent for the quantitative determination of (fluoro)quinolones in real honey sample. The adsorption behavior is performed under acidic conditions to enable ion-exchange interactions since the quinolone antibiotic possesses cationic formation as a result of the protonation of carboxylic and amino groups in the quinolone heterocyclic ring. The recoveries of all targeted analytes improved when the ratio of ammonia in methanol increased up to 40%. Moreover, the utilization of β-CD/ATP composite-DSPE under optimum conditions achieved low LODs between the range of 0.30 to 3.95 mg L^{-1} with good recoveries between 83.6 – 88.6% and relative standard deviations (RSDs) less than 7.4%. Next, the applicability of the DSPE technique in real honey samples has successfully quantified the presence of four (fluoro)quinolones antibiotics which are ciprofloxacin, ofloxacin, gatifloxacin, and norfloxacin. The established sample preparation methodology using β-CD/ATP composite demonstrated excellent extraction efficiency due to its mesoporous feature as well as the contribution from the affinity of the hydrophobic cavity and hydrophilic external surfaces [36]. Zhang et al. synthesized porous β-CD polymer derived from CD and rigid aromatic groups tetrafluoroacetonitrile for the determination of quinolones using DSPE method. Several factors were optimized during the execution of the DSPE, including the amount of adsorbent, eluent and adsorption mount, and desorption time. The LODs of four quinolones antibiotics were obtained between 2.67 to 5.50 ng mL^{-1} with relative recoveries ranging from 96.43 to 103.3% and RSDs less than 4.5%. In addition, the robustness of the porous β-CD polymer-DSPE expressed its reliability of the method during normal usage with RSD less than 6.7%. Additionally, the established method offers low-cost extraction with good recoveries, comparable LOD with the commercialized adsorbent, and relatively wider linear range between 25 to 5000 ng mL^{-1} [52].

Magnetic solid phase extraction (MSPE) was first introduced by Šafařiková and Šafařik in 1999. It involves the use of a copper-coloured dye with an adsorbent containing a silanized iron magnetite. After the adsorbent has been absorbed, a magnetic field is then used to separate it from the sample solution. The extracted analytes are then eluted using a solvent that is suitable for the process. The eluent is then isolated from the adsorbent using a magnet. Over time, the use of the micro magnetic adsorbents that were originally developed for use with the MSPE (Figure 2) has since been replaced by more diverse nanosized adsorbents that are composed of hybrid or advanced materials [63]. Recent works showed that β-CD is usually functionalized with iron (II, III) oxide or magnetic nanoparticles with other material such as graphene oxide [49], chitosan [50], and silica [51] to enhance its selectivity in capturing those antibiotics compounds. Since MSPE has shown a great affinity towards analyte, with easy preparation steps, and be less messy and non-toxic, several works have been published to study the interaction between β-CD and antibiotics molecule. Two studies [37,48] functionalized β-CD with metal organic framework (MOF) to achieve the magnetic field capability. Both studies were on sulfonamide antibiotic using HPLC for analysis. Yang et al. [48] showed a good calibration curve ranging from 2 to 100 ng/mL with r^2 value more than 0.993. This method has a good sensitivity with LOD of 0.8 – 1.6 ng/mL. The satisfactory repeatability and reproducibility (RSD < 8%) and acceptable relative recoveries in the range of 78 – 112% were produced in chicken sample. A similar work was produced by Li et al. [37] to determine sulfonamide in meat sample. MSPE was performed on the meat sample using CD-MOF. The developed method showed a good linearity in acceptable concentration

with low detection limit of 0.32 ng/mL. The reproducibility gives a good value of RSD < 7% and acceptable recoveries (76 – 102%). Another work by Al-Afy et al. used combination of β-CD with magnetic graphene oxide coated using silica composite to extract tetracycline antibiotic from milk sample. The method showed a good LOD at 1.8 – 2.9 µg/L. This might be due to the preconcentration factor of 667. The high enrichment is from two extraction techniques applied in this work: DLLME followed by MSPE. The reproducibility and repeatability of method is within acceptable range (RSD < 8.8%) and recoveries (70.6 – 121.5%) [49]. In two previous studies [50,51], magnetic nanocomposites of CD were synthesized for the determination of fluoroquinolones in wastewater samples. Li et al. [51] determined the residue of fluoroquinolones using HPLC-MS/MS. They grafted the CD to magnetic silica composite to form Fe_3O_4@SiO_2@CD nanocomposite. Due to its core-shell sandwich structure, the analytes adsorb better on the adsorbent surface making a good detection limit at 0.0014 – 0.023 µg/L. A set of very good linearity was established ranging from 0.5 to 500 µg/L (r^2 > 09981). The method also noted a high precision (RSD < 4%) and analytes recoveries of 93.2 – 105%. Mashile et al. [50] used magnetic mesoporous carbon/β-CD-chitosan. The selective and sensitive method was based on affinity of CD enhanced by chitosan giving a low detection limit of 0.45 – 1.1 ng/L. Under optimized parameter, the used method showed a good linearity (0 – 300 µg/L, r^2 > 0.9979), robustness, accuracy, and precision (RSD < 4.4%) of fluoroquinolones in wastewater sample.

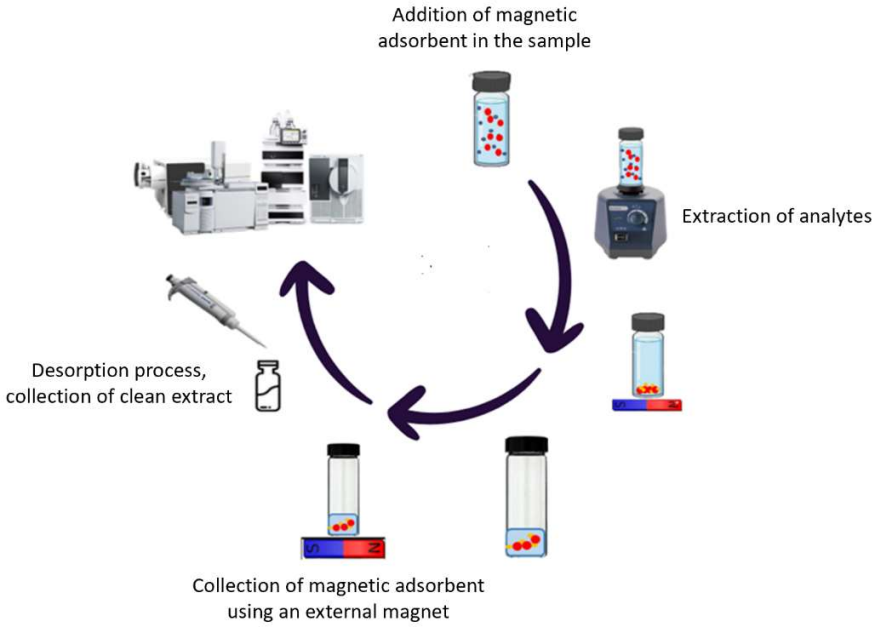

Figure 2. Schematic of MSPE process

Dispersive liquid-liquid microextraction

Dispersive liquid-liquid microextraction (DLLME) (Figure 3) is one of the liquid-based extraction techniques that involves dispersing tiny droplets of the extraction solvent throughout an aqueous sample. The exceedingly large collective surface area of the droplets allows for instant partitioning of analytes into the extraction phase. Compared to conventional liquid or solid phase extraction procedures, DLLME gives higher enrichment factors and minimal solvent consumption.

Hassan et al. developed a green method that utilizes deep eutectic solvent (DES) as a disperser/extraction co-solvent in the extraction of tetracyclines antibiotics (TCs) in water samples [31]. Hydrophobic DES octanoic acid/thymol and hydrophilic DES choline

chloride/ethylene glycol was synthesized and applied as extractant and disperser solvent respectively. The addition of β-CD in the extraction medium was to enhance its capability in higher extraction selectivity towards TCs. The dispersive effect of the extraction solvent and the stability of the murky solution were extremely higher with the addition of β-CD to DES. Furthermore, it has doubled the DLLME performance with higher recovery (74 – 113%) as compared to extraction solvent that only applied DES octanoic acid/thymol. The structure of β-CD that possesses a hydrophobic cavity and a hydrophilic external surface can interact with both hydrophobic/ hydrophilic DES. Through its hydrophobic cavity and hydrophilic surface, DES was dissolved during guest-host complexes formation and breaking into more fine droplets that maximized the contact surface of the analyte from aqueous into extraction medium. β-CD also acted as both co-extractants and co-disperser during the formation of supramolecular inclusion complexes (β-CD/TCs) and increased the selectivity during TCs migration from the sample solution. The extraction was analyzed with HPLC-DAD in environmental samples with reported LODs from 1.37 to 3.48 µg/L.

Another work by Nour Al-Afy et al. applied two types of sample preparation in combination: magnetic-SPE and DLLME in quantitation of tetracyclines (TCs) antibiotic in bovine milk samples [49]. The β-CD (Fe_3O_4@SiO_2@GO-β-CD) as the adsorbent material with the hydrophobic TC's aromatic ring can freely fit into the cavity of the β-CD and formed a strong and stable host-guest combination. The hydrophobic-hydrophobic interaction was the main factor in the inclusion complex within the inner side of the β-CD cavity instead of the amine and amide groups from TCs that was unfavorable to the formation. The hydrophilic adsorbent's structure had polar groups that made it faster to dissolve in a polar solvent, with methanol working as the best desorption solvent toward the extraction of TCs in milk samples. DLLME was utilized as the subsequent sample extraction, and it was discovered that n-hexane was the best dispersant since it was water-insoluble (low density) and offered a high enrichment factor for 667 with a cleaner baseline in the chromatogram. Fe3O4@SiO2@GO-β-CD is a favorable adsorbent due to its great ability to extract TCs from milk samples with recovery rates ranging from 70.6 to 121.5% in milk samples and from 78.5 to 109.3% in water samples. This proposed method offered high precision (RSD < 8.8%), satisfactory recovery and improved preconcentration factor with reported LODs ranged from1.8 to 2.9 µg/L.

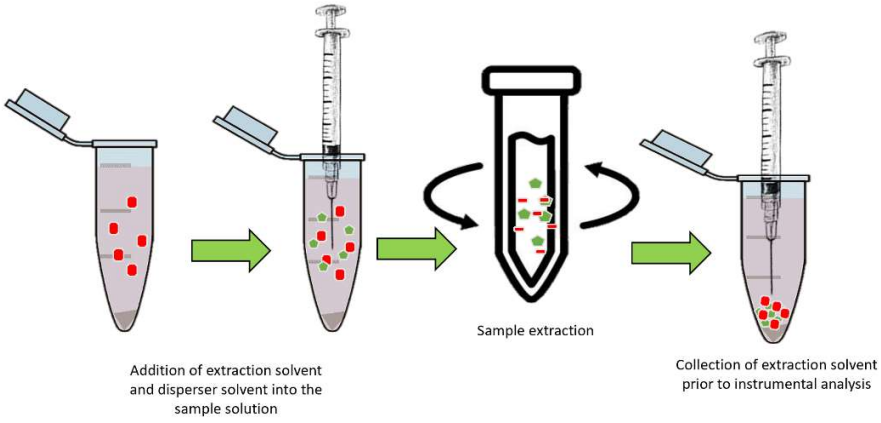

Figure 3. Schematic of DLLME process.

Table 3. The recent applications of CD-based adsorbents in sample preparation for the determination of antibiotics in various matrices.

Adsorbent	Extraction techniques	Quantitation instrument	Analytes	Sample matrix	Linearity	LOD	RSD (%)	Relative Recovery / Recovery (%)	Pre-Con factor	Reusability	Ref
β-Cyclodextrin-functionalized magnetic covalent organic framework (Fe_3O_4@COF@Au-β-CD)	MSPE	HPLC-MS/MS	Sulfonamides	Chicken	2-100 µg/kg, R^2 = 0.9936	0.8-1.6 µg/kg	2.4 – 8.6	78- 112	20	-	[48]
β-cyclodextrin functionalized silica-coated magnetic graphene oxide (Fe_3O_4@SiO_2@GO-β-CD)	MSPE	HPLC-DAD	Tetracycline	Bovine milk	10-200 µg/L, R^2 = 0.9929	1.8-2.9 µg/L	< 8.8	70.6 – 121.5	667	15	[49]
Magnetic mesoporous carbon/β-cyclodextrin–chitosan	DMSPE	HPLC-DAD	Fluoroquinolone	Wastewater	3.7-1000 ng /L, R^2 = 0.9979-0.9990	0.45-1.1 ng/L	< 4.4	93.5 – 98.8	90 – 150	-	[50]
cyclodextrin-derivatized hybrid magnetic nanocomposite (Fe3O4@SiO2@CD)	MSPE	HPLC-MS/MS	Fluoroquinolone	Water	0.5-500, µg/L, R^2 = 0.9981 - 0.9998	0.0014-0.023 µg/L	<4	93.2 – 105		5	[51]
CD-MOF	MSPE	HPLC-DAD	Sulfonamide	Meat	10-1000 ng/mL, $R^2 \geq 0.9907$	0.32-2.0 ng/mL	< 7	76 – 102	-	-	[37]

**Abbreviations: MSPE – magnetic solid phase extraction, SPME – solid phase microextraction, DLLME – dispersive liquid-liquid microextraction, DSPE – dispersive solid phase extraction, SPE – solid phase extraction, HPLC-MS/MS – high performance liquid chromatography tandem mass spectrometry, HPLC-DAD – high performance liquid chromatography diode array detector, LC-FLD – liquid chromatography fluorescence detector, UPLC-MS/MS – ultra performance liquid chromatography tandem mass spectrometry*

Conclusion

The present review discussed the development of sample preparation techniques of antibiotic molecules using CD-based adsorbents. Overall, in most of the synthesis methods, the CD is attached to the adsorbent via a linker. It was noted that β-CD has been commonly used and prepared as an adsorbent in the sample preparation of antibiotic molecules, compared to other types of CDs. CD is at advantages in terms of green adsorbent as it is easy to prepare, flexible to functionalize, and improve selectivity and efficiency of extraction. Antibiotic molecules that are of the right size to enter CD cavity will exhibit higher extraction efficiency. The CD-based adsorbents offer advantages such as selectivity, versatility, efficient extraction, reduced matrix interference, compatibility with various techniques, and enhanced sensitivity. These factors make them promising adsorbents for sample preparation in the determination of targeted compounds, enabling more accurate and reliable analytical results. Future research would likely be towards the improvement of functionalities of the developed adsorbents through (a) the preparation of amphiphilic adsorbents towards variety polarity of targeted molecules, (b) use of a mixture of CDs in the preparation of adsorbents that can expand their use and efficiency, (c) production of new generation of selective CD materials with molecularly imprinted technology, and (d) combination of CD with other nanomaterials to improve their properties such as surface area, stability, and selectivity. It can be summarized that there has been a rapid development in the extraction and enrichment techniques for antibiotic molecules using CD-based materials, which were useful for monitoring antibiotics and have the potential to reduce the environmental pollution and eliminate food-chain contaminations. In the following years, an increase in the number of advanced greener sorbents and green sample preparation methods designed for monitoring antibiotics can be expected with the ultimate goal to prevent the development of antibiotic resistance phenomenon.

Abstract

pH plays an important role in microplastics (MPs) removal during the electrocoagulation (EC) process. This study investigates the influence of the initial pH on the removal of polypropylene microplastics (PPMPs) from artificial wastewater using an EC process utilizing nickel electrodes. The effect of the initial pH has been investigated by commencing several sets of continuous flow experiments at five different initial pH values (2, 4, 6, 8, and 10), keeping the concentration of PPMPs, size of PPMPs, and electrode distance constant at 250 ppm, 250 µm, and 2 cm, respectively. The results showed that the removal efficiency increased gradually from 25% at initial pH 2 and reached its maximum level at initial pH 8 with 67% removal. Then it slightly decreased as the initial pH increased to 10. The kinetic studies showed that the EC process followed a first-order kinetic model. It can be said that the most favorable supporting pH for PPMPs removal utilizing nickel electrodes in this EC treatment technique is pH 8 due to the predominant species having a high adsorption capacity for PPMPs as a pollutant. The result showed that pH plays an important role in PPMPs removal from wastewater via the EC process utilizing nickel electrodes.

Keywords: Electrocoagulation, polypropylene, microplastics, nickel electrode, pH

Abstrak

pH memainkan peranan penting dalam penyingkiran mikroplastik melalui kaedah elektrokoagulasi. Kajian ini dilaksanakan bagi melihat pengaruh pH terhadap penyingkiran mikroplastik polipropelena (PPMPs) daripada air buangan melalui kaedah

elektrokoagulasi (EC) menggunakan elektrod nikel. Pengaruh pH telah disiasat melalui beberapa set eksperimen menggunakan lima pH awal yang berbeza (2, 4, 6, 8 dan 10) dengan mengekalkan masing-masing kepekatan PPMPs, saiz PPMPs, dan jarak elektrod pada 250 ppm, 250 µm, dan 2 cm. Keputusan yang diperolehi menunjukkan bahawa kecekapan penyingkiran meningkat secara beransur-ansur daripada 25% pada pH awal 2 dan mencapai tahap maksimum pada pH awal 8 dengan penyingkiran 67%, kemudian ia sedikit menurun apabila pH awal meningkat kepada 10. Kajian kinetik menunjukkan bahawa proses EC adalah mengikut model kinetik tertib pertama. Boleh dikatakan bahawa pH sokongan yang paling sesuai untuk penyingkiran PPMPs menggunakan nikel sebagai elektrod dalam teknik rawatan EC ini ialah pH 8 disebabkan oleh, spesis utama mempunyai kapasiti penjerapan yang tinggi untuk PPMPs sebagai bahan pencemar. Keputusan menunjukkan bahawa pH memainkan peranan penting dalam penyingkiran PPMPs daripada air sisa melalui proses EC menggunakan elektrod nikel.

Kata kunci: Elektrokoagulasi, polipropelena, mikroplastik, elektrod nikel, pH

Introduction

The rapid growth of industrialization has resulted in the extensive use of plastic products in industry, agriculture, and life globally. The world's annual plastic production is expected to reach 3.3 x 10^{10} tonnes by 2050, with most of the plastic (estimation of 1.15 x 10^{6} - 2.75 x 10^{6} tonnes) will end up in the water every year [1,2]. This plastic waste breaks down into smaller plastic through photooxidation, mechanical action, and biodegradation over an extended period of time [3]. Plastic with less than 5 mm particle size is known as microplastics (MPs). Most MPs have been found in the water and generate annual economic losses to marine ecosystems [4]. The presence of MPs in natural waters is cause for concern due to their possible adverse health effects on the environment and humans [5]. MPs are hard to degrade and can exist in water for a long time. The presence of abundant chemical bonds and functional groups, a large specific area, and small size provide MPs have certain adsorption behavior toward heavy metal, organic and inorganic pollutants, thus producing complex secondary pollutants with high toxicity [6,7]. Due to their toxicity, MPs may affect animal and human health by entering the circulatory system, affecting immune response, causing neurotoxicity, and increasing human cancer risk [8]. As a result, extensive research has been conducted on MPs as a new type of emerging pollutant. Wastewater treatment plants (WWTPs) are one of the primary sources of MPs contamination [9, 10]. It was estimated that the WWTPs discharge between 50,000 and 15 million MPs daily [11]. Due to their small size (<5 mm) and low density (<1.2 g/cm^3), MPs are not completely eliminated by standard wastewater treatment techniques and are discharged to natural bodies of water together with the final effluent [3]. Hence, it is crucial to have an alternative removal method to expedite the MPs removal to overcome the limitation in the WWTPs.

Electrocoagulation (EC) method has become the focus of interest among researchers as one of the potential methods for the removal of MPs from wastewater due to its simplicity, low-cost method with environmental compatibility, energy efficiency, and sludge minimization [6,12]. EC involves the electrochemical dissolution of a metal electrode to produce metal ions [13]. These metal ions, produced at the anode, combine with hydroxide ions to form metal hydroxide coagulants. The coagulants enable the production of flocs by neutralizing the oppositely-charged colloidal particles floating in the solution and by adsorbing the dissolved pollutants. Flocs with high specific gravity will sink to the bottom of the reactor, where they will be removed through filtration, whereas lighter flocs will float to the solution's surface and be removed using skimming devices [14].

The most commonly used sacrificial anode in EC is aluminum and iron due to their low price, abundant availability, and high reactivity towards the removal of contaminants. However, these electrodes suffer the limitation of producing a high amount of sludge, corrosion, and degradation over time. Therefore, the search for new electrode material is strongly encouraged. Nickel (Ni) offers advantages as an electrode material due to increased efficiency by having higher oxidation potential, reduced corrosion, and lower sludge production. Nonetheless, the use of Ni electrodes in EC remains largely unexplored. Another critical factor that affects the EC process is the pH of the

solution, as it can impact the performance and efficiency of the EC. pH affects the stability and behavior of different hydroxide species produced in the EC process, thus influencing the formation of flocs. Hence, it is important to understand the effect of pH and relate it to the performance of the EC process.

In this work, Ni electrodes were used to investigate the effect of pH on the removal of PPMPs. A series of pH-dependent (pH 2 to pH 10) studies were examined using an EC process using a Ni electrode. The effectiveness of Ni electrodes for PPMPs removal was evaluated based on their removal efficiency (%RE). To the best of our knowledge, only a few researchers have used Ni electrodes in the EC process. Our findings suggest that turbidity monitoring for the influence of pH can provide reasonable optimization of water treatment strategies for effective MPs removal.

Materials and Methods

Materials

Commercial Ni foil (99.99%) with a thickness of 0.3 mm and a length of 4 cm x 1 cm was used as electrodes. The electrodes were cleaned with acetone, ethanol, and deionized water under sonication to remove surface grease and impurities on the electrode surfaces. This study used polypropylene microplastics (PPMPs) prepared from fully aged polypropylene storage boxes as the pollutant. The fully aged polypropylene storage boxes were cleaned and shade dried for 5 days at room temperature. After 5 days, the polypropylene was shredded into small pieces and sieved to 250 µm. The pH of the solution was adjusted using 0.1 M NaOH (99%, QReC) and HCl (37%, QReC). Turbidity measurement was conducted using a Hach 2100Q turbidity meter. The resolution of the turbidity meter was ±0.01 NTU. An air pump (Xilong) and DC power supply (PHYWE) were used in this work.

Electrocoagulation process

The PPMPs removal study was investigated using the EC method, as shown in the schematic diagram in Figure 1. The EC system consists of a reactor, a pair of Ni electrodes, a DC power source, and an air pump. The effect of pH on the removal of PPMPs was evaluated using Ni foil with a length of 4 cm x 1 cm as electrodes. The distance between the two electrodes was set at 2 cm. At this stage, the concentration of PPMPs (250 ppm), the volume of the reactor (150 mL), voltage (60 V), and reaction time (30 min) were kept constant. The pH of the solution was adjusted to pH 2, 4, 6, 8, and 10 using 0.1 M of NaOH and HCl, respectively. Air gas flow using an air pump was continuously supplied to the solution to ensure the dispersions of the PPMPs. As to ensure the results of the experiments are reproducible, the experiments were run in triplicates. After the EC process, the floc was allowed to settle for 10 min before measurements were performed. A 15 mL of the sample from the middle of reactor was taken every 5 min (up to 30 min) to study the sedimentation rate. The sample was analysed using a turbidity meter to measure its turbidity. The PPMPs removal efficiency and kinetics studies at different pH (2–10) were analyzed based on equations 1, 2, and 3. The performance at the optimized condition was obtained and used to compare their performance with other studies.

$$\text{Removal efficiency (\%)} = \frac{Turb_{\circ} - Turb_{i}}{Turb_{\circ}} \times 100\% \quad (1)$$

$$\text{Pseudo-first order kinetic} = kt + \ln\left(\frac{Turb_o}{Turb_i}\right) \quad (2)$$

$$\text{Pseudo-second order kinetic} = kt + \left(\frac{1}{Turb_i}\right) - \left(\frac{1}{Turb_o}\right) \quad (3)$$

where $Turb_o$ is the initial turbidity, $Turb_i$ is the ultimate turbidity at time t, and k is the sedimentation rate constant. For this part, the turbidity of the solution was measured at 5 mins intervals for 30 min. From the data collected during the turbidity test, the removal efficiency, reaction rate, and kinetics of PPMPs removal can be determined.

Results and Discussion

Effect of pH

The pH of the solution is one of the main factors that can affect wastewater treatment efficiency in the EC process. In this study, the effect of initial pH on the MPs removal by Ni electrodes was explored in the range of initial pH values of 2-10. Figure 2(a) shows the removal efficiencies (%) of PPMPs at different reaction times with 5 min time intervals as a function of pH with the initial pH solution range of 2 to 10, and Figure 2(b) shows the removal efficiencies (%) of PPMPs at optimum reaction time (30 min). The experimental result indicates successful removal of PPMPs with a maximum removal efficiency of 67% was observed at pH 8. At pH 8, the anodic oxidation of the metal to insoluble metal hydroxide/oxyhydroxide predominates, leading to high floc formation and high PPMPs removal efficiency [16]. The optimum removal at pH 8 shows that this method can be used to treat ordinary domestic wastewater without the need to adjust the pH, as the pH of domestic wastewater is usually between pH 6-9.2 [12].

Figure 3 displays the zeta potential value of MPs suspension after EC. The zeta potential was positive at pH < 3 and has a negative surface charge at pH values >3. The negativity of the surface charge increases with increasing pH value. The isoelectric point (point of zero charges) was determined to be approximately at pH 3.21. The lower removal efficiency was observed below pH 3 at positive zeta potential due to electrical repulsion between the particles of similar charges, which prevents aggregation [15]. At high pH, the $Ni(OH)^{-}_3$ and $Ni(OH)^{2-}_4$ may be the predominant species that cannot be adsorbed or attached to the negatively charged surface, thus reducing the MPs removal efficiency. The same experimental trend on the effect of pH has also been reported by Kartikaningsih et al. [16] for the EC of boron using Ni foam electrode, where the maximum boron removal was observed at pH 8-9. In acidic pH, the low removal efficiency was observed due to the passivation of the electrode at a potential that was more positive than the Nernst-related value and was favored over the dissolution of the nickel electrode; thus, floc formation was not conducive and had low adsorption capacity for PPMPs [17]. A downward trend was observed at pH 10 with a removal efficiency of 28% owing to the fall in the over-potential of oxyhydroxide formation at high pH.

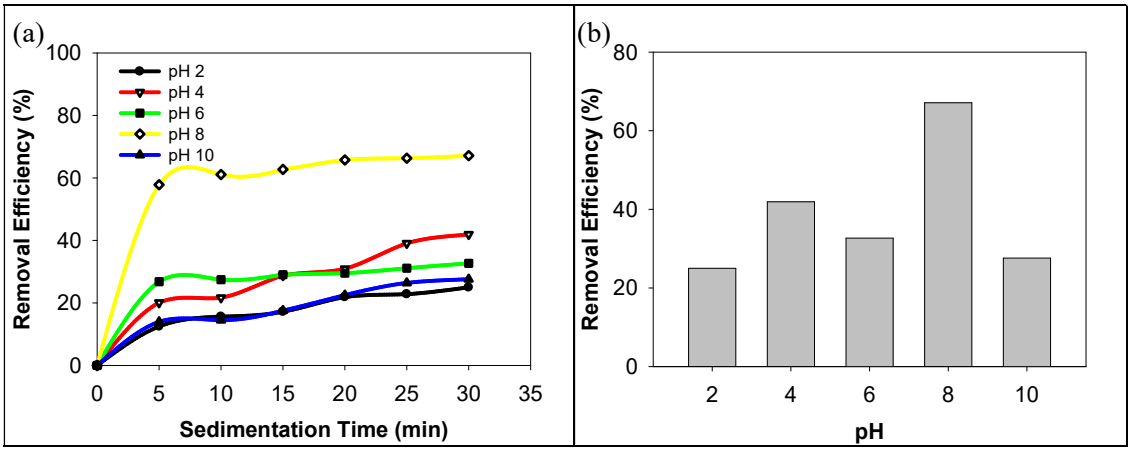

Figure 2. Effect of pH on removal efficiencies of PPMPs (a) at different reaction times and (b) at optimum reaction times

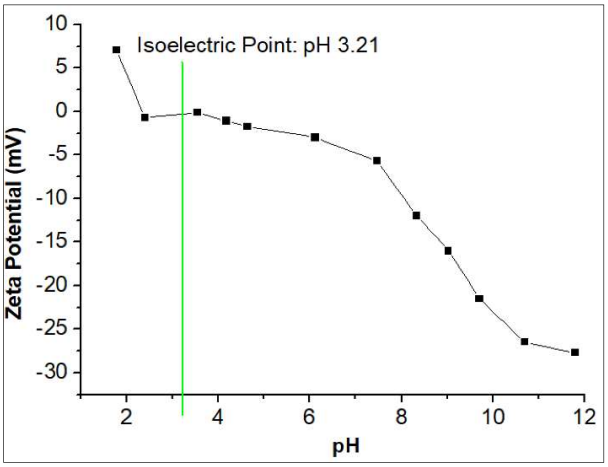

Figure 3. pH equilibrium (isoelectric measurement) for the MPs suspension after EC

As for the sedimentation behavior, it was observed that as the pH increased, the sedimentation increased, thus reducing the turbidity of the solution and resulting in higher removal efficiencies. The sedimentation was found to decrease with decreasing pH of the solution. This may be due to lesser floc formation at low pH leading to poor settling behavior. A similar effect of sedimentation for EC using Fe electrodes has been reported earlier by [18]. In the EC system, the precipitates are created by the oxidative dissolution of the metal from the anode surface's electrical double-layer structure, which is followed by the precipitation of metal hydroxides around the corrosion site [19]. The reaction is given in equations 4-6 below:

$$Ni \rightarrow Ni^{2+} + 2e^{-} \text{ (anodic dissolution)} \quad (4)$$

$$2H_2O + 2e^{-} \rightarrow 2OH^{-} + H_2 \text{ (cathodic hydrogen evolution)} \quad (5)$$

$$Ni^{2+} + 2OH^{-} \leftrightarrow Ni(OH)_2 \text{ (s) floc} \quad (6)$$

The metal undergoes anodic dissolution to produce metal ions. These metal ions then react with OH^{-} ions generated at the cathode to form different hydroxides to form flocculant. The low degree of the flocculant can remove the MPs by adsorption, while the high degree polymerization flocculant can capture and sweep MPs particles by netting because of its large surface area and many surfaces group [6].

Kinetic studies

The kinetic studies on PPMPs removal at different pH were also investigated using pseudo-first-order and pseudo-second-order kinetic models, as shown in Figures 4(a)-(e). The parameters of the pseudo-first-order and pseudo-second-order kinetic model are summarized in Table 1. For the first-order kinetic model, the straight linear line plot proves a good agreement of experimental data with R^2 of more than 0.95, which suggest that the PPMPs removal followed a pseudo-first-order kinetic model. The kinetics rate constant, *k,* was calculated from the slope of the plot and is given in Table 1. The value of *k* at the optimum pH is 0.0136 min^{-1} with the coefficient of determination (R^2) of 0.9923. However, the set of correlation coefficient (R^2) values obtained from the second-order-kinetic model was poor, suggesting that the removal of PPMPs is not a second-order-kinetic reaction.

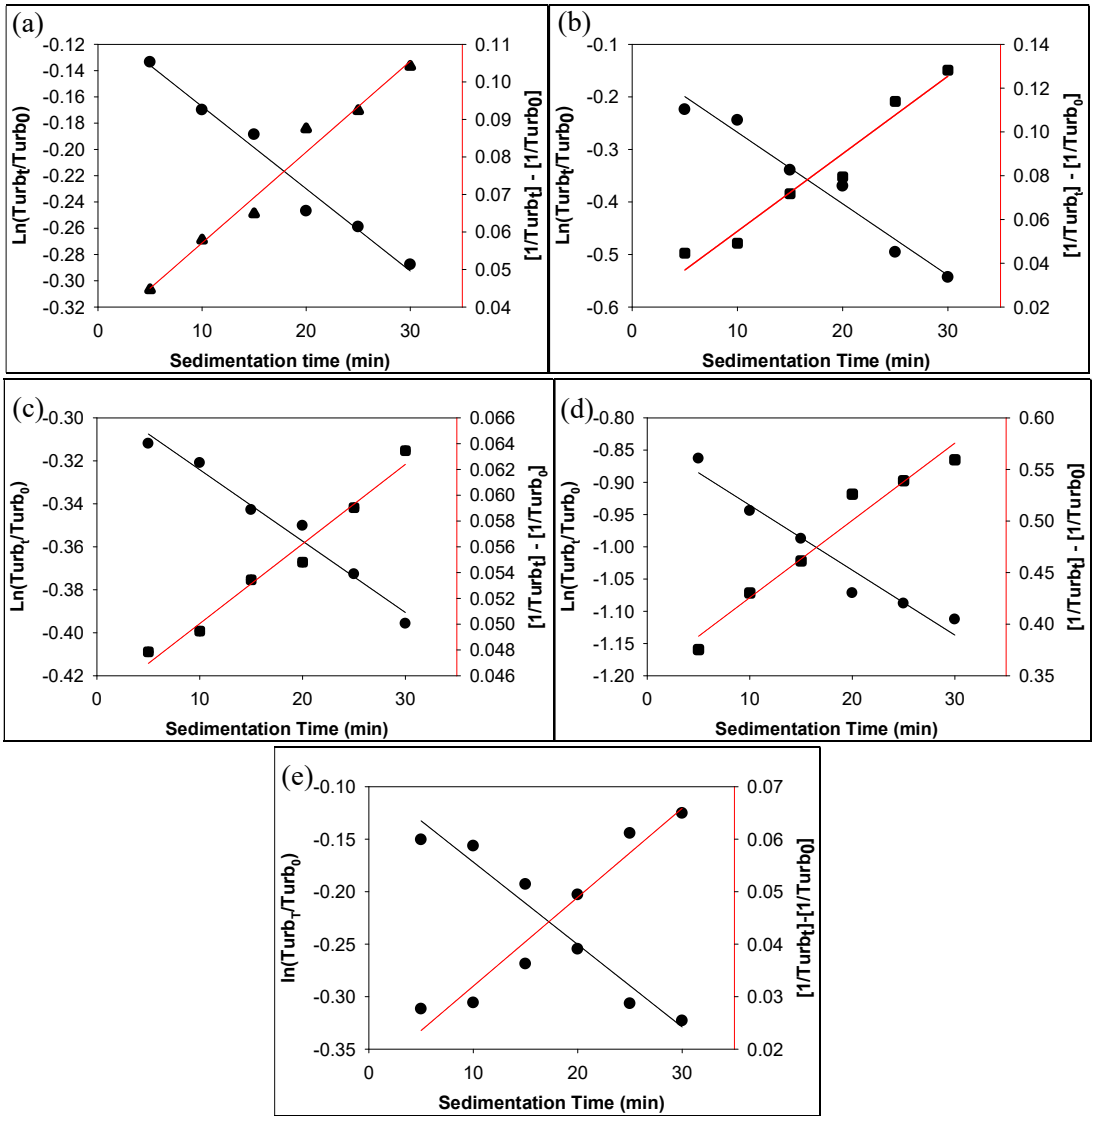

Figure 4. Pseudo-first-order (black line) and pseudo-second-order (red line) kinetics (a) pH 2 (b) pH 4 (c) pH 6 (d) pH 8 (e) pH 10

Table 1. Pseudo-first-order and pseudo-second-order rate constant

pH	Pseudo-first-order		Pseudo-second-order	
	Reaction Rate, k (min^{-1})	R^2	Reaction Rate, k (min^{-1})	R^2
2	0.0065	0.9729	0.0024	0.9220
4	0.0138	0.9639	0.0370	0.9752

Comparative studies on the effect of pH

Many researchers have reported on the use of EC to treat various pollutants. However, only a few studies focused on removing MPs via EC. Comparative experimental results of MPs from the literature and the result of this study are summarized in Table 2. The effect of pH on the EC process is commonly reported as one of the important parameters affecting microplastic removal efficiencies. However, most of this study focused on using conventional electrodes of Al and Fe in the EC process. Each MP is likely to respond differently to EC by the different electrodes. The results show that the EC process favors neutral pH of 7-8 for optimized MPs removal. Neutral to slightly basic pH was more conducive to the formation of floc. The floc formed gradually increased and improved the removal rate of MPs. Complete removal of PE was reported by Akarsu et al. [20] at pH 7 by utilizing an electrode combination of Al-Fe and Fe-Al. The use of different electrode combination improves the EC process and contribute to the successful removal of PE. The removal efficiencies of PPMPs in this study are lower compared to the other studies as we use the single Ni electrode without modification and shorter contact time. These are our preliminary results, and now we are focusing on improving the performance of MPs removal using Ni electrodes via the EC process by investigating the effect of other variable parameters, including the modification of the surface of Ni electrodes. The use of composite nickel electrodes may also be considered to improve the removal efficiencies of PPMPs.

Table 2. Studies on the effect of pH on microplastic removal

Electrode Material	Type of MPs	Optimum pH	Contact Time (min)	Removal Efficiency (%)	Ref
Al-Fe	PE	7.0	10	100	[20]
Al	Polyester	4.0	90	98.5	[3]
Al	PP	7.2	360	98.4	[6]
Al	PE	7.5	60	99.2	[12]
Ni	PP	8.0	30	67.0	This study

Conclusion

In this paper, the effect of pH on the removal efficiency of PPMPs via EC utilizing Ni electrodes was experimentally investigated. This is one of the early studies on this subject. A 67% removal efficiency followed a first-order- kinetic model with the kinetics rates constant (k) of 0.0136 min^{-1} with the coefficient of determination (R^2) of 0.9923 was achieved with EC using Ni electrode at 30 min reaction time which is in line with other studies. The findings suggested that EC technology is an effective method to remove MPs from simulated wastewater. However, studies should be further extended to improve the removal efficiency of PPMPs. It is suggested to modify the Ni electrode to improve its properties and optimize the EC parameter to boost its performance. Further research should focus on developing composite electrode for EC, as previous studies show that composite electrode provides excellent performance compared to a single electrode.

Abstract

Palm oil products (POP), *i.e.*, crude palm oil (CPO), crude palm kernel oil (CPKO), refined, bleached, and deodorized (RBD) palm oil (RBDPO), and RBD palm olein (RBDPOo), are among the most highly traded POP in the world. Therefore, the quality and biodegradability of POP need to be assessed to ensure the traded POP is safe to consume and environmentally friendly. This paper investigates the physicochemical properties of POP, including moisture, slip melting point, iodine value, fatty acid content, and free fatty acid, using MPOB p2.1:2004, AOCS C c3-25, AOCS Cd 1d-92, AOCS Ce 1a-13, and MPOB p2.5:2004 test methods, respectively. Analysis showed that all the POP were within the requirements as specified by the Malaysian Standards, the Palm Oil Refiners Association of Malaysia (PORAM), the Malayan Edible Oil Manufacturers' Association (MEOMA), Codex Alimentarius, and the Malaysian Palm Oil Association (MPOA). Meanwhile, the biodegradability assessment of these POP in the marine environment was carried out according to Organization for Economic Co-operation and Development (OECD) 306, Biodegradability in Seawater test method, using the closed bottle method. The results indicated that CPO, CPKO, RBDPO, and RBDPOo can be degraded in temperate marine water at 74%, 70%, 75%, and 72%, respectively.

Abstrak

Produk minyak sawit (POP), iaitu minyak sawit mentah (CPO), minyak isirung sawit mentah (CPKO), minyak sawit ditapis, diluntur dan dinyahbau (RBDPO) dan minyak sawit olein RBD (RBDPOo), adalah antara POP yang terkenal dan diperdagangkan di dunia. Oleh itu, kualiti dan kebolehbiodegradan POP perlu dinilai untuk memastikan POP yang diperdagangkan selamat untuk dimakan dan mesra alam. Kajian ini menyiasat sifat fizikokimia POP, termasuk lembapan, takat lebur gelincir, nilai iodin, kandungan asid lemak dan asid lemak bebas menggunakan kaedah ujian MPOB p2.1:2004, AOCS C c3-25, AOCS Cd 1d-92, AOCS Ce 1a-13 and MPOB p2.5:2004. Analisis menunjukkan bahawa semua POP berada dalam perincian seperti yang ditetapkan oleh Jabatan Standard Malaysia, Persatuan Penapis Minyak Sawit Malaysia (PORAM), Persatuan Pengilang Minyak Masak Malaysia (MEOMA), Codex Alimentarius dan Persatuan Minyak Sawit Malaysia (MPOA). Sementara itu, penilaian kebolehbiodegradan POP ini dalam persekitaran marin telah dilaksanakan mengikut kaedah ujian Organisasi bagi Pembangunan

dan Kerjasama Ekonomi (OECD) 306, Biodegradasi dalam Air Laut, menggunakan kaedah botol tertutup. Keputusan menunjukkan bahawa CPO, CPKO, RBDPO and RBDPOo boleh terdegradasi dalam air marin sederhana dengan 74%, 70%, 75% and 72%, masing-masing.

Introduction

Palm oil is an edible vegetable oil derived from the flesh or pulp (mesocarp) of palm fruits through the milling process and has been used for various purposes, including in food and non-food applications. Malaysia is a prominent exporter of palm oil since it represents 18.3% of the global oils and fats, thus contributing to 34.3% of the total palm oil trade in 2020 [1]. Meanwhile, in 2021, Malaysia exported 24.27 million tonnes of POP to various destinations, with more than 1.6 million tonnes exported to EU countries [2]. Further processing of crude palm oil (CPO) involves the removal of the products of hydrolysis and oxidation, color, and flavor for the production of refined products, *i.e.*, refined, bleached, and deodorized (RBD) palm oil (RBDPO) and RBD palm olein (RBDPOo), which are mainly used as cooking oil and in margarine, confectionery, non-dairy creamer, shortening, and others [3]. RBD palm kernel oil (RBDPKO) from CPKO has also been used in the same manner as CPO and in the production of oleochemical derivatives, *i.e.*, fatty acids, fatty amines, fatty alcohols, fatty methyl esters, and glycerin. These derivatives are mainly utilized as raw ingredients in the cosmetics, personal care, and household sectors for products including balms, lipsticks, soaps, detergents, and cleaning agents [3].

As product development and improvement evolve rapidly, it can be expected that there will be an increasing demand for quality improvement from consumers and their end-users. From a commercial point of view, quality is a valuable and significant attribute in edible oil commodities and their trades. Hence, it can be predicted that the trading specifications will become broader and more stringent over time. This will require reliable and accredited analysis methods to meet all statutory requirements. Failure to comply with quality specifications could affect the acceptance of the traded oils. In order to assess the quality of POP, several physicochemical analyses need to be conducted, including moisture, free fatty acid (FFA), iodine value (IV), fatty acid content (FAC), and slip melting point (SMP) [4].

Moisture is one of the most prevalent contaminants in POP. It is necessary to ensure the moisture content of POP is within the permitted limit since a high moisture content would affect hydrolytic stability [5]. In addition, some palm oil products tend to have a considerable amount of moisture and impurities due to insufficient processing, which may accelerate the microorganism's activities [6]. Besides moisture content, the amount of FFA is also a significant measure of the quality of POP since it is related to the economic value of edible oils [7]. In general, FFA is formed during oil storage through the reaction of oil and water, and a high level of FFA content implies poor POP quality [8].

The IV measures the degree of unsaturation [9] or double bonds in POP, which indicates the susceptibility of the oils to oxidation [10]. Meanwhile, the SMP is prevalently applied to analyze the melting and solidification properties of oil samples, at which the temperature of the solidified oil turns into fluid and flows into an open capillary tube [11]. The determination of SMP varies with the fatty acid chain length, trans fatty acid composition, and position of the fatty acids in the glycerol backbone, as well as unsaturation ratios [12].

Fatty acids can be classified according to their degree of saturation, *i.e.*, saturated or unsaturated fatty acids. Unsaturated fatty acids are either monounsaturated or polyunsaturated. Fatty acids play an important role in the oil and fat industry due to their health implications in the human diet and properties in industrial processes. Previous literature demonstrated the importance of the fatty acid content (FAC) of the oil in determining the biodegradation of vegetable oils [13-14]. The valuable data on the FAC of POP is also crucial since the type of fatty acids will determine the oil's nutritional status and storage stability. A previous study showed that POP was

stable up to 10 months of storage time at a low temperature of 6 ± 2 °C, indicating that these POP are suitable to be used as control samples for validation of test results [15].

Apart from the physicochemical properties, biodegradability is also considered a critical criterion for evaluating the behavior of substances or products in the environment. Assessment of the biodegradability of POP is deemed worthy since it is well known that vegetable oils, especially palm oil, are one of the most traded commodities transported *via* sea, and there is the possibility of oil spillage even though it is comparatively rare in the marine environment in comparison to mineral oil. Several incidents of accidental oil spillage caused by vessel accidents have been reported, with the most recent incidents occurring in Chinese waters, where about 9,000 tonnes of palm oil stearin were spilled. [16]. Vegetable oils are bulk liquid substances regulated as chemicals under the International Convention for the Prevention of Pollution from Ships (MARPOL) Annex II [17].

According to the GESAMP Composite List 2019 [18], most vegetable oils, including canola, sunflower, olive, and palm oils, are readily biodegradable. However, the conditions, as well as the rate of biodegradation, are yet to be revealed. Research conducted on the biodegradation of natural oils in seawater, *i.e.*, mustard, canola, and olive oil [19], revealed that canola oil could be easily degraded, followed by mustard and olive oils. The different trends in bacterial numbers were observed for the different types of oil. Most of the oil samples showed high bacterial numbers within 7 to 15 days of the biodegradation test, indicating that the oil samples are nontoxic and that the biodegradation process occurred rapidly in seawater. There was also research conducted on the microbes that possess the unique ability to bioremediate fat-containing waste. In this study, the marine strain, *Rhodococcus erythropolis* PR4, showed the potential to convert animal fats and vegetable oils into fatty acid methyl ester (FAME) derivatives in a relatively short time [20]. There was also a study on an isolated soil microbe, *Acinetobacter sp.* strain SOD-1, capable of degrading salad oil, which consists of soybean and rapeseed oil [21]. *Pseudomonas otitidis* strain was able to hydrolyze sunflower cooking oil to produce lipase [22]. Previous research on the degradation of CPO and CPKO in seawater using the modified shake flask method revealed an increase in bacterial population that peaked on days 7 and 21 before declining, indicating that palm oil is being used as a substrate for bacterial growth amidst degradation, which is aided by the lipase enzyme produced by selected bacteria [23].

The biodegradation test is crucial to assessing the biodegradation of substances in various environmental compartments. According to the OECD, Biodegradability in Seawater (OECD 306) and Marine BODIS test guidelines are frequently used to determine the biodegradability of substances in seawater, where the degradation of a substance is assessed by the measurement of dissolved oxygen over 28 days of the test period. This study aims to assess the physicochemical properties of POP under investigation, *i.e.*, moisture, FFA, IV, FAC, and SMP, using the American Oil Chemists Society (AOCS) and the Malaysian Palm Oil Board (MPOB) test methods, as well as the biodegradability of POP in the marine environment according to standard method OECD 306, Biodegradation in Seawater *via* the closed bottle method. This study can be used as a database in the event of an accidental oil spill.

Materials and Methods

The standard grade of palm oil products (POP), CPO, CPKO, RBDPO, and RBDPOo were obtained from Sime Darby Jomalina Sdn. Bhd., Selangor, Malaysia. All chemicals and solvents were utilized as received without further purification. Sodium acetate was used as a reference substance to check the validity of the test procedure and the suitability of the seawater used. A non-ionic surfactant, octylphenoxypolyethoxyethanol (IGEPAL CA-630), was used to emulsify the oil samples since they are insoluble in water.

Natural seawater was collected directly from Lowestoft, United Kingdom, and transferred into the laboratories through a pipe that extends below the sand some distance into the bay. The seawater was decanted and then filtered using Whatman 54 filters. Prior to the start

of the test, the seawater was equilibrated to the test temperature, which is 15-20 °C. Meanwhile, for the preparation of mineral stock solution A, potassium dihydrogen orthophosphate, KH_2PO_4 (8.50 g), dipotassium hydrogen orthophosphate, K_2HPO_4 (21.75 g), disodium hydrogen orthophosphate heptahydrate, $Na_2HPO_4.7H_2O$ (50.30 g), and ammonium chloride, NH_4Cl (0.50 g) were dissolved in water and made up to 1 L. Solution B was prepared by dissolving magnesium sulphate heptahydrate, $MgSO_4.7H_2O$ (22.50 g), in water and made up to 1 L. Solution C was prepared by dissolving calcium chloride dihydrate, $CaCl_2.2H_2O$ (36.40 g), in water and made up to 1 L. As for solution D, the solution needs to be freshly prepared by dissolving iron (III) chloride hexahydrate, $FeCl_3$ (0.15 g), in water and made up to 1 L. Mineral stock solutions used in the OECD 306 biodegradation test were prepared using analytical-grade reagents and deionized Ecotox Maxima-grade water. The mineral stock solutions A, B, and C were made in advance and stored at 4 ºC ± 2 ºC, while solution D was freshly made and not stored. All solutions were added at 1 mL/L to a total volume of 40 L of seawater. The prepared seawater mineral medium was aerated for 20 minutes and allowed to stand for 25 hours at 15-20 °C prior to use.

The equipment used in this study includes 300 mL Biological Oxygen Demand (BOD) bottles with glass stoppers, 4 L bottles with a liter mark, a dissolved oxygen meter (Multi 3410 WTW), an oven (ULM 500, Memmert), an analytical balance (HR 250A, A&D), a hot plate (SP 131320-33, Thermo Scientific Cimarec), gas chromatography with capillary column HP-88 (Agilent HP 6890 Series), a capillary tube for SMP with a length of 75 mm ± 0.02 mm, id 1.1 to 1.2 mm, od 1.3 to 1.4 mm, wall 0.2 mm ± 0.02 mm (Fisherbrand Microhematocrit), and a water bath (F34, Julabo).

Determination of moisture content

The moisture content of the POP was determined using the MPOB test method, MPOB p2.1:2004 [24]. This method involves heating the oil sample in an oven at 103 ± 2 °C, until all moisture and volatile substances are removed. The oil sample in a petri dish was dried and cooled in desiccators before it was weighed (approximately 10 g to the nearest 0.001 g). Then, the oil sample was heated at 103 °C for 2.5 h, left to cool to room temperature (23 to 25 °C) in a desiccator for 30 min, and further weighed. All of these stages were repeated until the weight remained constant. All analyses were conducted in duplicate, and the results were presented in the form of mean ± standard deviation. The moisture content was calculated using equation (1),

$$\text{Moisture (\%)} = \frac{\text{Mb}-\text{Md}}{\text{Mb}-\text{M}} \times 100 \quad (1)$$

Where: M = weight of the petri dish, Mb = weight of the petri dish and oil and Md = weight of the petri dish and oil after drying.

Determination of free fatty acid (FFA)

The MPOB p2.5:2004 test method [24] was used to measure the FFA in POP as a palmitic acid percentage. The oil was melted and homogenized before being weighed into a conical flask. Subsequently, neutralized isopropanol (50 mL) was poured into the flask containing the oil sample. Afterwards, a few drops of phenolphthalein were added to the mixture. The conical flask was then placed on a hot plate at 40 °C and titrated with a sodium hydroxide (NaOH) standard solution with continuous swirling before the first permanent pink color appeared. The FFA content was determined according to equation (2):

$$\text{FFA as palmitic acid (\%)} = \frac{25.6 \times \text{M} \times \text{V}}{\text{m}} \quad (2)$$

Where: M = molarity of NaOH solution, V = volume (mL) of NaOH solution, and m = weight (g) of the oil sample.

All analyses were conducted in duplicate, and the results were presented in the form of mean ± standard deviation.

Determination of iodine value (IV)

The AOCS Cd 1d-92 method was used to measure IV of the POP [25]. The oil sample was melted, homogenized, and filtered, and then the temperature was left to reduce to 68–71 °C before being weighed into a conical flask. The flask was then filled with cyclohexane: acetic acid (1:1) solution (15 mL) and Wijs solution (25 mL). The substances were thoroughly stirred before being stored for an hour in dark conditions at room temperature. Thereupon, a 10% potassium iodide (KI) solution (20 mL) was added, followed by distilled water (100 mL). The mixture was then titrated with a 0.1M sodium thiosulfate ($Na_2S_2O_3$) standard solution until the yellow color almost disappeared. The mixture was then added with a starch indicator solution (1–2 mL), followed by titration with $Na_2S_2O_3$ until the blue color diminished. These steps were repeated for the blank sample. All analyses were conducted in duplicate, and the results were presented in the form of mean ± standard deviation. The IV was expressed using equation (3):

$$\text{IV} \left(\frac{\text{g}}{\text{100g}}\text{oil}\right) = \frac{12.69 \times C \times (V1\text{-}V2)}{M} \quad (3)$$

Where: C = molarity (M) of the $Na_2S_2O_3$ solution, V1 = blank volume (mL) of $Na_2S_2O_3$ solution, V2 = test sample volume (mL) of $Na_2S_2O_3$ solution, and M = weight (g) of the oil sample.

Determination of fatty acid composition (FAC)

The AOCS Ce 2-66 and AOCS Ce 1a-13 methods were used in the preparation of fatty acid methyl esters (FAME) and quantitative analysis of FAC, respectively [25]. The preparation of FAME is important in order to enhance the volatility of the methyl ester derivatives. The FAC of the POP was determined using Agilent 6890 gas chromatography with a flame ionization detector (FID) and a capillary column HP-88 (60 m × 250 µm × 0.2 µm). The flow rate of the column was set at 0.8 mL/min. Meanwhile, the injector temperature and FID temperature were set at 250 °C. Initially, the oven temperature was programmed at 150 °C, then heated to 210 °C for 10 min with a heating rate of 3 °C/min. The injection volume was 1 µL, with a total run time of 30 min. FAME standards were used to analyze the GC chromatogram peaks. All analyses were conducted in duplicate, and the results were presented in the form of mean ± standard deviation.

Determination of slip melting point (SMP)

The SMP of POP was determined using the AOCS C c3-25 method, which applied the open capillary tube technique [25]. The palm oil samples need to be melted and homogenized first before they are filtered at 60°C in the oven and left in the oven for 10 min. Capillary tubes in triplicate were immersed in the melted oil portion until the oil ascended to a height of about 10 mm in the tube. Subsequently, the tubes with the oil sample were rapidly chilled by holding the ends of the tubes against ice until the sample hardened. These tubes were inserted into a beaker and stored in a refrigerator at 10 ± 1°C for 16 h. The tubes were taken out of the refrigerator after 16 h and affixed to a thermometer, whereby the lower ends of the tubes were even with the bottom of the thermometer's mercury bulb. The thermometer was immersed in a 400-mL beaker of distilled water, with its bottom reaching the level of the immersion mark. The water bath's initial temperature was fixed at 8–10 °C below the slip point of the oil sample. Then, the water bath was stirred with a magnetic stirrer, and the temperature was adjusted at a rate of 1 °C/min, then slowed to 0.5 °C/min as the slip point was nearly reached. The heating was carried on until the oil ascended in each tube, and the temperature was recorded. The average temperature of triplicate capillary tubes was calculated as the SMP. All analyses were conducted in duplicate, and the results were presented in the form of mean ± standard deviation.

Determination of chemical oxygen demand (COD) value

The COD test was carried out following Standard Methods for the Analysis of Water and Wastewater [26]. COD is an indicative measure of the oxygen required to oxidize soluble and particulate organic matter in water.

The sample was oxidized by refluxing in the presence of sulphuric acid/silver sulphate, and potassium dichromate. Unreduced potassium dichromate was determined by titration with a standardized iron (II) ammonium sulphate solution. The amount of dichromate reduced is proportional to the amount of oxygen required to oxidize the test substance and is expressed as mgO_2/mg. The test material was added to duplicate round bottom flasks (0.0121 g and 0.0125 g) containing deionized water, sulphuric acid/silver sulphate, mercuric sulphate, and potassium dichromate. In order to check the integrity of the test procedure, readily oxidizable reference material was tested. Blank vessels containing only reagents and deionized water were also tested. The vessels were refluxed for two hours, cooled, rinsed, and titrated with a standardized iron(II) ammonium sulphate solution (FAS) using a redox indicator.

Biodegradation tests using the OECD 306 test method

The OECD 306, Biodegradability in Seawater test method [27] is a modification of the established OECD 301D Closed Bottle and the OECD 301E Modified Screening Test [28]. The OECD 306 test evaluates the biodegradation of a substance over a set period by analyzing indirect parameters in a closed system containing seawater, the test substance, and nutrients. No additional microorganisms are added to the system. The biodegradation test was performed at Chemex Environmental International Limited, United Kingdom (UK). The natural seawater was collected from the Centre for Environment, Fisheries, and Aquaculture Science laboratories in the UK. The biodegradation test was conducted according to the OECD 306 test method at 15-20°C. The study on the effect of POP in a temperate environment is deemed necessary due to the high export of these products to EU countries.

Sodium acetate was used as a reference substance to ensure the test procedure's validity and the suitability of the inoculum used. Since the test materials are insoluble in water, a surfactant was introduced to emulsify the samples. About 0.50g of each POP was mixed with 0.25g of a non-ionic surfactant (IGEPAL CA-630). The resulting emulsion stock solution was gradually diluted by adding deionized water and then made up to volume (500 mL) to give a concentration of 1.0 g/L. The sample stock solution was then prepared by adding 1.0 g/L of the emulsion stock solution to 3.5 L of seawater mineral medium at 2.0 mL/L to give a final test concentration of 2.0 mg/L. Several replicates of BOD bottles were filled to absolute volume (300 mL) with the sample stock solution.

In order to account for any degradation of the surfactant in the test vessels, an additional 100 mL of 0.10 g of IGEPAL CA-630 stock solution was prepared and used in a series of surfactant control bottles. The surfactant control bottles were prepared by adding the surfactant stock solution to seawater mineral medium (1 ml/L) to give a final concentration of 1.0 mg/L, representing the final concentration of the surfactant used in the test sample bottles. These were used as the blank values for the calculation of the BOD for the test material. Initial dissolved oxygen (DO) concentrations were measured using a dissolved oxygen meter. The bottles were incubated in the dark at 18.7–19.2 ºC for the test period. Further measurements of DO concentration were made on bottles removed after 7, 14, 21, and 28 days. All analyses were conducted in duplicate, and the results were presented in the form of mean ± standard deviation. The BOD and percentage of degradation were calculated using equations (4) and (5), respectively.

$$\text{BOD } (mgO_2)\text{calculation } = \frac{(DOt0 - DOtt) - (DOb0 - DObt)}{\text{Concentration of test material } (\frac{mg}{L})} \times 100 \quad (4)$$

Where: DOt0 = DO of the test sample on day 0, DOtt = DO of the test sample on day t, DOb0 = DO of the blank on day 0, DObt = DO of the blank on day t*

* If materials are added using a surfactant, the DO of the surfactant control at days 0 and t are used in the place of the blank.

$$\text{Percentage of degradation (\%)} = \frac{\text{BOD} \times 100}{\text{COD}} \quad (5)$$

Results and Discussion

The physicochemical properties of the selected POP were compared with known standards for crude and refined oils such as the Malaysian Standards (MS 814:2007, Palm Oil – Specification; MS 816:2007, Palm Olein – Specification; MS 80:2011, Palm Kernel Oil – Specification), the Palm Oil Refiners Association of Malaysia (PORAM), the Malayan Edible Oil Manufacturers' Association (MEOMA), Codex Alimentarius, and the Malaysian Palm Oil Association (MPOA). The primary data were obtained from analyses conducted in the laboratory, and they were also compared with extracted data from the certificate of analysis (COA) issued by Sime Darby Jomalina Sdn. Bhd. The properties of POP from the laboratory were expressed in the form of mean value and standard deviation from three replicates, as in Tables 1–4.

Table 1. Comparison of quality characteristics of CPO

Characteristics	Specification	Primary data	COA
Moisture, %max	0.25[b]	0.17 ± 0.01	0.19
FFA, as palmitic acid, %max	5.0[a]	5.3 ± 0.00	4.1

Moisture content

Lipids are primarily hydrophobic; however, small amounts of moisture can easily be absorbed and preserved. The presence of moisture is often unfavorable since it facilitates microbial growth and stimulates the hydrolysis of lipids, thus increasing the FFA content. In addition, it can adversely affect the oil's taste, scent, and appearance, thus reducing customer acceptance and marketability.

Tables 1–4 depict the moisture content of the POP obtained from primary and secondary sources. The maximum permissible amount of moisture is 0.25%, 0.5%, 0.1%, and 0.1% for CPO, CPKO, RBDPO, and RBDPOo, respectively [5]. It was observed that the moisture content of POP from both sources was below the permissible limit set in the specifications. It is important to ensure the moisture content is within the

limit specified by the standards since an abundance of ample moisture could facilitate microbial growth. Previous studies have shown that microorganisms species such as *Penicillium sp*. and *Aspergillus niger* can be detected in the CPO when the moisture content value is higher than 0.69% [29].

Free fatty acid (FFA)

FFA is formed by the hydrolysis of triglycerides in the oil. FFA is an undesirable component since it gives the oil an unpleasant metallic taste. High FFA content will ultimately result in rancidity, which consequently changes the sensory and nutritional quality of POP [30].

It was observed that the FFA values of CPO (Table 1), CPKO (Table 2), RBDPO (Table 3), and RBDPOo (Table 4) are still below the maximum limit stated in the specifications. However, the FFA values observed through data from the laboratory analysis were slightly higher, and this may be due to the long storage period of oils that causes hydrolysis due to the presence of moisture. In addition, CPO releases FFA naturally through the activity of enzymes in the palm fruit and by microbial lipases, which further increases the FFA value [8]. It was specified that the maximum FFA content for CPO is 5%, as stated by MPOA. Meanwhile, PORAM stipulates that the maximum FFA content for RBDPO and RBDPOo is 0.1% [31]. As for CPKO, MEOMA and MS 80:2011 standardized the FFA value not exceeding 5% [5].

Iodine value (IV)

The IV is an indicator of the relative degree of unsaturation in oil components, as calculated by the uptake of halogen. A higher IV value indicates greater unsaturation, and the oil is more prone to oxidation [32]. According to MS 814:2007, the admissible range of IV for CPO is 50.1–54.9 [33]. As for CPKO, the permissible range is 19.0 according to MEOMA [5] and 16.5–18.75 according to MS 80:2011 [34]. Meanwhile, PORAM standards stipulate that the permissible IV range for RBDPO is 50-55, and the minimum IV for RBDPOo is 56 (PORAM, 2012). According to the results obtained in Tables 1 to 4, it can be assumed that most POP possess good quality in terms of IV since the value is within the specified maximum limit. As for CPO, the IV obtained from the laboratory analysis slightly exceeds the allowable range stated in MS 814:2007. However, the IV of CPO, when tested at Sime Darby Jomalina Sdn Bhd, is still within the limit, suggesting that the CPO might have undergone some changes in its properties during storage before the procurement of oils. Significant changes in the IV of CPO after 3 months of storage at room temperature have been reported in a previous study [35]. The difference in storage duration and condition, a higher storage temperature, and the presence of sunlight can lead to a higher IV [36]. Another study suggested that high temperatures increase the oxidation rate of unsaturated fatty acids [15].

Slip melting point (SMP)

Based on the data in Tables 1 to 4, the SMP of the tested POP met the requirement specified by MS 814:2007 with a value of 33.8°C–39.2°C for CPO [33], MS 80:2011 with a value of 27.3°C–28.0°C for CPKO [34], and PORAM with a value of 33°C–39°C for RBDPO and a maximum of 24 °C for RBDPOo [31].

Fatty acid composition (FAC)

Table 5 confirmed the presence of all main components of fatty acids in oils. It was observed that the FAC of CPO, RBDPO, and RBDPOo were within the range stated by MS 814:2007 and MS 816:2007 for palm oil and palm olein, respectively [33; 37]. The specifications of the processed POP were also included in the standards mentioned. As for CPKO, the FAC value slightly exceeded the allowable range stated in MS 80:2011 but is still within the range based on the Codex standard [38].

Chemical oxygen demand (COD)

The COD value of POP obtained from the accredited laboratory that conducted the biodegradation test is shown in Table 6. It was observed that all of POP showed quite similar COD values. The COD value is essential to determining the amount of oxidizable organic material in the sample, which will reduce the dissolved oxygen (DO) levels. Low DO concentrations in water can lead to anaerobic conditions, which are unfavorable to aquatic life [39].

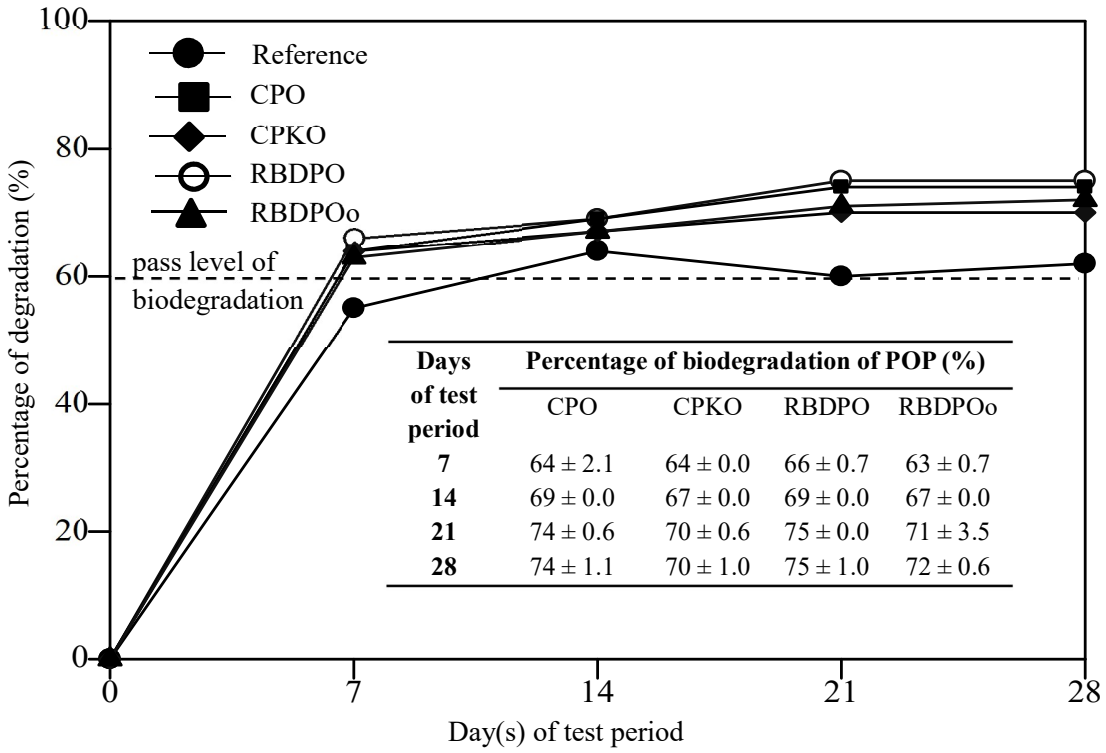

Table 6. COD value of POP

POP	ThOD/COD Value (mgO_2/g)
CPO	2456
CPKO	2489
RBDPO	2382
RBDPOo	2662

The oxygen demand value for the reference substance, sodium acetate, was calculated based on the test method (OECD, 1992), giving its theoretical oxygen demand (ThOD) value of 780 mgO_2/g.

Biodegradability assessment

All tested POP are insoluble in water; therefore, a surfactant (IGEPAL CA 630) was used to emulsify the sample. The effects of surfactant degradation were considered when calculating the degradation of the POP. It was observed that CPO, CPKO, RBDPO, and RBDPOo showed a positive result with more than 60% degradation relative to the COD value, with 60% being reached by day 7 and a maximum of 74%, 70%, 75%, and 72%, respectively, recorded on day 28 (Figure 1). A positive result of more than 60% ThOD removal within 28 days indicates that the material has the potential to biodegrade in the marine environment (OECD, 1992). This is supported by previous research on bacterial degradation of palm olein that revealed RBD palm olein was biodegradable in seawater, as indicated by the decreased DO value with increasing microbial counts over the 5 days of study. In addition, the fatty acid concentration was also found to decrease after the incubation period in seawater [40].

Days of test period	Percentage of biodegradation of POP (%)			
	CPO	CPKO	RBDPO	RBDPOo
7	64 ± 2.1	64 ± 0.0	66 ± 0.7	63 ± 0.7
14	69 ± 0.0	67 ± 0.0	69 ± 0.0	67 ± 0.0
21	74 ± 0.6	70 ± 0.6	75 ± 0.0	71 ± 3.5
28	74 ± 1.1	70 ± 1.0	75 ± 1.0	72 ± 0.6

Figure 1. Biodegradation of POP during 28-day test period

A previous study demonstrated the importance of the FAC of the oil in determining the biodegradation rate [13]. It was observed that the biodegradation process resulted in the formation of biodegradation intermediates and autoxidation products [13]. Autoxidation is a natural process of spontaneous oxidation in the presence of oxygen and can be expedited with free fatty acids, mono- and diacylglycerols, metals, e.g., iron, and thermally oxidized compounds [41]. Autoxidation of vegetable oils depends on their degree of unsaturation [42], and oils with a high unsaturated fatty acid content are more susceptible to autoxidation. The relative oxidation rates of stearic (C18:0), oleic (C18:1), linoleic (C18:2), and linolenic (C18:3) acids were reported to be 1, 100, 1200, and 2500 at 25 °C, respectively. According to Romero and Morton [43], the reaction rates of the autoxidation of oleic-linoleic acid mixtures decreased with decreasing linoleic acid molar fractions. In addition, several studies suggested the transformation of fatty acids during the degradation process [44-45]. Therefore, it can be deduced that there is a correlation between the fatty acid composition of oil and its degradation rate.

The structure of fatty acid molecules, *i.e*., characterized by the length of the carbon chain, the number of double bonds, and the exact position of these double bonds, can define and determine the biological reactivity of the fatty acid molecules [19]. Therefore, the chemical structure affects the biodegradability of a substance [46]. Table 7 shows the percentage of saturated, monounsaturated, and polyunsaturated fatty acids in POP. Based on the literature, the saturated fatty acids composition in palm oil is around 50%, with 44% palmitic acid (C16:0), and approximately 5% of stearic acid (C18:0) and remaining are the trace amounts of myristic acid (C14:0). The unsaturated fatty acids are approximately 40% of oleic acid (C18:1) and 10% consists of polyunsaturated linoleic acid (C18:2) and linolenic acid (C18:3) [47-48]. Meanwhile, for palm kernel oil, the saturated fatty acids and unsaturated fatty acids are roughly 79.1% and 20.9%, respectively [49].

Table 7. Percentage of saturated, monounsaturated and polyunsaturated fatty acids in POP

Fatty Acid Composition (%)	**POP**			
	CPO	**CPKO**	**RBDPO**	**RBDPOo**
Total saturated	50.49	74.75	49.75	43.85
Total monounsaturated	38.98	16.59	39.28	43.67
Total polyunsaturated	9.43	2.71	9.95	11.36

CPKO has the highest amount of saturated fatty acids and the lowest amount of monounsaturated and polyunsaturated fatty acids. This explained why CPKO showed a slightly low percentage of biodegradability since it is the most stable oil with the highest saturated fatty acid content compared to other POP. However, CPKO still showed the potential to be degraded in the marine environment. Meanwhile, RBDPO showed a high biodegradation percentage, mainly due to its high unsaturated fatty acid content. Unsaturated fatty acids are less stable than saturated fatty acids, making them more susceptible to oxidation [41].

In terms of microbial degradation, the initial stage for the degradation of POP would be the dissociation of ester bonds from fatty acids through the action of enzymes, including esterases and lipases. These two enzymes are synthesized by various microorganisms [50-51]. Meanwhile, the cleavage of carboxyl ester bonds is catalyzed by lipases, which are hydrophobic proteins. The carboxyl ester bonds are tri-, di-, and monoacylglycerols, the major components of animal, plant, and microbial fats and oils [52]. Both saturated and unsaturated fatty acids are biodegraded *via* a process known as β-oxidation after the initial stage of degradation.

Conclusion

The quality and biodegradability of POP are the key points in terms of their industrial use. The quality of four POP, *i.e*., CPO, CPKO, RBDPO, and RBDPOo, was determined through moisture, FFA, IV, FAC, and SMP

analyses. The properties of the POP were within the specified values as stipulated in the Malaysian Standards and also PORAM, MEOMA, Codex, and MPOA standards. Meanwhile, some of the values slightly deviated from the specified value, possibly due to the storage condition and time prior to the analysis of the sample. As for the biodegradability assessment of these POP, all samples achieved more than 60% biodegradability and, therefore, can be considered biodegradable in the marine environment. Hence, POP are not expected to cause any harm to the environment.

Abstract

Palm oil is one of the potential renewable resources in biolubricant production. However, the direct application of palm oil as biolubricant is restricted because of its low oxidative stability. It is due to the presence of oxidation active sites β- hydrogen in a glycerol backbone structure. This oxidative drawback can be overcome by molecule structural redesign through a chemical modification process such as esterification with polyhydric alcohol. The esterification of palm oil fatty acids (POFAs) with pentaerythritol (PE) was carried out in a mole ratio of 4.5:1, 1% of sulphuric acid, reaction temperature of 165 °C and reaction time of 7.2 hours. Gas Chromatography equipped with a Flame Ionization Detector (GC-FID) was used to determine the percentage of ester composition in palm oil pentaerythritol (POPE) ester. The structure of the POPE ester was confirmed by Fourier Transformation Infra-Red (FTIR) and proton and carbon Nuclear Magnetic Resonance (^{1}H-NMR and ^{13}C-NMR) spectroscopy. Results showed that POPE ester has been successfully synthesized with 85% of yield and 97.4% composition of tetraesters. The existence of the ester functional group is evidenced by FTIR at 1740 cm^{-1}, the chemical shift of ^{1}H NMR at 2.29-2.33 ppm and ^{13}C NMR at 173.24 ppm. Physicochemical properties analysis showed that POPE ester has oxidative stability at 189 °C, pour point at 17 °C, flash point at 300 °C and 147 viscosity index which makes POPE ester suitable to be used in many industrial lubrication applications.

Keywords: Esterification, oxidative stability, palm oil fatty acid, pentaerythritol

Abstrak

Minyak sawit merupakan salah satu sumber boleh diperbaharui yang berpotensi dalam penghasilan biopelincir. Walau bagaimanapun, penggunaan minyak sawit secara terus sebagai biopelincir adalah terhad kerana kestabilan oksidatifnya yang rendah. Ini disebabkan oleh kehadiran tapak aktif pengoksidaan β- hidrogen dalam struktur tulang belakang gliserol. Kelemahan

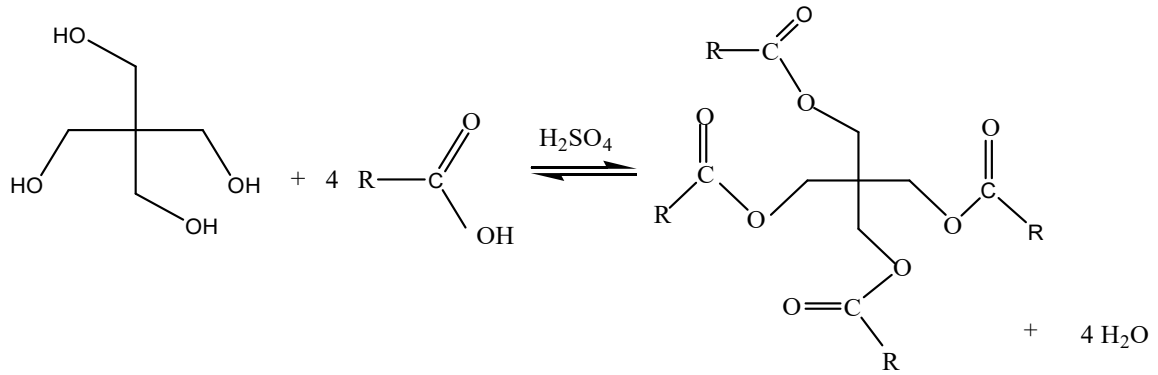
oksidatif ini boleh diatasi dengan reka bentuk semula struktur molekul melalui proses pengubahsuaian kimia seperti pengesteran dengan alkohol polihidrik. Pengesteran asid lemak minyak sawit (POFAs) dengan pentaeritritol (PE) dijalankan dalam nisbah mol 4.5:1, 1% asid sulfurik, suhu tindak balas 165 °C dan masa tindak balas 7.2 jam. Kromatografi Gas yang dilengkapi dengan Pengesan Pengionan Nyala (GC-FID) digunakan untuk menentukan peratus komposisi ester dalam ester pentaeritritol minyak sawit (POPE). Struktur ester POPE telah disahkan oleh spektroskopi transformasi Fourier infra-merah (FTIR) dan spektroskopi resonan magnetik nukleus proton dan karbon (NMR) (^{1}H-NMR dan ^{13}C-NMR). Keputusan menunjukkan bahawa ester POPE telah berjaya disintesis dengan 85% hasil dan 97.4% komposisi tetraester. Kewujudan kumpulan berfungsi ester dibuktikan melalui FTIR pada 1740 cm^{-1}, anjakan kimia ^{1}H NMR pada 2.29-2.33 ppm dan ^{13}C NMR pada 173.24 ppm. Analisis sifat fizikokimia menunjukkan bahawa ester POPE mempunyai kestabilan oksidatif pada 189 °C, takat tuang pada 17 °C, takat kilat pada 300 °C dan indeks kelikatan 147 yang menjadikan ester POPE sesuai digunakan dalam pelbagai kegunaan pelinciran industri.

Kata kunci: Pengesteran, kestabilan oksidatif, asid lemak minyak sawit, pentaeritritol

Introduction

In recent years, the development of renewable resources-based lubricants has increased due to the increasing cost of petrochemicals and rising concern for environmental pollution [1]. Rapidly depleting crude oil reserves and crude oil production also initiated high demand for industrial biolubricants. In the European region, subsidies, tax breaks and labeling programs are triggering high demand for biolubricants, especially for hydraulic fluid applications. It transmits the power to hydraulic machinery that is mostly used in the mining, industrial, agricultural and marine sectors. In this region alone the market is expected to reach US$884.6 million by 2026 [2].

The development of biodegradable and environmentally friendly biolubricants is very much needed nowadays. The world is moving rapidly towards the use of biolubricants, especially in industrial and automotive applications. More than 1700 lubricant manufacturing industries play an important role worldwide [3]. The global biolubricants market is estimated to be worth US$1.9 billion in 2020 and is expected to reach a revised size of US$2.5 billion by 2026 with a Compound Annual Growth Rate (CAGR) of 5.2%. The top market is the U.S. market at US$360.2 million in 2021, while the Chinese market is expected to reach US$230.4 million by 2026. Japan and Canada are forecast to grow at 3.7% and 4.1% CAGR respectively. In Europe, Germany is expected to grow at about 5% CAGR while the rest of the Europe market will reach US$246.8 million by the end of 2026. The driving demand for biolubricants is due to the advances in the development of engine design and operational efficiency and stringent government regulations particularly in North America and Europe, which discourage the use of synthetic and chemical-based lubricants [4].



Plant oils are found to be the best alternative source to replace petrochemical because plant oils are biodegradable, non-toxic and cheaper compared to conventional sources of petrochemicals [5, 6]. Plant oils themselves exhibit good lubricity with high viscosity index [7]. However, plant oil cannot be used directly as a lubricant because of its low oxidative stability [7, 8, 9]. It is due to the presence of oxidation active sites β-hydrogen in the glycerol backbone structure, which will cause plant oil to become unstable at higher temperatures [10]. The β-hydrogen is easily removed from triacylglycerol molecules and it will form acid and olefin (unsaturated compounds). The resulting unsaturated compounds will undergo polymerization and will cause the formation of a precipitate that will increase the viscosity of plant oil [11]. The oxidative stability drawback that incurs in plant oil can be overcome by molecule structural redesign through chemical modifications.

Chemical modification processes such as transesterification and esterification are among important industrial processes due to their simplicity, viability, achievability and low-cost processes [4]. One modification that can be used is esterification with a polyhydric alcohol such as neopentylglycol (NPG) [12], trimethylolpropane (TMP) [13] and pentaerythritol (PE) [14], which will replace the glycerol backbone in plant oil structure. The advantage of using polyhydric alcohol is the absence of hydrogen in the beta position (β-

hydrogen), which enhances the thermal and oxidative stability of the lubricant at high temperatures [15,16]. The esterification of plant oil-based fatty acids with various polyhydric alcohols has been reported to successfully achieve high yields percentage and high esters selectivity [4].

Recently, palm oil which is abundantly available all over Malaysia become one of the potential plant oils that can be used as biolubricant base stock [17,18]. There are many studies reported on the production of biolubricant from palm oil and polyhydric alcohols. The production of biolubricant via transesterification of palm oil methyl ester (POME) with trimethylolpropane (TMP) was reported by Yunus et al. [19]. TMP is polyhydric alcohol that has three hydroxyl groups. The transesterification of POME and TMP that was carried out in a mole ratio of 3.9:1, a reaction temperature of 120 °C, a reaction time of 1 hour, 20 mbar of pressure, and 0.8% sodium methoxide catalyst has successfully produced 98% palm oil TMP triesters. Sulaiman et al. [20] also reported the optimization of the transesterification of POME and TMP. The optimum conditions were obtained at 3.8:1 mole ratio, a reaction temperature of 120 °C, a reaction time of 2 hours, 20 mbar of pressure and 0.9% sodium methoxide catalyst. At these optimum conditions, 86% of palm oil TMP triesters were successfully synthesized. In 2013, Salih et al. [21] reported the esterification between palm kernel oil fatty acids (PKOFAs) with TMP in a mole ratio of 4:1, reaction temperature of 150 °C, a reaction time of 5 hours and 1% sulphuric acid as catalyst. The results showed that a 68% yield of TMP ester was successfully synthesized with good lubrication properties such as a high flash point (over 300 °C), a pour point at 3 °C and a high viscosity index (157).

Other than TMP, there was also a study using pentaerythritol (PE) in the production of biolubricant. PE is polyhydric alcohol with four hydroxyl groups. In 2014, Aziz et al. [22] reported the production of biolubricant through transesterification between POME and PE in a mole ratio of 4.5:1, a reaction temperature of 158 °C, a reaction time of 1 hour and 1.19% sodium methoxide catalyst. The transesterification has produced a 40% yield of PE ester which has a flash point at 302 °C and 12.7 cSt viscosity at 100 °C. However, there is a lack of study reported on the esterification of palm oil fatty acids (POFAs) and PE. Hence, in this study, the esterification of POFAs with PE to produce palm oil pentaerythritol (POPE) ester as shown in Figure 1 is reported. Fatty acid composition of POFAs and POPE ester, as well as ester composition in POPE ester, will be analyzed by GC-FID, while the structure of POPE ester will be confirmed by FTIR and NMR spectroscopy. The physicochemical properties of POPE ester were examined by using several tests such as oxidative stability, pour point, flash point and viscosity index.

Pentaerythritol Palm Oil Fatty acid Palm Oil PE Ester Water

R= Mixed palm oil fatty acids (myristic, stearic, palmitic, oleic and linoleic acid)

Figure 1. Esterification of palm oil fatty acids (POFAs) with pentaerythritol (PE)

Materials and Methods

Materials

Palm oil was obtained from Jomalina Refinery, Teluk Panglima Garang, Selangor, Malaysia. Pentaerythritol was purchased from Sigma Aldrich. Sulphuric acid, toluene, ethyl acetate, sodium bicarbonate, sodium chloride, sodium sulphate, hydrochloric acid, n-hexane, potassium hydroxide and ethanol were purchased from Systerm.

Hydrolysis of palm oil

The hydrolysis process involves two stages which are saponification and acidification. In saponification, 50 grams of palm oil was mixed with 300 mL of alkaline ethanol in a 500 mL three-neck round bottom flask equipped with a mechanical stirrer, thermometer and reflux condenser and heated at 60 °C for 2 hours [23]. After the reaction was complete, the mixture underwent an acidification process in which 150 mL of 6N hydrochloric acid was added to neutralize the alkaline solution. The washing was continued using 200 mL of distilled water and 100 mL of hexane as solvent. The product, palm oil fatty acids (POFAs), was kept overnight by adding anhydrous sodium sulphate. The product was filtered by Whatmann No. 1 filter paper and the solvent used was isolated by a rotary evaporator at 70 °C. The product (POFAs) was analyzed using Gas Chromatography equipped with a Flame Ionization Detector (GC-FID).

Esterification of palm oil fatty acids and pentaerythritol

The esterification process was conducted by mixing palm oil fatty acids (POFAs) and pentaerythritol (PE) in a mole ratio of 4.5:1 in a 500 mL three-neck round bottom flask, equipped with a thermometer and Dean-Stark apparatus. 1% sulphuric acid and 100 mL of toluene were added to the mixture. The mixture was heated at 165 °C for 7.2 hours with continuous stirring. The product, palm oil pentaerythritol (POPE) ester, was neutralized with 150 mL of sodium hydrogen carbonate solution (5%), 150 mL of sodium chloride solution (5%) and 100 mL of ethyl acetate. The product was kept overnight by adding anhydrous sodium sulphate. The product was filtered by Whatmann No. 1 filter paper and the solvent used was isolated by a rotary evaporator at 70 °C. The POPE ester was analyzed using GC-FID, Fourier Transformation Infra-Red (FTIR) and proton and carbon Nuclear Magnetic Resonance (^{1}H-NMR and ^{13}C-NMR).

Characterization of palm oil, palm oil fatty acids (POFAs) and palm oil pentaerythritol (POPE) ester

The fatty acid composition of palm oil, POFAs and POPE ester was analyzed using GC-FID (column BPX-70). Fatty acid methyl esters (FAMEs) were prepared using two methods: base-catalyzed for palm oil and POPE ester and acid-catalyzed for POFAs. For base-catalyzed, FAME was prepared by blending 0.1 mL of oil sample with 1 mL of hexane. 1 mL of sodium methoxide solution (1.55 grams of sodium hydroxide and 50 mL of methanol) was added to the oil solution and the solution was stirred vigorously using a Vortex stirrer for 10 seconds. The solution was allowed to stand for 10 minutes to separate the clear solution of FAME from the cloudy aqueous layer. The upper FAME layer was slowly collected and injected into GC for analysis. For acid-catalyzed, 1 gram of POFAs was weighed into a 250 mL three-neck round bottom flask equipped with a mechanical stirrer, a thermometer and a reflux condenser. 3.75 mL of methanol was added with 0.75 mL of reagent mixture (5 mL of methanol and 1.25 mL of concentrated hydrochloric acid (36.5%)), followed by 0.75 mL of toluene. The mixture was heated at 65 °C for 1.5 hours. The mixture was then transferred into a separation funnel. 7.5 mL of hexane and 5 mL of distilled water were added to the mixture. The mixture was allowed to stand to separate two layers. The upper layer was slowly collected and dried using anhydrous sodium sulphate overnight. The sample was filtered and injected into GC for analysis.

The percentage of ester composition in POPE ester was determined using GC-FID (column DB-5HT). The sample was prepared by mixing 0.3 µL of POPE ester with 1mL of ethyl acetate. Subsequently, the structure of the POPE ester was confirmed using Fourier Transformation Infra-Red (FTIR) and proton and carbon Nuclear Magnetic Resonance (^{1}H-NMR and ^{13}C-NMR) spectroscopy. FTIR spectra were recorded on Perkin Elmer Infrared Spectrophotometer in the range of 500-4000cm^{-1}. ^{1}H and ^{13}C NMR were recorded on JEOL-

ECP 400 spectrometer (400 MHz ^{1}H/100.61 MHz ^{13}C) using $CDCl_3$ as a solvent.

Physicochemical properties tests of palm oil pentaerythritol (POPE) ester

The American Society for Testing Materials (ASTM) standards such as ASTM D-6186, ASTM D-5853, ASTM D-92 and ASTM D-2270 were used to measure oxidative stability, pour point, flash point and viscosity index [24]. The oxidative stability test was conducted using Differential Scanning Calorimetry (DSC). 1.5 mg of POPE ester was placed into an aluminum pan with a pinhole cover to allow interaction between the ester product and oxygen gas which acts as a reaction gas. Then, the aluminum pan was put into DSC and heated for 20 minutes up to temperatures of 250 °C by using nitrogen gas. The onset temperature was recorded to determine oxidative stability.

In the pour point test, the POPE ester was filled into a U-shaped glass tube until it reached a height of 4 cm. The thermometer was placed at one end of the U-shaped tube and both ends of the U-shaped tube were covered with parafilm. The U-shaped tube containing the POPE ester was placed in a refrigerator (minimum temperature -80 °C) for 24 hours to ensure that the POPE ester froze completely. After being left overnight, the U tube was removed and flipped upside down. The lowest temperature at which movement of the POPE ester was observed was recorded as the pour point.

For flash point testing, 2 mL of the POPE ester was placed in a crucible and heated on a heating plate. A thermometer with a maximum reading temperature of 360 °C was placed on the POPE ester to measure the temperature. The temperature was rapidly increased at first and then at a slow constant rate as the flash point approached. The lowest temperature at which the vapors above the surface of the liquid ignited was taken as the flash point.

For the viscosity index test, the Rheometer Anton Paar (Physica MCR 301 model) was used to measure the viscosity and viscosity index of the POPE ester. The diameter used for the samples was 0.051 mm. POPE ester was tested at 40 °C and 100 °C. The POPE ester's viscosity index was calculated based on the formula below:

$$\text{Viscosity index} = (L-U)/(L-H) \times 100$$

Where: U= oil's kinematic viscosity at 40 °C, L and H = values based on the oil's kinematic viscosity at 100 °C.

Results and Discussion

Palm oil (PO) is golden yellow and exists in a semi-solid form at room temperature. The liquid fraction contains unsaturated triacylglycerol (TAG) whereas the solid fraction contains more saturated TAG. TAG and fatty acid composition analyses were performed to determine their main composition in palm oil. Table 1 shows that the main TAG in palm oil is POP (39.89%), followed by POO (26.69%), PLP (7.43%), PLO (7.34%) and other TAGs. POP and POO show higher percentages because palmitic acid and oleic acid are the main fatty acid in palm oil. It is evidenced by the fatty acid composition shown in Table 2. The main fatty acid composition of palm oil is oleic acid with 44.8%, followed by palmitic acid (41.9%), linoleic acid (9.1%), stearic acid (3.6%) and myristic acid (0.6%).

The hydrolysis process was carried out to convert triacylglycerols in palm oil into palm oil fatty acids (POFAs), which will be used in the esterification process with pentaerythritol (PE). The percentage yield of POFAs after hydrolysis is 95%. Figure 2 shows a GC-FID (column BPX-70) chromatogram of fatty acid compositions in palm oil (before hydrolysis) and POFAs (after hydrolysis). The percentage composition of each fatty acid has been simplified in Table 2. POFAs also consist of five types of fatty acids. The major fatty acid composition in POFAs is oleic acid at 43.5%, followed by palmitic acid (42.5%), linoleic acid (9.5%), stearic acid (3.7%) and myristic acid (0.8%). The fatty acid composition of palm oil and POFAs is close to the value of the fatty acid composition of palm oil reported by Chowdhury et al. [25].

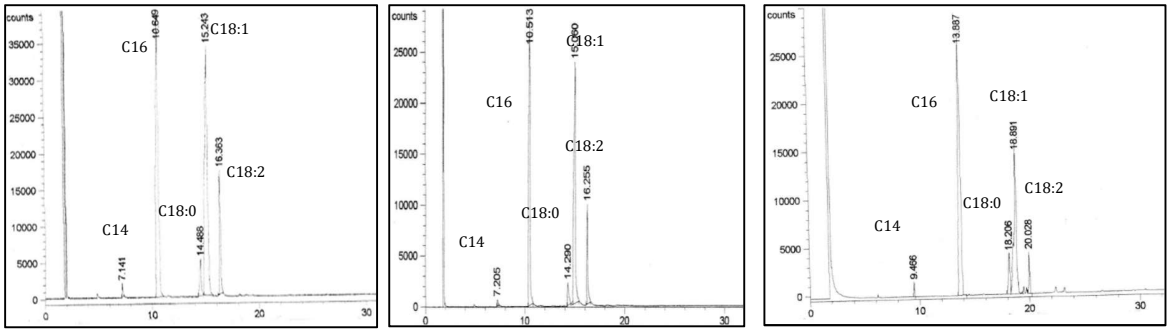


Table 1. Triacylglycerol composition (percentage) of palm oil

Triacylglycerol	Percentage (%)
Free fatty acid	7.03
Monoacylglycerol + Diacylglycerol	2.88
1-oleoyl-2,3-dilinoleoyl-glycerol (OLL)	0.04
1-palmitoyl-2,3-dilinoleoyl-glycerol (PLL)	0.68
1-miristoyl-2-linoleoyl-3-palmitoyl-glycerol (MLP)	0.07
1,3-dioleoyl-2-linoleoyl-glycerol (OLO)	0.45
1-palmitoyl-2-linoleoyl-3-oleoyl-glycerol (PLO)	7.34
1,3-dipalmitoyl-2-linoleoyl-glycerol (PLP)	7.43
1,2,3-tri-oleoyl-glycerol (OOO)	1.55
1-palmitoyl-2,3-dioleoyl-glycerol (POO)	26.69
1,3-dipalmitoyl-2-oleoyl-glycerol (POP)	39.89
1,2,3-tri-palmitoyl-glycerol (PPP)	3.11
1-sterioyl-2,3-dioleoyl-glycerol (SOO)	0.61
1-palmitoyl-2-oleoyl-3-sterioyl-glycerol (POS)	1.99
1,2-dipalmitoyl-3-sterioyl-glycerol (PPS)	0.24

Table 2. Fatty acid composition (percentage) of palm oil, POFAs and POPE ester

Fatty Acid Composition	Palm oil	POFAs	POPE Ester	Reference[25]
Myristic acid (C14)	0.6	0.8	1.0	1.2
Palmitic acid (C16)	41.9	42.5	53.5	41.8
Stearic acid (C18)	3.6	3.7	6.5	3.4
Oleic acid (C18:1)	44.8	43.5	35.1	41.9
Linoleic acid (C18:2)	9.1	9.5	3.9	11

The esterification process was carried out between POFAs and PE in the presence of sulphuric acid as a catalyst to produce POPE ester. The percentage yield of POPE ester was 85% and obtained in the semi-solid form at room temperature. Figure 2(c) shows the fatty acid compositions in POPE ester and it has been simplified in Table 2. The GC result showed that POPE ester contains 61% of saturated fatty acids and 39% unsaturated fatty acids. It means saturated fatty acids which have a straight-chain structure have a higher tendency to react with PE compared to the bent structure of unsaturated fatty acids due to less steric hindrance.

(a) (b) (c)

Figure 2. GC-FID (column BPX-70) chromatogram a) Palm oil; b) POFAs; c) POPE ester

POPE ester identification and characterization

The percentage of ester composition in POPE ester was determined by GC-FID (column DB-5HT) analysis as shown in Figure 3. Four types of esters will be produced from the esterification process, which are monoesters, diesters, triesters and tetraesters. In the esterification process, monoesters, diesters and triesters were formed as intermediate products towards the completion of the reaction producing POPE tetraesters. Figure 3 shows that 97.4% of tetraesters and 2.6% of triesters were produced in the POPE ester. Almost all hydroxyl groups in PE were successfully esterified with POFAs. This result was supported by the low hydroxyl value of POPE ester, which was 33.42 mgKOH/g compared to the hydroxyl value of PE, which was 1645 mgKOH/g. However, there were still hydroxyl groups that unsuccessfully reacted in this esterification. It can be seen by the presence of trace triester which has a hydroxyl group in its structure.

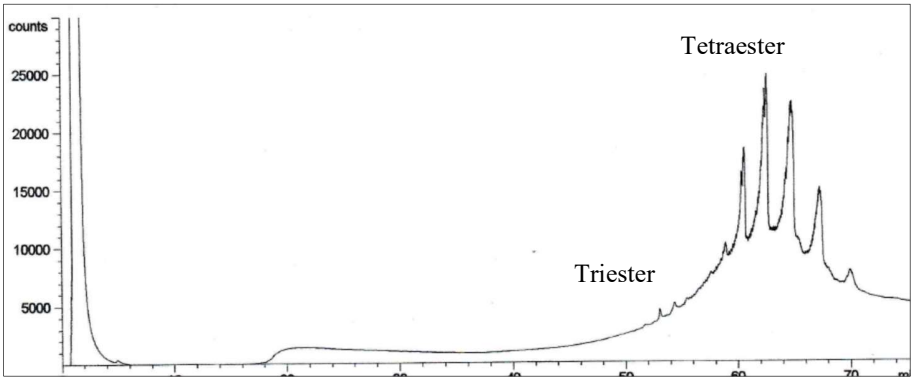

Figure 3. GC-FID (column DB-5HT) chromatogram of POPE Ester

Identification of the functional group present in the POPE ester was confirmed by FTIR analysis. The comparison between FTIR spectra of POFAs (before esterification) and POPE ester (after esterification) is shown in Figure 4. FTIR spectrum of the POPE ester shows the appearance of a C=O ester peak at 1740 cm^{-1} and the stretching of the C-O ester group exists at 1154 cm^{-1} and 1234 cm^{-1}. These values are supported by the study conducted by Nor et al. [4], which states the appearance of the stretching of the C=O ester peak is at 1738 cm^{-1} and the stretching of the C-O ester peak is at 1161 cm^{-1} and 1241 cm^{-1}. On the other hand, the FTIR spectrum of POFAs shows the stretching of the C=O group of carboxylic acid appeared at 1696 cm^{-1} and the stretching of the C-O carboxylic acid exists at 1291 cm^{-1} and 1247 cm^{-1}. According to Nor et al. [4], the stretching of the C=O group of carboxylic acid is at 1696 cm^{-1} and the stretching of C-O carboxylic acid is at 1291 cm^{-1} and 1247 cm^{-1}. The shift in wavenumbers for both spectra showed that POFAs have been successfully esterified with PE to form POPE ester.

Figure 5 shows the ^{1}H NMR spectrum of the POPE ester. In the ester structure, there are two types of protons, which are the proton of C**H**$_2$-O and the proton of C**H**$_2$-C=O. The proton of C**H**$_2$-O for the POPE ester was detected at 4.05-4.11 ppm and the proton of C**H**$_2$C=O was detected at 2.29-2.33 ppm. These values agree with the reference that exhibits a chemical shift for proton C**H**$_2$-O at 3.5- 4.8 ppm and a chemical shift for proton C**H**$_2$C=O at 2.1- 2.5 ppm [26]. POPE ester consists of a mixture of acyl groups such as myristate, palmitate, stearate, oleate and linoleate. The presence of unsaturated fatty acids was determined by the identification of the alkene group. In the alkene group, there are two types of protons, which are protons of double bond (-C=C-**H**) at chemical shift of 4.5-6.5 ppm and protons of methylene group, which are bound to double bond (-C=C-C-**H**) at chemical shift of 1.6-2.6 ppm [26]. Figure 5 shows the existence of both protons at chemical shifts of 5.33-5.39 ppm (-C=C-**H**) and 2.02-2.29 ppm (-C=C-C-**H**).

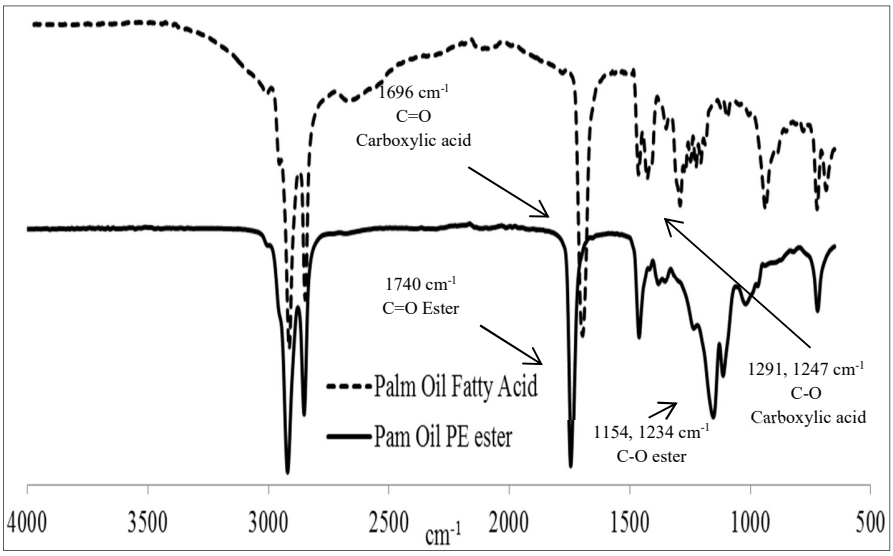

Figure 4. FTIR Spectra of POFAs and POPE ester

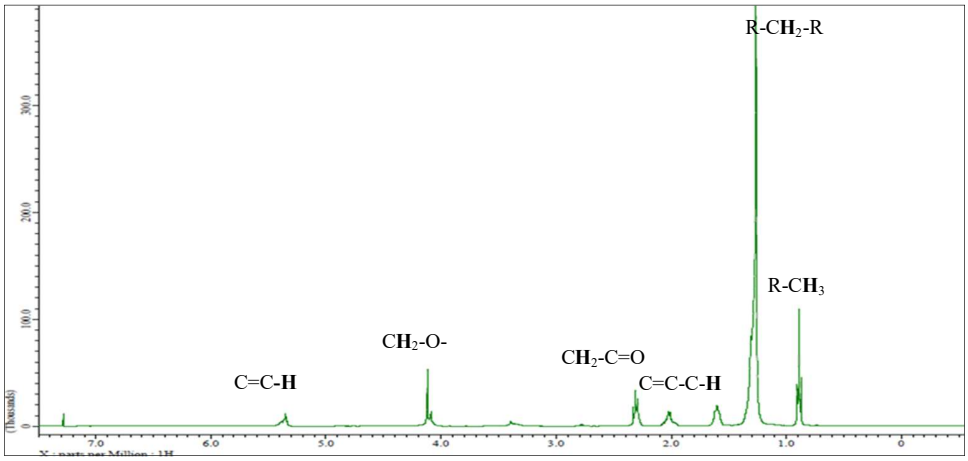

Figure 5. ^{1}H NMR Spectrum of POPE ester

Figure 6 shows the ^{13}C NMR spectrum of the POPE ester. The existence of carbon carbonyl ester (**C**=O) in the POPE ester was detected at a chemical shift of 173.24 ppm. This value is in agreement with Pavia et al. [26], who showed that the chemical shift for carbon carbonyl ester (**C**=O) was in the range of 155-185 ppm. The signal peak for carbon **C**-O, which bind fatty acid to PE was detected at chemical shift of 62.12-62.51 ppm. The presence of both carbons indicates the presence of an ester bond between POFAs and PE, which form POPE ester. The quaternary carbon for POPE ester **C**-$(CH_2OCOR)_4$ was detected at 41.78 ppm and this value is in agreement with the reference, which shows a chemical shift for quaternary carbon at 20-60 ppm [20]. The presence of unsaturated acyl groups was determined by the identification of the alkene group (**C**=C) at a chemical shift of 100-150 ppm [26]. The alkene group (**C**=C) in the POPE ester was detected at a chemical shift of 127.88-130.55 ppm.

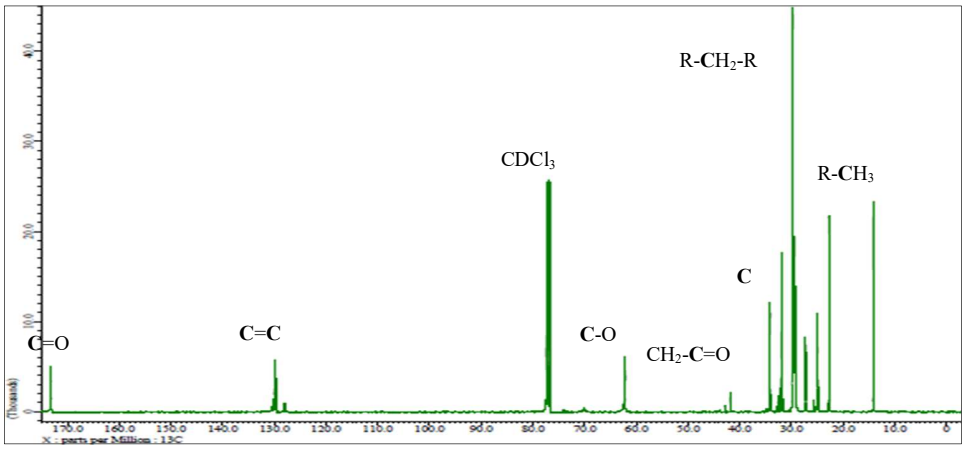

Figure 6. ^{13}C NMR Spectrum of POPE ester

Physicochemical properties of POPE Ester

POPE ester was characterized for physicochemical properties such as oxidative stability, pour point, flash point, viscosity and viscosity index. The physicochemical properties results obtained are shown in Table 3. The ability of a substance to resist oxidative degradation is an important property of biolubricant. Oxidative stability is determined by the onset temperature (OT) using Differential Scanning Calorimetry (DSC). OT is the temperature at which the occurrence of a sharp increase in the rate of oxidation of the sample. A higher onset temperature indicates that the lubricant has high oxidation stability [9]. In this study, POPE ester possesses good oxidative stability with a higher onset temperature of 189 °C compared to palm oil (181°C) due to its high percentage of saturated fatty acid (61%). Reduction of unsaturated fatty acid will reduce oxidation active site; thus, it will make POPE ester more stable at high temperatures.

The ability of a substance to remain liquid at low temperatures is an important attribute for several industrial materials, such as biolubricants, surfactants and fuels [27]. The pour point is a good indicator of its low-temperature fluidity. POPE ester has a higher pour point (17 °C) compared to palm oil (7 °C) due to the high saturated fatty acids content. High saturated fatty acids content has caused lubricant tends to form macro crystalline structures through uniform precipitation at low temperatures.

The efficiency of biolubricant in reducing friction and wear is greatly influenced by its viscosity. The least viscous biolubricant, which still forces the two moving surfaces apart is desired. If the biolubricant is too viscous, it will require a large amount of energy to move and if is too thin, the surfaces will rub and friction will be increased [9]. The viscosity of the POPE ester is in the medium range which is 60.18 cSt at 40 °C and decreased to 11.38 cS at 100 °C. It shows the viscosity of biolubricant decreases as temperature increases. The viscosity index highlights how the viscosity of biolubricant changes with variations in temperature [9]. POPE ester has a higher viscosity index which is 147 compared to palm oil (130). It shows the viscosity of the POPE ester is less affected by temperature changes and does not drastically change when the temperature varies. This is a good indicator and it is suitable for use in a large temperature range.

Flash point is often used as a descriptive characteristic of fuel oil and it is also used to describe oils that are not used as fuels such as a lubricant. The oils with a flash point that is less than 43 °C are flammable, while those having a flash point above this temperature are combustible. POPE ester showed a higher flash point at 300 °C compared to palm oil (240 °C) due to the high molecular weight of the ester and the big branched molecular structure that requires more energy to burn. A high flash point value is important to ensure that the biolubricant is not burned in the engine during its operation. Biolubricant which has a low flash point value is considered to have been contaminated by

volatile and usually requires precautions and special care when handling this biolubricant [9].

Table 3 also shows a comparison of lubrication properties between the biolubricant base stock produced (POPE ester) with commercial lubricants in the market. The selected commercial lubricants are ISO VG 100 grade lubricants, namely Denicol Compressor Oil (100A) [28] and SubsTech Hydraulic Oil (100B) [29]. Based on the comparison made, the POPE ester has a higher flash point and a higher viscosity index compared to 100A and 100B lubricants.

Table 3. Physicochemical properties of RBD palm oil and POPE ester

Physicochemical Properties	Palm Oil	POPE Ester	100A[a]	100B[b]
Oxidative stability (°C)	181	189	n/a	n/a
Pour point (°C)	7	17	-19	-27
Flash point (°C)	240	300	276	254
Kinematic viscosity at 40°C	56.97	57.47	96	96.7
Kinematic viscosity at 100°C	9.24	10.87	10.9	11
Viscosity index (VI)	130	147	97	100
ISO viscosity grade	46	46	100	100

a: 100A: Denicol Compressor Oil ISO VG 100 [22], b: SubsTech Hydraulic Oil ISO 100 [23].

Conclusion

POPE ester has been successfully synthesized from palm oil fatty acids and pentaerythritol with 85% of yield and 97.4% of tetraesters compositions. POPE ester showed good lubrication properties such as having higher oxidative stability, higher flash point and higher viscosity index compared to palm oil. The removal of β-hydrogen in palm oil and replacing pentaerythritol in POPE ester has successfully increased the lubricity properties. This makes POPE ester suitable to be used as biolubricant.

Abstract

This work underlined the fluorescent light-driven photocatalytic degradation of methylene blue by using cauliflower-like molybdenum disulfide (MoS_2). In this study, molybdenum disulfide (MoS_2) was synthesized by using Teflon-stainless steel autoclave via the hydrothermal method. The synthesized MoS_2 were comprehensively characterized using Fourier transform infrared (FTIR), UV-visible spectroscopy, X-ray diffraction (XRD), scanning electron microscopy (SEM), and thermal gravimetry analysis (TGA). The characterization studies reveal that the composites have been successfully synthesized in which a black precipitate was obtained. Degradation of methylene blue was conducted using the synthesized MoS_2 under fluorescent light using response surface methodology (RSM) of three-factor-three-level Box-Behnken design (BBD). The parameters studied were MoS_2 weight loading, contact time under fluorescent light, and methylene blue pH value. The most effective parameter observed in the degradation of methylene blue were weight loading, followed by contact time and pH. The results showed that the optimum condition for the degradation were with the parameters of 15mg of MoS_2 weight loading, with pH 6.5 methylene blue, has the highest degradation percentage 99.93% with 120 minutes exposed time under fluorescent light for degradation.

Keywords: molybdenum disulfide, photocatalytic degradation, methylene blue, response surface methodology, Box-Behnken

Abstrak

Penyelidikan ini menggariskan degradasi fotokatalitik dipacu cahaya pendarfluor biru metilena dengan menggunakan molibdenum disulfida (MoS_2) yang berbentuk kobis bunga. Dalam kajian ini, molibdenum disulfida (MoS_2) telah disintesis dengan

menggunakan autoklaf keluli tahan karat Teflon melalui kaedah hidroterma. MoS_2 yang disintesis telah dicirikan secara komprehensif menggunakan inframerah transformasi Fourier (FTIR), spektroskopi boleh dilihat UV, pembelauan sinar-X (XRD), mikroskop elektron pengimbasan (SEM), dan analisis gravimetri terma (TGA). Kajian pencirian mendedahkan bahawa komposit telah berjaya disintesis di mana mendakan hitam diperolehi. Degradasi metilena biru telah dijalankan menggunakan MoS_2 yang disintesis di bawah cahaya pendarfluor menggunakan metodologi permukaan tindak balas (RSM) reka bentuk Box-Behnken (BBD) tiga faktor-tiga peringkat. Parameter yang dikaji ialah pemuatan berat MoS_2, masa sentuhan di bawah cahaya pendarfluor, dan nilai pH biru metilena. Parameter paling berkesan yang diperhatikan dalam degradasi metilena biru ialah pemuatan berat, diikuti dengan masa sentuhan dan pH. Keputusan menunjukkan bahawa keadaan optimum untuk degradasi adalah dengan parameter 15mg beban berat MoS2, dengan pH 6.5 metilena biru, mempunyai peratusan degradasi tertinggi 99.93% dengan 120 minit masa terdedah di bawah cahaya pendarfluor untuk degradasi.

Kata kunci: molibdenum disulfida, degradasi fotokatalitik, biru metilena, metodologi permukaan tindak balas, Box-Behnken

Introduction

With the advancements of the textile industry in recent years, an increasing number of dyes, like methylene blue have been developed. According to the World Bank analysis, textile dyeing and finishing operations accounted for over 20% of global industrial water contamination [1]. Synthetic dyes are widely utilised in a variety of industries, including food, textile, paper, rubber, plastics, cosmetics and pharmaceuticals. These manufacturers dumped massive amounts of effluent into waterways with no prior treatment. These discharges are a significant source of contamination and contributed to the deterioration of human health and environmental [2]. Dyes also have an impact on aquatic life by interfering with the photosynthesis process of aquatic plants, causing eutrophication and causing disturbance [3, 4]. Due to methylene blue (MB) properties of limited biodegradability, traditional treatment methods, such as the physical-chemical approach is ineffective [5]. The conventional water-treatments approaches applied in individual or combined systems may be applicable to treat mild polluted waste, unfortunately, all these methods do not comprehensively eliminate the pollutant and the detrimental sludge remains after the treatment. Recently, photocatalytic degradation became one of the efficient techniques to degrade pollutants [6, 7].

Photocatalytic degradation is a technique that utilize light source and forms electron-hole which produce radicals that can convert contaminant to safe and less poisonous substances. Special feature of photocatalytic degradation is that it can degrade organic pollutants that has high photochemical stability by effectively utilize light irradiation [8]-[9]. According to Poorsajadi et al., 88% of MB was degraded by using CuO/Bi_2O_3 nanocomposite as photocatalyst under UV irradiation [10]. Meanwhile, γ -Fe_3/Fe_3O_4/ SiO_2 (Ar modified) composite successfully synthesized and degraded MB in 120 min with 87.5% of degradation [11]. On the other hand, 99% of MB was removed by only 4 min by using Ternary $MoS_2/Bi_2S_3/TiO_2$ heterostructure as photocatalyst under simulated solar irradiation as the light source [12]. Molybdenum disulfide (MoS_2) can be used in degradation of organic pollutant. MoS_2 is a crystal structure that comprised S-Mo-S layers that are poorly coupled, whereby a Mo atom layer is in between two S atom layers. A spontaneously existing layered solid, namely MoS_2, seeks uses for production in either its bulk or dispersed forms. The discrete sandwiched S-Mo-S layers are fused together by poor Van der Waals interactions in hexagonally packed frameworks. These layers may shift efficiently towards each other, which enables MoS_2 as a commonly applied dry lubricant. The Van der Waals gaps between the layers are responsible for its properties like anisotropy, good catalytic property, chemical inertness, photo corrosion resistance, optical properties and biological applications [13]-[15]. Due to its distinct layered properties, cost-effectiveness, and use of solar energy, MoS_2 has been identified as a renowned metal free photocatalyst for the degradation of organic contaminants. The layered MoS_2 has effectively synthesized and reported that the metal free photocatalyst exhibited photocatalytic activity under visible light irradiation for the elimination of organic contaminants from aqueous solution [16]. MoS_2 has high photocatalytic activity and inexpensive that it has become preferable in water purification.

In this study, MoS_2 was synthesised through the hydrothermal method as fine powder to be used in the photocatalytic degradation of MB under fluorescent light via response surface methodology by using Design Expert Software of Box-Behnken design. To the best of authors' knowledge, there is no study on box Behnken optimisation design on the degradation of MB under fluorescent light by using MoS_2 as photocatalyst. Therefore, this study could pave a way for the development of facile and optimised approaches for the degradation and treatment of organic pollutants, especially dyes.

Materials and Methods

Materials

Methylene blue, 37% hydrochloric acid (HCl), distilled water, deionised water, sodium molybdate (Na_2MoO_4) and 99% Thiourea (H_2NCSNH_2) were purchased from Sigma Aldrich and all the chemicals are of analytical grade.

Instruments

Fourier transform infrared spectroscopy (FTIR) were recorded between 400 cm^{-1} and 4000 cm^{-1} (Model 100 Spectrometer, Perkin Elmer), UV-visible spectroscopy with 200 nm -800 nm of scanning wavelength (model Lambda 750, Perkin Elmer), X-ray diffractometer analysis were conducted with Panalytical model Empyrean X-ray by keeping 2θ = 10°-90° using Cu, Kα radiations (λ= 1.54059 Å). Scanning electron microscopy (model TESCAN, VEGA3) and thermal gravimetry analyser (TGA) was done by using (model NETZSCH TG 209F3) from 200 °C to 900 °C with the heating rate of 10 °C/min.

Preparation of MoS_2

Sodium molybdate dihydrate ($Na_2MoO_4.2H_2O$) of 3 g and 3.8 g of thiourea (H_2NCSNH_2) was added to 80 mL of deionised water and was stirred for 30 min. 1M HCl of 10 mL was added to the solution and then was transferred into a 100 mL of Teflon stainless steel autoclave. Next, it was heated in an oven at 120 ºC for the next 24 h. The solution was cooled at room temperature. After that, the solution was centrifuged three times and washed with deionised water. The solution was oven dried at 70 ºC for 24 h.

Characterizations of MoS_2

Sodium molybdate dihydrate ($Na_2MoO_4.2H_2O$) of 3g and 3.8g of thiourea (H_2NCSNH_2) was added to 80 mL of deionised water and was stirred for 30 min. 1M HCl of 10 mL was added to the solution and then was transferred into a 100 mL of Teflon stainless steel autoclave. Next, it was heated in an oven at 120 ºC for the next 24 h. The solution was cooled at room temperature. After that, the solution was centrifuged three times and washed with deionised water. The solution was oven dried at 70 ºC for 24 h.

Photocatalytic activity

The photocatalytic properties of MoS_2 were evaluated by employing MB as a target degradation product. To determine the MB degradation, the MoS_2 powder was first screened. Next, 0.1 g of MB contamination was added to 100 ml volumetric flask. It was then diluted to 1000 ppm followed by 100 ppm to the desired concentration of 10 ppm by using deionized water. 10 ml from 10 ppm stock solution was pipetted into the immersion tube containing the sample. Then, the sample was placed in a photoreactor for approximately 30 min in the dark to reach an equilibrium. Then, the MB containing the sample was treated under the fluorescent light for 1 h. The reacted MB was next filtered by using the syringe filter. By using UV-vis, the final products were analyzed. The MB showed a strong absorption from deep UV-region to 664 nm. A continuous screening was performed without the involvement of photocatalyst, and a control MB was left incubated without the catalyst and treatment.

$$\text{Percentage degradation efficiency (\%)} = \frac{C_0 - C}{C_0}\ x\ 100 \quad (1)$$

Where, C_o is initial concentration of MB and C is concentration of MB after the photocatalytic degradation at the specific time given [19].

Results and Discussion

Characterization of MoS_2: Fourier transform infrared spectroscopy (FTIR)

Figure 1 shows various peaks in the spectrum on MoS_2 before and after treatment with MB under fluorescent light, within range from 400 cm^{-1} to 4000 cm^{-1}. The characteristic peak of MoS_2 can be confirmed by a strong peak at 539.90 cm^{-1} indicating the presence of Mo-S in MoS_2. The presence of S-S bond at 878.73 cm^{-1}, meanwhile, absorption band at 1603.54 cm^{-1} was caused by Mo-O bonds along with OH group and their stretching vibrations. The absorption band appearred at 3376.76 cm^{-1} was due to the stretching vibration of existing OH group [20].

The FTIR spectrum of MoS_2 after the MB degradation under the fluorescent light treatment. The absorption band for the Mo-S bond at 539.9 cm^{-1}, the peak of S-S bond at 878.73 cm^{-1} and the peak of Mo-O bond at 1603.54 cm^{-1} were not as substantial as they were before the degradation. After the degradation, the absorption band of 3376.76 cm^{-1} for stretching vibration of the existing OH group was no longer visible. Several functional groups of MoS_2 were not observed after the degradation due to the leaching of the samples by repetition of drying and washing.

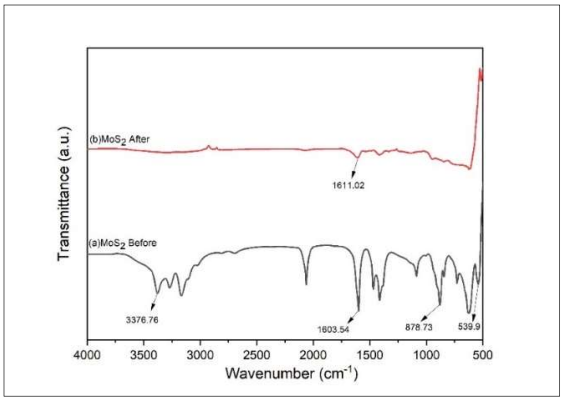

Figure 1. FTIR spectrum of MoS_2 (a) before and (b) after degradation of methylene blue under fluorescent light

UV-visible analysis

As shown in Figure 2, the synthesized MoS_2 nanoparticles showed a strong absorption in UV region with a maximum at 226 nm and a weaker broad absorption in the visible region of 400 nm, which was very similar to that of MoS_2 nanoparticles reported by [21]. Visible light covered the range of approximately 390 nm-700 nm, or 1.8-3.1 eV from the Tauc plot (in-set) the bandgap of MoS_2 was found to be 2.38 eV which revealed that it can be active in the fluorescent light region and effectively degraded the MB.

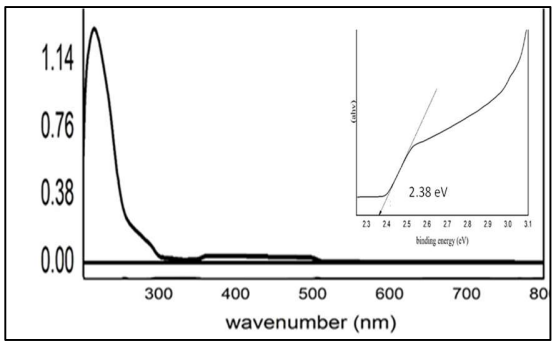

Figure 2. (a) UV-Vis spectra and in-set Tauc plot of MoS_2

X-ray diffraction analysis

Figure 3 indicates diffractogram of MoS_2 exhibited diffraction peaks at 2θ = 14.307°, 32.599°, 40.317°, and 58.235° which can be represented as indices of (002), (100), (103) and (110) of hexagonal phase for the MoS_2 structure, respectively [22]. The crystallinity size calculated was 2.6555Å with the most intense peak. The crystallinity size was calculated by using the Scherrer Equation 2.

$$D = 0.9\ \lambda / \beta \cos \theta \quad (2)$$

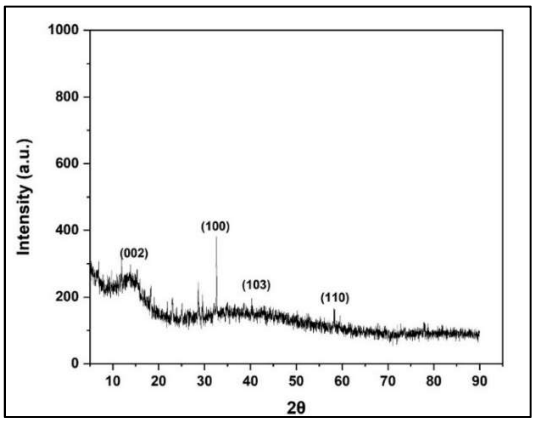

Figure 3. XRD analysis of MoS_2

Morphology analysis

SEM was utilized comprehensively to understand the morphological property of synthesized MoS_2. Figure 4 shows the surface morphology of MoS_2 in flower-like particle. the sheets of MoS_2 stacked together and displayed a 3D cauliflower-like architecture [23]-[24]. Micro-flowers of aggregated MoS_2 nano-sheets were seen in all cases, with no substantial differences. Similar hydrothermally produced materials showed the same morphology [25].

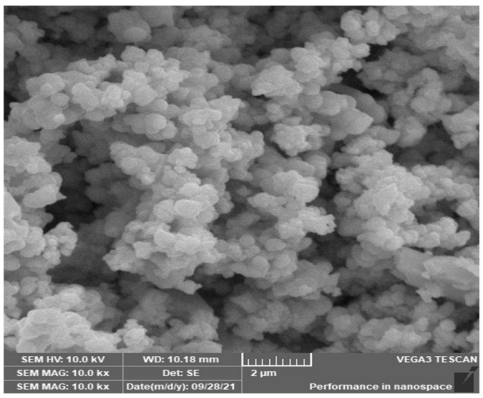

Figure 4. SEM image of MoS_2

Thermogravimetric analysis

Figure 5 illustrates product composition of MoS_2. At the temperature ranging from 200 °C to 470 °C, the TG curve can be interpreted to show three phases of decomposition. MoS_2 exhibited significant initial weight loss at about 200 °C, which could be attributed to water evaporation because of the sample not being completely dried. Furthermore, at 270 °C, MoS_2 lost weight, which could be attributed to oxidation of MoS_2 into MoO_3. The continuous weight loss in the second

phase of TG curve decomposition was caused by the thermal decomposition of the organic group. Beyond 400 °C in the final stage, this was primarily due to MoS_2 burned in the air [26].

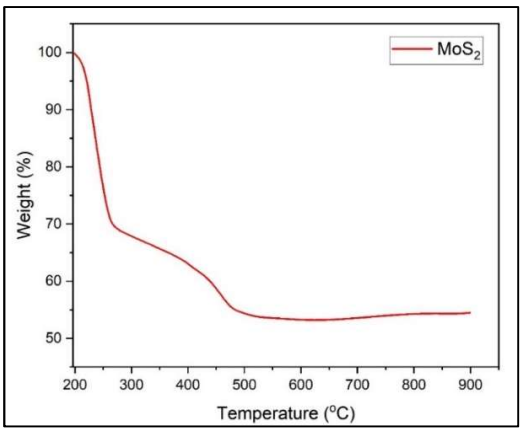

Figure 5. TGA analysis of MoS_2

Photocatalytic activity study: The photocatalytic activity of MoS_2 and methylene blue

The degradation of MB was determined by the screening study of MoS_2 powder. The degradation study of MB was then conducted by using UV-Vis spectroscopy with a maximum absorption at wavelength of 664 nm. The MB underwent treatment for 1 h after incubating for 30 min to reach an equilibrium. Figure 6 shows the UV-Vis spectra of MB before photodegradation and after photodegradation with MoS_2 under the fluorescent light in 120 min. After the photodegradation, the intensity of MB maximum peak decreased showing that MoS2 had successfully degraded MB.

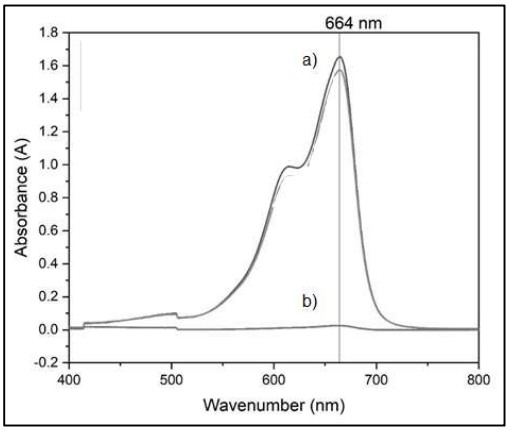

Figure 6. UV-vis spectrum of screening study of methylene blue a) before photodegradation b) after photodegradation

The response surface study

The data were analyzed and interpreted by using Design Expert Software for response surface methodology. Table 2 represents the design experiment of various variables together with experimental and predicted degradation percentage for three-factor-three-level of Box-Behnken design (BBD) response surface analysis for the degradation of MB. The effective parameters studied included A: weight loading (A: 1 mg, 8 mg and 15 mg), B: contact time (B: 5 min, 62.5 min and 120 min) and C: pH value (C: pH 4, pH 6.5 and pH 9). A total of 17 experiments were obtained at random to study

the optimized parameters and maximize the photocatalytic degradation of MB. The experimental values are tabulated in Table 2.

Table 2. Response surface analysis for design experiment of degradation of MB

Std	Weight Loading (mg)	Contact Time (min)	pH	Degradation (%)
1	1	5	6.5	24.04
2	15	5	6.5	99.00
3	1	120	6.5	52.99
4	15	120	6.5	99.93
5	1	62.5	4	37.06
6	15	62.5	4	99.23
7	1	62.5	9	47.94
8	15	62.5	9	99.08
9	8	5	4	94.03
10	8	120	4	99.57
11	8	5	9	97.44
12	8	120	9	99.00
13	8	62.5	6.5	99.43
14	8	62.5	6.5	97.87
15	8	62.5	6.5	95.73
16	8	62.5	6.5	94.59
17	8	62.5	6.5	94.24

The data pointed out in Figure 7 was compared to a straight line, indicating that the residual was normally distributed. The residual versus predicted response value, on the contrary, placed the implication of constant variance to the test. The plot should be in random scatter with a constant range of residuals within the residual range [25].

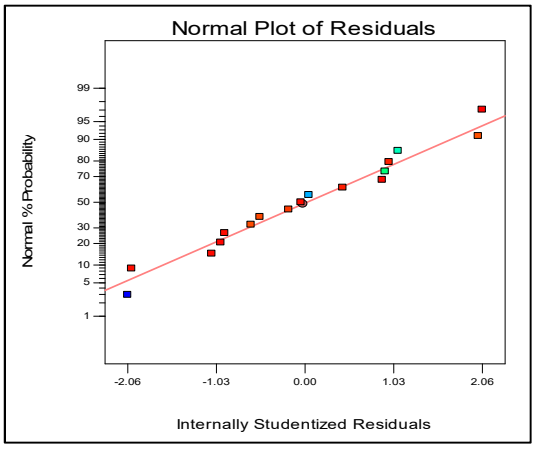

Figure 7. The normal percentage probability and internally studentized residual graph

ANOVA was used to determine the statistical significance of the BBD model. Table 3 summarizes the ANOVA results. The results showed that the acquired models can be used to successfully navigate the design space. The correlation coefficients of R^2 and adjusted R^2 were both high, with values of 0.9904 and 0.9779 demonstrating a close fit between the predicted and experimental values, respectively. The model *F*-value of 79.85 and *p*-values less than 0.0001 implied that the model was significant. Values of *"*Prob>*F"* less than 0.0500 suggested that the model terms were significant. Thus, in this case, *A*, *B*, *AB*, and A^2 were significant model terms. From the ANOVA analysis, the Lack of Fit *F*-value" was not significant. As can be seen in Table 3, the obtained *F* values for effect of weight loading, contact time and pH value were 476.46, 11.78 and 1.59, respectively, showing that the weight loading was the most significant parameter, followed by contact time and pH value. By comparing the interactive model term, *AB* had the highest *F* value of 13.52, followed by *AC* with 2.10 and BC with 0.27, indicating that the interaction of *AB* was the most significant towards photodegradation of MB.

The different MoS_2 weight loading in MB towards photocatalytic reactions are presented in Figure 8(a). It could be seen that when the weight loading of MoS_2 increases, it will increase the number of photocatalyst's active sites that were exposed to the fluorescent light. However, when weight loading exceeded 11.5 mg, the degradation decreased due to the agglomeration of the photocatalyst [27]. According to Figure 8(b), the effect of contact time of MoS_2 on the degradation efficiency of MB was studied within the range of 5 min-120 min during the photocatalytic degradation under the fluorescence light utilizing a photoreactor. It showed that the increase in contact time to 120 min elevated the efficiency of degradation. The first increase in contact time enhanced the efficiency of degradation because actives site of MoS_2 were still vacant and more photodegradation could occur rapidly. Figure 8(c) reveals that the maximum degradation took place within the pH value range of pH 6.5-pH 9 [28].

The response surface plot in three dimensional was plotted to show the interaction between the two parameters towards the photodegradation of MB. In this approach, two parameters were varied within the experimental ranges, while another one parameter was kept constant. The 3-D surface plot of photodegradation of MB as a function of weight loading and contact time is shown in Figure 9.

Table 3. Analysis of variance

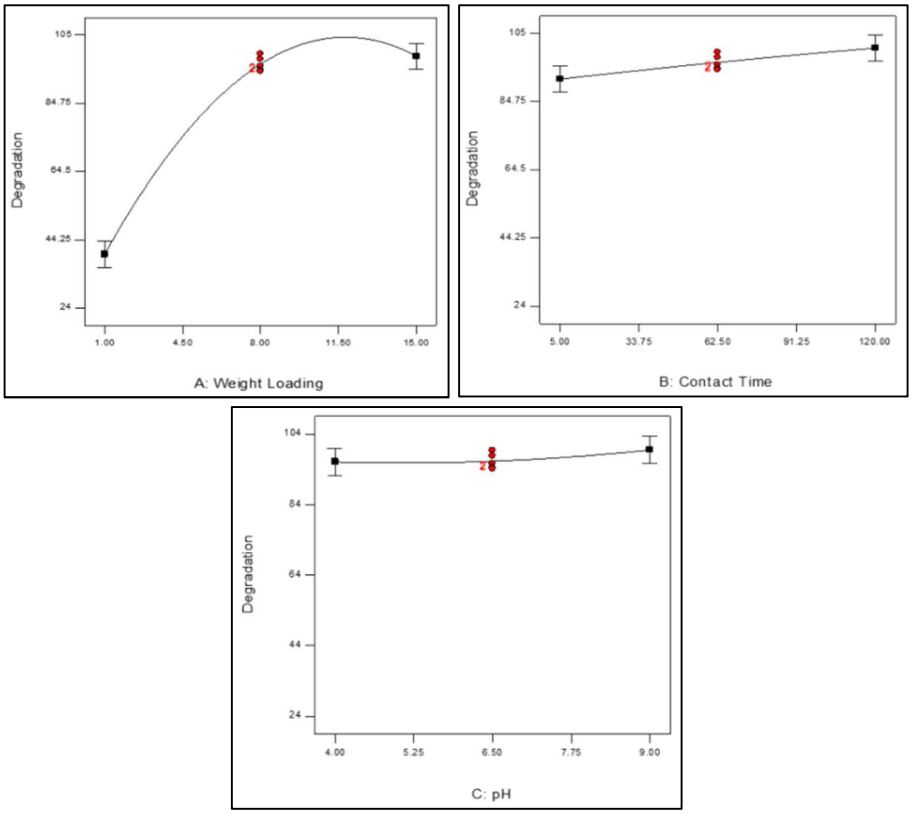

Figure 8. (a) One factor plots of degradation versus weight loading, A (b) degradation and contact time, B plotted graph (c) percentage degradation of methylene blue versus pH, C.

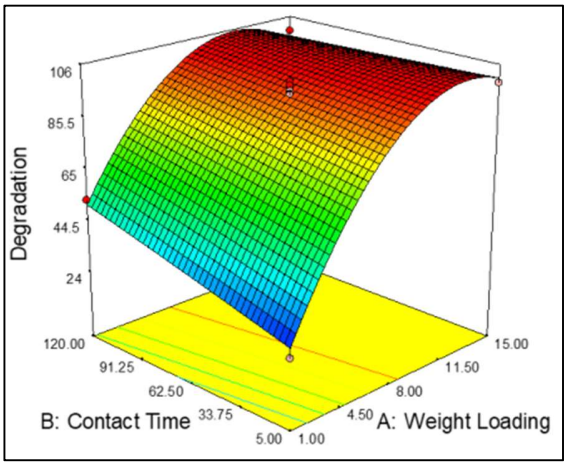

Figure 9. 3-D surface plot of two parameters toward degradation of methylene blue for weight loading and contact time

The pH value was kept constant at pH 6.5. The straight line of the contour plot indicated the interaction of weight loading and contact time. As the weight loading increased along with contact time, the percentage

degradation of MB increased. However, as the contact time increased but the weight loading decreased, the percentage degradation was low. This showed that weight loading had significantly contributed to the degradation of MB. Nevertheless, pH value did not play a significant role in the degradation of MB by using MoS_2 under the fluorescent light.

Conclusion

Based on the overall result and discussion, it can be concluded that the MoS_2 was successfully synthesised by the hydrothermal method. The synthesised MoS_2 was characterised by using FTIR, UV-vis solid, XRD, SEM and TGA analyses. The characterisation results clearly revealed that a flower-like MoS2 has been successfully synthesised. For the photocatalytic study of MB, the optimum condition for photodegradation of methylene blue by using MoS_2 were observed under pH 6.5 for MB with MoS_2 weight loading of 15 mg which ran for 120 min which had the highest percentage degradation with value 99.93% as compared to other samples under the fluorescent light. As observed, the most effective parameters in the degradation of MB were weight loading followed by the contact time and pH value.

Abstract

This study aimed to determine the major compounds present in local dammar resin and its potential as an anticorrosive property. Dammar resin from a stingless bee hive was subjected to solvent extraction using an aqueous system; 70:30 v/v of ethanol: water. The yield of extraction was characterized through Fourier transform infrared (FTIR) and gas chromatography-mass spectrometry (GC-MS). A linear polarization resistance (LPR), potentiodynamic polarization, and weight loss test were performed to evaluate the corrosion rate of steel. The result shows that longipinane (18%) was the major compound present in the extract, followed by ursolic aldehyde (14%), 1H-cycloprop[e]azulene (6.85%), 3,4-dichlorophenyl thiocyanate (6%), azulene, 1,2,3,3a,4,5,6,7-octahydro-1,4-dimethyl-7-(1-methylethenyl) (4.48%), and 2,4-heptadienal (4%). The existence of aromatic structure, phenyl group, C=C, and C=O provides an active site for adsorption on the metal surface to inhibit steel corrosion. LPR and weight loss test revealed the lowest corrosion rate at the 600 ppm dammar extract and recorded about 60% and 74% inhibition efficiency respectively. Tafel analysis showed a decrease in current density from 5.8×10^{-3} to 8.0×10^{-4} after 600 ppm dammar extract was employed in the corrosive medium of 3% NaCl, eventually, giving an inhibition efficiency at 86.2%. This research signifies that the local dammar resin of stingless bee hives has great potential as a corrosion inhibitor.

Keywords: dammar resin, gas chromatography-mass spectroscopy, corrosion rate, corrosion inhibition, Tafel

Abstrak

Kajian ini bertujuan untuk menentukan sebatian utama yang terdapat dalam resin dammar tempatan dan mengenalpasti potensi sifat antikarat. Dammar daripada sarang lebah tanpa sengat telah melaui pengekstrakan pelarut menggunakan sistem akueus; 70:30 v/v etanol: air. Hasil pengekstrakan telah dicirikan melalui inframerah transfromasi Fourier (FTIR) dan kromatografi gas-

spektrometri jisim (GC-MS). Rintangan polarisasi linear (LPR), pengutuban potensiodinamik dan ujian kehilangan berat telah dilakukan untuk menilai kadar kakisan keluli. Keputusan menunjukkan bahawa longipinan (18%) merupakan sebatian utama dalam ekstrak, diikuti oleh aldehid ursolik (14%), 1H-cycloprop[e]azulene (6.85%), 3,4-diklorofenil tiosianat (6%), azulena, 1,2,3,3a,4,5,6,7-oktahidro-1,4-dimetil-7-(1-metiletenal) (4.48%) dan 2,4-heptadienal (4%). Kewujudan struktur aromatik, kumpulan fenil, C=C dan C=O menyediakan tapak aktif untuk penjerapan pada permukaan logam bagi menghalang kakisan keluli. Keputusan LPR dan ujian kehilangan berat menunjukkan kadar kakisan terendah pada ekstrak dammar 600 ppm, dan masing-masing merekodkan kira-kira 60% dan 74% kecekapan perencatan. Analisis Tafel menunjukkan penurunan ketumpatan arus dari 5.8×10^{-3} kepada 8.0×10^{-4} selepas ekstrak dammar 600 ppm digunakan dalam medium 3% NaCl, akhirnya memberikan kecekapan perencatan 86.2%. Penyelidikan ini menunjukkan resin dammar sarang lebah tanpa sengat yang diperoleh dari sumber tempatan berpotensi besar sebagai perencat kakisan logam.

Kata kunci: dammar, kromatografi gas-spektrometri jisim, kadar kakisan, perencatan kakisan, Tafel

Introduction

The strategies in managing the degradation of metal and its structure must always synchronize with the aspect of cost, energy, time, nature of the environment, and materials. Failure in handling the strategies can cause severe damage and losses, especially on a metal structure with complex designs as well as hidden structures that are hard to inspect routinely. An effort in using good substances or chemicals in controlling the corrosion attack such as corrosion inhibitors is the most practical in such conditions. The organic inhibitors adsorb on the metal surface, form a thin protective film, and give protection from the corrosive environment. Since the principle of corrosion inhibitors is to alter the corrosiveness of the environment, the technology in exploiting natural sources and organic chemicals is encouraged as well in coatings. Attempts have been made on using metals and plant-based extracts as corrosion inhibitors such as carbon, carbon black, graphene, graphite, silver, glycosides, alkaloids, amino acids, flavonoids, and many more [1-3].

However, another less researched potential source is the organic chemical originating from natural sources such as dammar resinous or propolis from beehives. This native chemical is one of the potential materials to be introduced in corrosion control strategies. It offers abundance, availability, and renewable as compared to other metallic inhibitors. Dammar resinous or propolis is a resinous substance formed by honeybees from buds, leaves, and exudates of trees and plants mixed with pollen, wax, and enzymes secreted from the bees [4, 5]. The resinous substance is generally composed of approximately 50% resin (polyphenolic fraction), 30% wax, 10% essential oils, 5% pollen, and 5% various organic and inorganic compounds. Chemicals compounds (such as flavonoid and polyphenol) in dammar and propolis or beehive extract were found to have an antioxidant property that reflects the role for inhibits an oxidation process. The use of the dammar resinous or propolis extract from bee hives as corrosion inhibitors has developed interest among researchers. Rizvi et al. reported the ethanolic extract of propolis at 250 ppm was able to inhibit steel corrosion at 70% efficiency with comprehensive adsorption [6]. While Gapsari et al. stated that 2000 ppm bee wax propolis extract was feasible to inhibit the stainless steel corrosion in sulfuric acid with up to 97% efficiency with the formation of the complex and protective film [7]. The inhibition was reported due to physisorption and temperature-dependent. The efficiency of propolis also has been discussed by Fouda et al. who explained the inhibitive action based on the adsorption of the stable complex at the carbon steel surface [8, 9].

Apart from steel, other metals also have been treated by dammar resin/bee nest/wax base [7]. A study by Hachelef et al. revealed that the efficiency of propolis extract as a corrosion inhibitor for copper alloy in NaCl gives the maximum value of the inhibitory (73.28%) at an optimum concentration of 1.25 g/L of propolis extract [8]. Varvara et al. investigated the ability of propolis against the corrosion of bronze and found that 100 ppm propolis gives up to 98% with 12h exposure to weak acid of sodium sulphate and sodium bicarbonate [9]. The inhibitory effect was reported due to the adsorption of flavonoids and phenolic compounds on the bronze surface. The anticorrosive behaviour of propolis in combating aluminium corrosion was studied by Islami et al. and it was found that the high concentration of

propolis extract may cause agglomeration thus decreasing the efficiency [10].

However, not much literature on the chemical constituents of propolis from stingless bee hives has reported the inhibition properties [4, 11]. The composition of raw propolis depends on the geographical location, nature of plants, and bee species. A study by a group of Malaysian researchers has found that the local propolis extract is composed of volatile and non-volatile compounds [12]. While Leonhardt et al. revealed the propolis from the stingless bees in Borneo comprise terpenes, alkanes, and alkenes [13]. A constituent of triterpenes and flavonoids from stingless bee hives originated from Northeast Brazil also has been explored by Freitas et al. through chemical isolation and characterization [14]. In another study, Kartal et al. reported that flavonoids, aromatic acids, diterpenic acids, and phenolic compounds were the major components accountable for the biological activities of propolis samples [15]. Since the geographical was a strong factor in the variation of bee hive constituents, hence, each of the bee hive extracts may compose of a unique constituent locally.

The extraction methods play crucial roles in determining the obtained green inhibitor's functional compounds. It includes soaking, heating reflux, enzymatic hydrolysis, Soxhlet extraction, and ultrasonic extraction methods [16]. However, in this research, the usage of the aqueous extraction technique is preferred as compared to the organic extracts as it gives polar phytochemicals that offer strong bonding with the metallic surface than the non-polar in the latter technique [2]. The preferred aqueous method using ethanol is cost-saving and commonly known as a green extractant in providing high yield efficiency [17].

Therefore, the study of potential chemical constituents extracted from local bee hives was embarked as a corrosion inhibitor focusing on properties of the main constituent present in the extract of a stingless bee hive that may contribute to the potency of anticorrosive properties against steel. This work begins with the extraction, characterization, and identification of bee hives constituents through chemical analysis, followed by a corrosion inhibitors test.

Materials and Methods

Extraction of dammar resin

Dammar resin from a stingless bee hive (Figure 1a) or locally known as *damar kelulut* was collected from a local bee farm in Merbok, Kedah, Northern Peninsular Malaysia. The dried dammar resin was crushed into a fine powder and subjected to solvent extraction in 70:30 v/v of ethanol: water. The solvent mixture was heated below 60 ºC, stirred for 24 hours, filtered, and kept at 4 ºC for 3 days before removing the ethanol using a rotary evaporator. The light brown solution obtained was dried using a freeze-dryer to remove water and moisture and kept in a closed container before characterization. Light brown powders of dammar resin extracts were obtained (Figure 1b). The powder was used to form an inhibitors solution (Figure 1c).

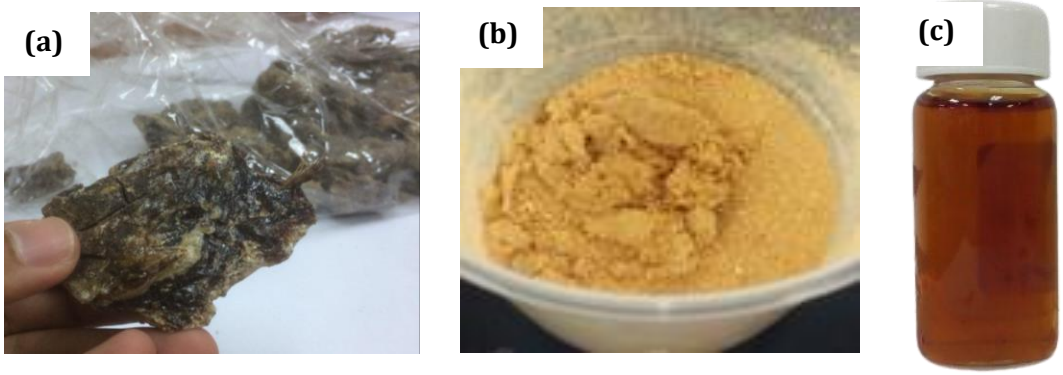

Figure 1: (a) Dammar resin; (b) Dammar resin powder after the extraction; (c) Dammar resin extract in ethanol/water system 70:30)

Characterization of dammar resin

Characterization of dammar resin extract was performed via Fourier transmission infrared (FTIR) and gas chromatography-mass spectrometry (GC-MS). FTIR analysis was carried out on a powder of dammar resin (before and after extraction) to identify the functional group present. The chromatograph and mass spectrometer calibration was performed using GC-MS Agilent 7890A gas chromatograph with a triple-axis detector. The chromatographic column used was SGE BPX-5 (30 m x 0.32mm i.d x 0.25 μm film thickness) with 5% phenyl polyphenylene-siloxane at a temperature from 50 C for 2 min, then 20 ^{o}C min^{-1} to 280 ^{o}C for 10 min, and finally 20 ^{o}C min^{-1} to 320 ^{o}C for 50 min.

Preparation of metal sample and corrosion inhibitor solution from dammar resin extract

A carbon steel S50C with a dimension of 1 cm x 1 cm x 0.6 cm was embedded in an epoxy resin with an exposed area of 1 cm^2. The specimen was polished by using different sizes of emery paper grades (from 400 to 1200), washed thoroughly with distilled water, and rinsed with ethanol [18, 19]. A solution of 3 wt.% NaCl was prepared in the 1 L flask and was used as a corrosive medium in a glass cell corrosion test. The carbon dioxide gas was purged for 1 hour to provide the glass cell containing 3 wt.% NaCl with saturated gases.

Electrochemical test

Linear polarization resistance (LPR) measurement was performed via ACM Instrument Gill 12 Weld Tester for data acquisition. A typical three-electrode glass cell was used consisting of a saturated calomel electrode AgCl (SCE) as a reference electrode and graphite as the counter electrode. The experiment was carried out at a constant temperature (within ±1° C). The potentiodynamic polarization test was performed for 24 hours. The measurement of LPR was recorded at a constant sweep rate of 0.167 mVs^{-1} and the scanning range was from -250 to +250 mV with respect to the open circuit potential (OCP). Inhibition efficiencies percentage (%IE) were determined from the corrosion current densities, I_{corr} calculated by the Tafel extrapolation method. The persistence test was carried out by immersing the metal sample in dammar extract for 1 hour to form a film. The metal samples were then dried before being exposed to a corrosive medium. The introduction of an inhibitor in 3 wt.% NaCl was carried out after a 2-hour measurement for stabilization of open circuit potential (OCP). The concentration of dammar extract as an inhibitor for this test was selected from the maximum inhibition efficiency achieved by the weight loss and LPR analysis.

Weight loss test

The weight loss test (immersion test) was carried out in a 1 L glass cell beaker containing 3 wt.% NaCl with different concentrations of dammar extract (200-1000 ppm). The immersion test was performed for 24 hours and the weight before and after immersion was recorded. The corrosion rate, CR was calculated using Eq. (1);

$$\mathrm{CR\ (mm/y)} = \frac{\mathrm{W}}{(\mathrm{D}\times\mathrm{A}\times\mathrm{T})} \times \mathrm{K} \quad (1)$$

Where, W = weight loss in grams, K = constant (87600), D = metal density in g/cm^3, A = area of the specimen (cm^2), and T = time (hour).

The inhibition efficiency was quantified using Eq. (2);

$$\mathrm{IE\%} = \frac{\mathrm{CR_0} - \mathrm{CR_i}}{\mathrm{CR_{0l}}} \times 100 \quad (2)$$

Where, CR_0 = Corrosion rate of the uninhibited system, and CR_i = Corrosion rate of the inhibited system.

Results and Discussion

Characterization of functional group in dammar extract via FTIR

Figure 2 illustrates the combination of the FTIR spectrum for dammar resin powder before extraction, after extraction and dammar extract in an aqueous solution of 70% ethanol; designated as (a), (b) and (c) respectively. The peak assignment for each spectrum was shown in Table 1.

In Figures 2 (a) and 2 (b), the spectrum shows an absorption around 3400 cm^{-1} assigned to the OH broadened band of either hydrogen bonded or hydroxyl group in the phenolic and aliphatic compounds. The absorption peaks at 2929 and 2943 cm^{-1} were due to the C-H stretch band of a methyl group. The peaks at 2868 and 2869 cm^{-1} were assigned as alkyl units of CH for a sample before extraction and ethanoic content for a sample after extraction correspondingly. The intense peak around 1693 and 1694 cm^{-1} were assigned as carboxylic acid groups (C=O). While the vibration around 1513, 1515, 1456, and 1453 cm^{-1} shows the presence of aromatic groups, C=C [7, 9]. Several peaks around 1380, 1313, 1273, 1109, 1087, and 1046 cm^{-1} for both samples exhibit the C-O stretching band of the carbonyl group and C-OH bending band. Meanwhile, a peak around 887 and 826 cm^{-1} was attributed to primary and secondary alcohol for a sample after extraction [6]. The existence of C=O, C=C, and OH in the dammar extract might contribute to the anticorrosive properties as the common criteria for a corrosion inhibitor is to have oxygen, functional groups, and aromatic rings for the best site of interaction [20, 21].

Spectra in Figure 2 (c) represent the FTIR result for dammar extract in aqueous 70% ethanol. The broad peak was observed at 3358 cm^{-1} corresponding to the OH group. Meanwhile, a peak around 2976 and 2893 cm^{-1} was assigned as ethanoic content for an extract in an aqueous solution. A peak at 1648 cm^{-1} was attributed to the C=C of the alkene and aromatic group. Several bands at 1453, 1382, 1086, and 1045 cm^{-1} were considered alcoholic functional groups of the C-O bond. Meanwhile, a band of 879 and 672 cm^{-1} is also related to the primary and secondary alcohol.

Identification of chemical constituents in dammar extract via GC-MS

A total of 46 constituents were finally identified via GC-MS analysis of dammar resin extract in 70% ethanol within 62.4 minutes as depicted in Table 2. The first compound, 1,3,6-Heptatriene, 2,5,6-trimethyl was detected around RT=19.5 min with an amount of 0.35%. The highest amount 18.42% was detected at RT=56.8 assigned as longipinanne. The less volatile in this extract was methyl 3 beta-hydroxyolean-18-en-28-oate since it was the last compound detected, with 3.33% amount.

Table 2. Chemical constituent of dammar extract in dammar resin (70:30 of ethanol:water) identified via GC-MS

Peak Number	**RT**	**Compound Detected**	**Total Amount (%)**
1	19.457	1,3,6-Heptatriene, 2,5,6-trimethyl	0.35
2	20.635	Copaene	1.40

Chemical structure of major identified compounds in dammar resin extract

Figure 3 shows the chemical compounds found in dammar extract deduced from GC-MS. Out of 46 constituents in dammar extract, about 6 main compounds were identified in the range of 4 to 18%. Longipinane (18%) was the most abundant compound present followed by ursolic aldehyde (14%), 1H-cycloprop[e]azulene (6.85%), 3,4-dichlorophenyl thiocyanate (6%), azulene, 1,2,3,3a,4,5,6,7-octahydr o-1,4-dimethyl-7-(1-methylethenyl) (4.48%) and 2,4-heptadienal (4%). Most of the components present in dammar extract are classified as terpenoids.

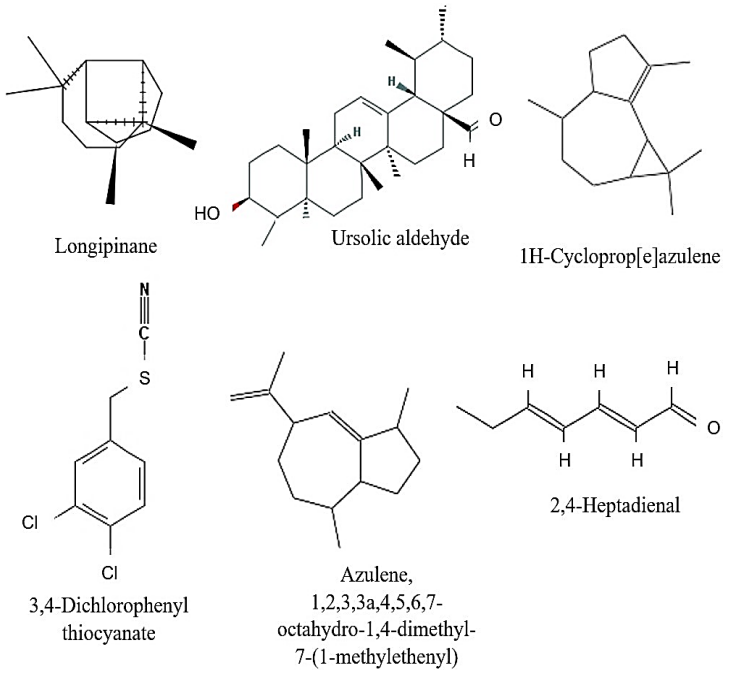

Figure 3. A main chemical compound present in dammar extract as deduced from GC-MS

Molecular structure criteria for corrosion inhibition

Table 3 summarized the main compound contains in propolis obtained from different regions. The listed propolis types have been extracted and analyzed for corrosion studies. The main compound was reported to have an anti-corrosive property.

Most of the chemical compounds in extracted dammar or propolis were built with an aromatic structure, for example, quercetin, cinnamic, and caffeic acid. Aromatic structure with delocalized electrons and functional groups provides an optimum site for interaction with metal. It is found that organic compounds containing aromatic rings and polar substituents are served as the most effective corrosion inhibitors. This agrees with studies that report each extract consists of complex phytochemicals (polar functional groups and multiple bonds) providing electron-rich sites and aiding in the adsorption of phytochemicals on a metal substrate [2, 23].

Aliphatic groups also may contribute to the interaction since their structure may occupy the limited adsorption site to retard the corrosion process. However, corrosion inhibition affected by the structure of inhibitors depends on its orientation, size, and the distribution of the electrons cloud. In agreement with a study by Varvara et al., besides aromatic structure, the presence of oxygen atoms in functional groups and various phenolic compounds are also factors for the corrosion inhibition of bronze corrosion in sodium solution [24].

Besides, the existence of methyl, CH_3 in almost all structures identified in both extracts plays an important

role in inhibition as methyl also provides a significant reaction site. The presence of particular repeating units (such as methyl and phenyl groups) of the parent chain and other substituent groups may improve the bonding strength of the group on the metal [21].

Table 3. List of main compounds in propolis discovered from different types and regions

Propolis Type	Extraction Method	Analysis	Main Compound	Ref
Bee wax propolis	Liquid-liquid extraction	FTIR and HPLC	Quercetin (2-(3,4-dihydroxyphenyl)-3,5,7- trihydroxy-4H-chromen-4-one)	[7, 9]
Propolis sample collected from Henan province (China)	Solvent extraction using ethanol	FTIR and HPLC	Pinos-trobin, trans-cinnamic acid, galangin and pinocembrin	
Ethanolic extract of propolis was provided by the Duzce University Beekeeping Research, Development and Application Centre, Yigilca, Turkey	Solvent extraction using 96% ethanol	FTIR and HPLC	3,4-dimethoxycinnamic acid, pinobanksin, caffeic acid, apigenin, isorhamnetin, curcumin, naringin, myristic acid and luteolin	[6]
Collected from Daqahlia province (delta Nile) of Egypt	Water extraction	Not included	Pinocembrin, caffeic acid, phenyl ester, quercetin and galangi	
Croatian propolis	Commercial alcoholic extract of propolis	Not included	Luteolin, 7-O- prenylpinocembrin, Cearoin, Linalool, P-methoxycinnamic acid, 3-prenyl-4-hydroxy-suberosin cinnamic acid, 3-prenylresveratro, l 6-methoxydiphyllin and Prenylated coumarin	[5, 22]
Propolis collected from the region of Bordj El Menaiel in Algeria	Ethylene glycol (30%) / water (70%)	FTIR	Not included	[8]

Linear polarization resistance (LPR)

Table 4 shows the resistance polarization value, Rp obtained from the LPR measurement. The Rp value for the blank solution without inhibitors (0 ppm) shows the lowest value with only 1225 Ohm.cm^2. Meanwhile, the highest values of Rp with 2971 Ohm.cm^2 are shown by the inhibitor's concentration at 600 ppm. It can be seen that the Rp value was increased as the concentration inhibitors increased from 200 to 600 ppm. However, the value then declined when the addition of inhibitors concentration was increased up to 800 and 1000 ppm.

The lowest value of Rp demonstrates small resistance to corrosion since no dammar extract was applied in the systems. Thus, the corrosion of steel might increase with a decrease in resistance. The greater value of Rp shown at 600 ppm was assigned that the dammar extract was capable to provide resistance to corrosion. This attributes to good inhibition which resists the chloride attack against the steel surface. The decrease in Rp values as the concentration of extract increased was due to the overdosage of inhibitor molecules that may promote the complexation. This phenomenon affects the formation of a protective film to resist corrosive ions due to repulsive interactions, thus weakening the adsorption for inhibition [25].

Table 4. Resistance polarization (Rp) value of steel corrosion by dammar extract at different concentrations

Concentration Inhibitor (ppm)	Rp (Ohm.cm^2)
0	1225
200	1413
400	2750
600	2971
800	1469
1000	1397

Corrosion rate measurement

Figure 4 shows the corrosion rate measurement employed through the weight loss method and LPR technique. The high values of corrosion rate were shown in all measured concentrations via the LPR technique compared to the weight loss method. The highest value of corrosion rate was shown by the steel sample without corrosion inhibitors (0 ppm) for both the weight loss method (0.19 mm/yr) and LPR (0.25 mm/yr). The addition of 200 to 600 ppm dammar extract reduced the corrosion rate concentration and gradually increased as the inhibitors were increased. The lowest corrosion rate was achieved via weight loss methods at 0.05 mm/yr for 600 ppm. Above the 600 ppm dammar resin, the increase in inhibitor concentration has increased the corrosion rate values up to 0.22 mm/yr. The corrosion rate values for both measurement methods showed a similar trend.

In this result, the low concentration of dammar extract provides low corrosion protection as inhibitors were unable to prevent the corrosive ion, (eg: Cl^-). Consequently, the corrosion rate was increased due to insufficient dammar extract to interact on the surface for better corrosion inhibition. Meanwhile, the overdosage of dammar extract contributes to the excess of inhibitor molecules in the solution. Eventually, various ions in the solution create the Van der Waals effect where the mutual repulsion or attraction force is triggered among the inhibitors molecules and ions in the metal/solution interface [25]. Therefore, the high corrosion rate at high inhibitor concentration is also due to the complexity of dammar extracts composition causing the desorption process [26].

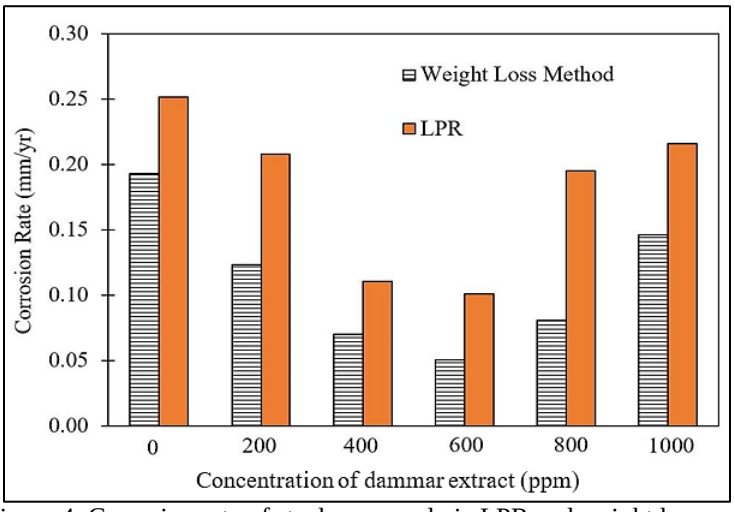

Figure 4. Corrosion rate of steel measured via LPR and weight loss method

Table 5 shows the inhibition efficiency value of steel corrosion calculated from corrosion rate values obtained via LPR and weight loss analysis in different concentrations of inhibitor. Generally, the addition of corrosion inhibitors shows enhanced corrosion inhibition. However, our results showed the inhibition efficiency was dependent on the concentration of the inhibitor.

Table 5. Inhibition efficiency of steel corrosion by dammar extract at a different concentration calculated from corrosion rate values obtained via LPR and weight loss analysis

Concentration (ppm)	**Inhibition Efficiency (IE%)**	
	LPR Analysis	**Weight Loss Analysis**
0 ppm	0	0
200 ppm	17	36
400 ppm	56	64
600 ppm	60	74
800 ppm	22	58
1000 ppm	14	24

From the tabulated data, it can be seen that the inhibition efficiency increased up to 60% and 74% as 600 ppm dammar resin was used in LPR and weight loss methods correspondingly. While the use of 1000 ppm dammar resin exhibits the lowest efficiency. The values decreased as the concentration become increased to 1000 ppm The highest efficiency was achieved at the concentration of 600 ppm of dammar resin. The maximum efficiency was shown by the 600 ppm dammar resin for both methods. It is believed that the inhibitor molecules affect the reactions and adsorbed on the mild steel plate by blocking the active sites situated on the metal surface hence inhibiting the corrosion reaction. The compounds establish a barrier associated with mass charge transfer. The hindrance against the transport of corrosive ions into the solution was contributed by the adsorption of phenolic compounds via an aromatic ring, as well as the heteroatoms of nitrogen and oxygen upon the steel plate [1].

This situation also explained the phenomenon of limiting or critical concentration and the solubility effect [27-29]. At the concentration of 600 ppm, the dammar resin molecules have covered an optimum surface coverage and inhibit the corrosion at high efficiency. As more inhibitors are added into the corrosive medium, there is a limited site for adsorption. It is observed that before and after the 600 ppm, the inhibition efficiency in both LPR and weight loss method was lesser than 60% and 74% respectively. The low efficiency shown by the highest concentration (1000 ppm) was due to the desorption process. This indicates the presence of improper surface protection on the metal substrate. The weak interaction among the inhibitor molecules and metal surfaces generated from dipole-dipole interactions has declined the adsorption capability [25]. Therefore, the adsorption and inhibition were controlled by the major structure of the chemical components in the inhibitors [27, 30] such as alkyl chain length in the inhibitor, presence of heteroatoms and heterocycles in the molecule, existence of electron donating/withdrawing functionalities, and size of rings in the inhibitors molecules as can be further investigated in Figure 3.

Figure 5 shows the Tafel plots obtained from the electrochemical measurement of steel exposed to 3% NaCl solution. The presence of 600 ppm dammar extract in 3% NaCl was measured and the electrochemical parameter was summarized in Table 6.

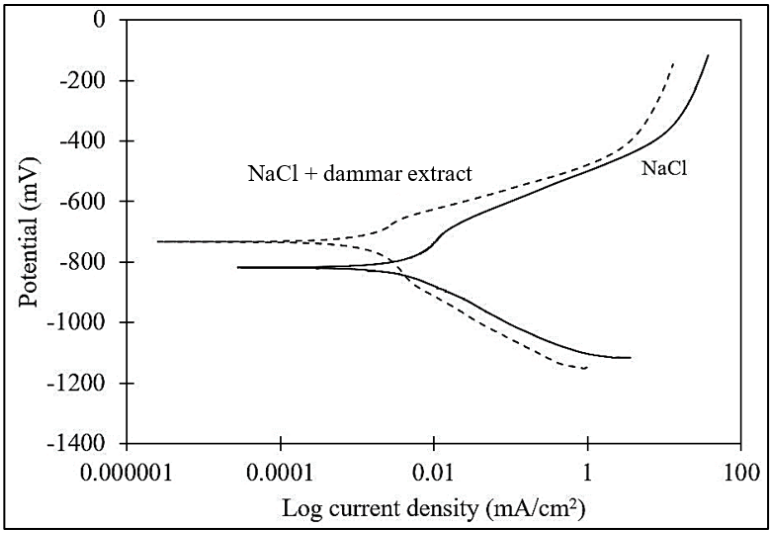

Figure 5. Potentiodynamic polarization curve of steel in NaCl and the absence and presence of 600 ppm dammar extract

Table 6. Tafel parameter obtained from potentiodynamic polarization test

Inhibitor System	**Corrosion Potential, E_{corr} (mv)**	**Current Density, I_{corr} (mA/cm^2)**	**Inhibition Efficiency (IE%)**
NaCl	-818	5.8×10^{-3}	0
NaCl + dammar extract	-725	8.0×10^{-4}	86.2

The presence of dammar extract inhibitors in 3% NaCl has shifted the E_{corr} value to a more positive potential. This signified the dammar extract inhibitors act as an anodic inhibitors type by decreasing the steel dissolution. Simultaneously, the value of current density, I_{corr} was reduced from 5.8×10^{-3} to 8×10^{-4} mA/cm^2 assigned the flow of electrons is hindered by the mass of dammar extract molecules. The changes of both E_{corr} and I_{corr} values attribute the corrosion inhibition due to the adsorption of dammar extract on the steel surface. The dammar extract molecules have hindered the corrosive ions from NaCl from further attacking the steel.

Conclusion

The overall findings from this study can be concluded as follows: The chemical constituents of dammar extract have been determined and the six major compounds were found; longipinane (18%), ursolic aldehyde (14%), 1H-cycloprop[e]azulene (6.85%), 3,4-dichlorophenyl thiocyanate (6%), azulene, 1,2,3,3a,4,5,6,7-octahydr o-1,4-dimethyl-7-(1-methylethenyl) (4.48%) and 2,4-heptadienal (4%). The existence of various functional groups such as C=C, C=O, C-OH, CH_3, phenyl group, and aromatic structure contributed to the good anticorrosive properties of the local *kelulut* dammar extract towards steel corrosion. The best concentration of dammar extract was 600 ppm with 86.2% inhibition efficiency may exhibit a practical, efficient, and excellent potential for alternative green corrosion inhibitors. Below 600 ppm, the adsorption of inhibitor on the metal surface happened at an intermediate level of inhibition. Whilst, more crowding inhibitor molecules at the metal/solution interface do not improve the corrosion inhibition. The inhibition efficiency of the dammar extract obtained from LPR and weight loss measurements were in good agreement.

Abstract

Diet and lifestyle changes are essential alternative treatments for hypertension. Consumers are increasingly more interested in health-promoting ingredients. The use of red tilapia (*Oreochromis* sp.) by-products (RTBP) has been established as a precursor for protein hydrolysate with angiotensin I-converting (ACE)-inhibitory activity. However, the complexity of the protein hydrolysate reduces its potency. Thus, this work aimed to purify and characterise the ACE-inhibitory hydrolysate derived from red tilapia (*Oreochromis* sp.). Thermoase PC10F (EC 3.4.24.27) was used in this study to hydrolyse red tilapia by-products (*Oreochromis* sp.). Meanwhile, ultrafiltration (UF), anion-exchange principle (AEX) and hydrophobic interaction chromatogram (HIC) were applied to purify the hydrolysate. Two molecular weight cut-offs (MWCO) were used for ultrafiltration: 3 kDa and 1 kDa. The 1 kDa hydrolysate showed the highest bioactivity of 85.42% (IC_{50}=0.41 mg mL^{-}). Subsequently, the 1 kDa RTBP hydrolysate was purified based on charge using AEX. Positively charged hydrolysate demonstrated significant bioactivity of 72.32%. In the final purification steps, the hydrophobic fractions showed the highest ACE-inhibitory activity obtained through the hydrophobic interaction chromatogram. The chromatogram yielded two fractions of peaks of high ACE-inhibitory activity on the hydrophobic fraction, which were 90.44% and 95.28%, respectively. Thus, ACE-inhibitory hydrolysate of small molecular size, positive charged and hydrophobic contributed significantly to its potency.

Abstrak

Penukaran enzim yang dikenali sebagai Angiotensin-1 kepada Angiotensin-2 bertanggungjawab ke atas kenaikan tekanan darah yang menyebabkan hipertensi. Perubahan diet dan gaya hidup perlu diterapkan sebagai pelan rawatan alternatif. Pasaran untuk kompoun penggalak kesihatan didalam makanan semakin dicari-cari pengguna. Sejak sedekad lalu, pelbagai kajian dijalankan ke atas hasil sampingan ikan tilapia (*Oreochromis* sp.) kerana sifat biologinya terutamanya sebagai agen antihipeternsi. Kenaikkan permintaan bekalan terhadap filet ikan turut meningkatkan kadar penangkapan ikan. Maka, terdapat lebihan model pengeluaran yang dapat dieksploitasi dengan cara yang menguntungkan. Di dalam kajian ini,Thermoase PC10F menghasilkan hidrolisat penghambat ACE daripada hasil sampingan ikan tilapia merah (*Oreochromis* sp.). Manakala hidrolisat ini ditulenkan melalui ultrafiltrasi (UF), prinsip pertukaran anion (AEX) dan kromatogram interaksi hidrofobik (HIC). Dua berat molekul 3 kDa dan 1 kDa digunakan didalam proses ultrafiltrasi. Penghambatan aktiviti ACE untuk berat molekul 1 kDa lebih tinggi berbanding 3 kDa dengan jumlah 85.42%. Seterusnya, hidrolisat 1 kDa ditulenkan melalui prinsip pertukaran ion dan hidrolisat bercas positif mempunyai penghambatan aktiviti ACE yang tertinggi (72.32%) berbandingkan dengan hidrolisat bercas negatif. Akhir sekali, proses penulenan dilakukan melalui kromatogram interaksi hidrofobik dan pecahan hidrofobik mempunyai penghambatan aktiviti ACE yang tertinggi. Kromatogram menghasilkan dua bagian puncak hidrofobik yang mempunya peringkat aktiviti penghambatan ACE tertinggi sebanyak 90.44% dan 95.28%. Maka, sifat molekul yang kecil, bercas positif dan hidrofobik merupakan ciri-ciri hidrolisat penghambatan aktiviti ACE yang manjur.

Introduction

Multiple biological activities in fish protein hydrolysate, such as antioxidative, lipid homeostasis regulation, anti-inflammatory, anticancer, neuroprotective and antihypertensive, can be utilised as a functional food ingredient. [1]. ACE inhibitors comprise a novel class of medications used to treat hypertension and heart failure. In addition to their well-known role and ease of availability, synthetic medications include unwanted side effects [2-4]. Thus, the quest for alternative natural ACE-inhibitory peptides has been expanded to various food protein sources, which include aquatic protein sources.

Numerous studies on the freshwater fishes' by-product hydrolysate derived from Grass carp, Tilapia, Snakehead fish, shortfin scad fish and catfish have shown promising antihypertensive properties [4-11]. Tilapia is a freshwater fish that is widely cultured in Asian countries [4] as it multiplies and has low feed requirements [10]. With the rapid increase in fish production to cope with the fish filleting demand, more than 50% of the residuals from the total fish capture become unused as nourishment, which involves nearly 32 million tonnes of the fish by-product that can be processed into a desirable functional food [12, 13]. Tilapia is one of the most important freshwater fish species sold internationally owing to its popularity among people of various cultural, religious and economic backgrounds. Besides, red tilapia scales have between 41% and 84% protein, the highest among residues of fish farms [14, 15].

Protein complexes are among the most essential functional elements for deriving cellular biological functions [16]. Hence, the search begins for antihypertensive bioactive peptides that are inactive within the sequence of the parent protein but can be released during gastrointestinal digestion or food processing like enzymatic hydrolysis [5,13]. However, protein extracted from complex biological systems contains a complex protein combination suspended in a mixture of organic and aqueous solvents [1, 17]. The production of bioactive peptides involves several steps including the screening of enzymes, optimisation of hydrolysis conditions, as well as the purification of protein hydrolysate. Thermoase PC10F was chosen for enzymatic hydrolysis in this study, which is a commercial enzyme for thermolysin. The primary site for thermolysin cleavage specificity accommodates long hydrophobic residues. Thermolysin preferentially cleaves hydrophobic or bulky amino side chains [6,18,19]. Nevertheless, no research on the antihypertensive properties of RTBP hydrolysate using thermolysin or the commercial enzyme, Thermoase PC10F, has been conducted. In addition, purification of the protein hydrolysate-containing peptides is one of the most crucial steps in improving ACE-inhibitory

potency. The most common considerations to purify peptides are based on their specific characteristics such as molecular size (ii) charge and (iii) hydrophobicity as peptide activities are heavily influenced by the structure-determined characteristics [4-7, 9-11, 17-23].

The goal of this study was to separate and purified the hydrolysate from a red tilapia (*Oreochromis* sp.) by-products (RTBP) treated with Thermoase PC10F based on molecular size, surface charge and hydrophobicity. The core technique for protein purification was quite straightforward: all impurities were removed while preserving as much of the peptide of interest with high ACE-inhibitory activity as possible.

Materials and Methods

Protein hydrolysate preparation

Enzymatic hydrolysis was done using Thermoase PC10F enzyme. The hydrolysis of 2g of sample was mixed with Thermoase PC10F enzyme and hydrolysed with phosphate buffer, pH 7. The ratio of enzyme to sample was 1:160 was incubated at 68 °C for 6 hours in a shaking bath. The sample was immersed in boiling water for 5 minutes to stop the hydrolysis. Then, the hydrolysate (sample) was centrifuged, whereas the supernatant was collected for further analysis.

Total protein assay (Lowry assay)

Bovine serum albumin (BSA) was used as protein standard at the concentration of 50, 100, 200, 300 and 400 µg mL^{-1}. Lowry reagent solution of 1 mL was added to each sample and incubated for 20 minutes at room temperature. Then, 0.5 mL of Follin Ciocalteu's Phenol working reagent was added and mix immediately. Eppendorf tubes were incubated for 30 minutes at room temperature to allow the colour to be developed. After incubation, the values of absorbance were measured by UV-VIS spectrophotometer at 595 ηm followed by the plotting of absorbance.

Determination of ACE-inhibitory activity: Enzymatic assay with ACE

HHL of 5 mM was prepared using 0.1 M sodium phosphate buffer (pH 8.2) containing 0.3 M NaCl. The same buffer was used for solution preparation of captopril, substrate, hippuric acid, peptides and enzyme dilute. ACE (60 mU mL^{-1}) was prepared from the initial unit (2 U mL^{-1}) using the same buffer. In each assay, 10 µL of the sample and buffer (control) was pipetted into the sample Eppendorf tube. After that, 30 µL of ACE (60 mU mL^{-1}) was added to the sample and gently mixed. Next, the mixture was incubated for 10 minutes at 37 °C. 90 µL of 5 mM HHL was then added to the samples and incubated for another 60 minutes at 37 °C. Finally, 8 µL of 5M HCl was added to stop the reaction and the mixture was filtered through a 0.2 µm PVDF filter into vials.

HPLC method to determine ACE-inhibitory activity

The samples were analysed with Shimadzu LC-20AP Low Gradient System (SPD-20AV) HPLC by a C18 Thermo Scientific ODS Hypersil HPLC column. The sampler and the column temperature were kept at 4 °C and 30 °C, respectively. The injection volume with the flow rate of 20 µL and 1 mL min^{-1}, respectively, for 12 minutes was used with an isocratic solution of 0.1% trifluoroacetic acid in 12.5% acetonitrile. The absorbance was monitored with ultraviolet (UV-VIS) detection at 228 nm. Serial dilutions of HA from 0.02 to 1 mM were applied to determine the calibration curve.

Calculation of ACE-inhibitory activity

The percentage of ACE-inhibitor activity (ACEi%) was calculated based on the hippuric acid liberated using the hydrolysates sample and control (buffer) as follows (1):

$$ACEi\% = \left[\frac{(HAcontrol) - HAsample)}{HAcontrol}\right] x\ 100 \quad (1)$$

Where (ACEi%) was the percentage of angiotensin-converting enzyme inhibitory activity of hydrolysates; [$HA_{control}$] was the concentration of hippuric acid (HA) liberated using buffer instead of inhibitor in the mixture and; [HA_{sample}] was the concentration of hippuric acid liberated in the presence of inhibitors (hydrolysates).

IC_{50} determination of the hydrolysates

The IC_{50} value is defined as the concentration of hydrolysates that can inhibit half-maximal of the ACE. Sample or protein hydrolysates that yielded more than 50% ACEi% were then selected and evaluated for ACEi% in different concentrations. The IC_{50} of the hydrolysates with different enzymatic conditions were determined by the regression analysis of plotting the inverse of serially diluted hydrolysates concentration (1/1, 1/2.5, 1/5, 1/10, 1/20) as a function of the inverse of their ACEi% and expressed as mg of protein per mL. The IC_{50} of the peptides were compared with the IC_{50} of captopril as positive standards.

Determination degree of hydrolysis (DH)

The degree of hydrolysis (DH) was estimated using the o-phthaldialdehyde (OPA) method as described by Nielsen [24] and Pa'ee [25] with some modifications. The o-phthaldialdehyde (OPA) reagent was freshly prepared, comprising 0.025g of OPA (dissolved in 500 µL of pure ethanol) and 25 µL of β-Mercaptoethanol in 50 mL of 50 mM carbonate buffer pH 10.5. This OPA reagent should be protected from direct light and used within 2 hours, or it can eventually be stored under nitrogen in an ambered glass vial for 1-2 weeks at 4 °C. An aliquot of 400 µL of standard or sample was added into the 3 mL of OPA reagent and mixed for 5 seconds. The mixture was incubated at room temperature before being read at 340 nm at a spectrophotometer by UV-VIS 1800 Shimadzu. Deionised water was used as a blank and leucine dilution as a standard. The DH was calculated using the equation from the method.

Fractionation and Purification of RTBP hydrolysate: Ultrafiltration (UF)

Hydrolysates were fractionated using ultrafiltration membranes in a dead-end mode system (Amicon Model 8200 stirred ultrafiltration cell, Amicon Corp., Danvers, MA) utilising the procedures outlined by Roslan [26] with a few minor adjustments.

A stirred ultrafiltration cell has a suspended bar impeller and a stirring hot plate. Flat sheet RC membranes with 1 kDa and 3 kDa MWCO were employed. With a constant pressure at 2.5 bar and continuous stirring speed, an ultrafiltration membrane fractionated the RTBP hydrolysate. Optimal RTBP hydrolysate was separated through a 3 kDa membrane before a 1 kDa membrane. The ACE inhibitory activities and IC_{50} of 1 kDa and 3 kDa permeate were evaluated. Permeate flux was also calculated. The calculation was done as described by Roslan [26] using the following equation (2):

$$Flux = \left(\frac{Total\ quantity\ passed\ throu\ \ membrane}{Membrane\ Area}\right) L/(m^2.h) \quad (2)$$

Flux is the rate at which a membrane separation process works. It is determined by the properties of the membrane, the transmembrane strain, the system's hydrodynamics, the properties of the solvent and protein, and the amount of protein in the feed.

Adsorption equilibrium

The anionic exchanger resin (STREAMLINE DEAE) was used in this work applying a batch adsorption approach. Initially, the resin was washed twice with 10 mM potassium phosphate buffer at pH 7.0 to equilibrate the adsorption conditions. The buffer was decanted once the resin settled at the bottom of the test tube. The RTBP hydrolysate of 5 mL was added and stirred for 10 minutes to adsorb negatively charged peptides to the resin. The resin was then separated from the supernatants by centrifugation. The resin containing the adsorbed protein was eluted with potassium phosphate buffer pH 7.0 containing 1 M NaCl. The resin was regenerated using the same elution buffer. RTBP hydrolysate and supernatant were subjected to total protein assay determination. The difference in concentration between fresh feed RTBP supernatant and concentrated RTBP hydrolysate protein indicates the concentration of trapped RTBP hydrolysate protein. The percentage was calculated using the following formula:

$$Adsorption\ (\%) = \frac{RTBP\ Hydrolysate_{Feed} - Supernatant}{RTBP\ Hydrolysate_{Feed}} \times 100\% \quad (3)$$

Fractionation of hydrolysate by reverse phase-high performance liquid chromatography (RP-HPLC)

Ultrafiltered hydrolysate from subsection 2.4.3 was then subjected to RP-HPLC for hydrophobicity fractionation. Shimadzu UFLC system with column (HypersilTM BDS C18 Column, 5 µm, 250×4.6 mm, 130 Å Thermo ScientificTM) was used for the fractionation. An isocratic solution of 100% of 0.1% TFA was used to separate hydrophilic fraction, while 100% of 0.08% of TFA in Acetonitrile was used to separate the hydrophobic fraction. Hydrolysates were collected into 12 fractionations. The absorbance was monitored with ultraviolet (UV-VIS) detection at 323 nm. Each fraction was assayed for ACE-inhibitory activity.

Results and Discussion

The production of RTBP hydrolysate with ACE-inhibitory activity

A high degree of hydrolysis (DH) applying specific proteases can result in a hydrolysate with strong ACE-inhibition activity. RTBP hydrolysate with the highest DH (73.80%) was observed using Thermoase PC10F (E.C. 3.4.24.27). The hydrolysis of peptide bonds containing hydrophobic amino acids was selectively catalysed by Thermoase PC10F, producing hydrophobic peptides with known ACE-inhibitory action [25]. Ghassem [27] used thermolysin to break apart sarcoplasmic and myofibrillar muscle protein derived from *Clarias batrachus* for producing ACE-inhibitory peptide GPPP and IEKPP. GPPP has mixed inhibition mechanisms that are competitive and non-competitive, whereas IEKPP has a competitive inhibition mechanism. Hydrophobic amino acids like glycine and proline (Gly and Pro) may be key factors in ACE-inhibitory activity [25].

A series of purification steps were performed after the hydrolysis, including UF, ion-exchange chromatography and RP-HPLC to separate ACE-inhibitory peptides according to size, charge and hydrophobicity, respectively. According to Pa'ee [28], ACE activity is determined by tracking the amount of hippuric acid (HA) formed as a result of the ACE-catalysed hydrolysis of N-Hippuryl-His-Leu (HHL). As a result, ACE-inhibitory activity increases with increasing concentrations of HA catalysed by the enzyme. The ACE-inhibitory activity value of each purified technique applied to RTBP hydrolysate is shown in Table 1.

Table 1. Overall results for ACE-inhibitory activity of each purification technique

Procedure		ACE-Inhibitory Activity (%)
Crude RTBP Hydrolysate		70.67 ± 2.40
Ultrafiltration (1kDa)		85.42 ± 0.98
Ion exchange Chromatogram (IEX)		72.32 ± 1.01
Hydrophobic fraction	Peak 1	90.44 ± 4.54
	Peak 2	95.28 ± 1.63

The effect of membrane size towards permeates flux and peptide transmission

Fractionation of RTBP hydrolysate was done by a dead-end UF with two different membrane pore sizes. The cellulose membrane (RC) of MWCO of 3 and 1 kDa were used with a constant pressure of 2.5 bar and a constant stirring speed applied. Permeate flux refers to the rate at which permeate is produced during membrane separation relative to the membrane's total surface area and the amount of time involved [29]. It was shown in Figure 1 that a bigger membrane pore size, 3 kDa, has a higher permeate flux compared to 1 kDa. The line trend in Figure 1 is similar to the previous study done by Roslan [30] at different pH and stirring speeds. The MWCO describes the pore of the membrane, while the membrane represents the molecular weight of a molecule that is rejected at 90% [12, 13]. The bigger the MWCO, the more porous the membrane, whereas smaller MWCO has a smaller membrane pore [31, 32, 33]. The nature of the membrane influences the permeate flow as can be observed that the permeate flow of 3 kDa was faster compared to 1 kDa, which was 4 hours and 5 hours, respectively. The decrease in permeate flow through the membrane was attributable to

fouling, which happens due to nonpermeating solutes tending to form a gel on the surface of the membrane, thus affecting the permeate flow [34]. The formation of cake fouling was due to the perpendicular feed flow of the solutions in a dead-end UF and the concentrated suspended solid on the surface of the membrane. Nonetheless, this can be improved by applying a crossflow UF since the feed solution is tangible.

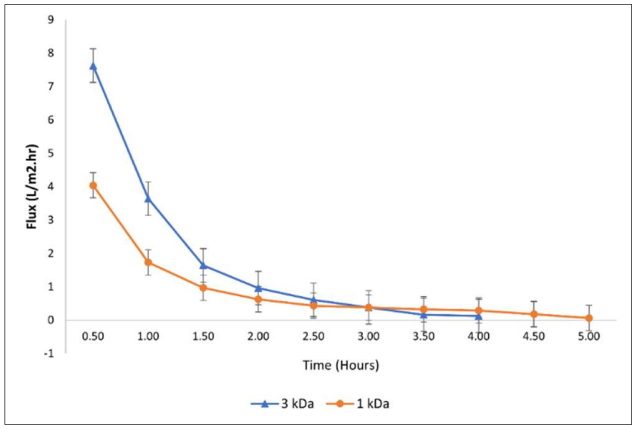

Figure 1. Effects of UF membrane pore size on permeate flux

In addition, the membrane pore size influences peptide transmission. The transmission of peptides through the membrane is highly dependent on the size and direction of membrane pores [26]. In Figure 2, the peptide transmission in 3 kDa was slightly higher compared to 1 kDa, which were 37.40% and 32.62%, respectively. Roslan [26] mentioned that transmissions of peptides through a membrane with a small pore size are lower compared to those of a larger membrane pore size, which may be due to the tendency of a larger peptides size to be retained and accumulated on the membrane surface of the smaller membrane pore size resulting a severe membrane fouling. In his study, the red tilapia by-product hydrolysate was fractionated by a single (10 and 5 kDa) and multilayer (10/5 and 5/5 kDa) membrane pore size. The highest peptide transmission was achieved at a membrane pore size of 10 kDa (87.3%), followed by 10/5 kDa (54.4%), 5 kDa (36.1%) and 5/5 kDa (20.0%). Therefore, it can be concluded that larger MWCO membranes, such as the 3 kDa membrane used in this study, produce greater permeate flux flow and higher peptide transmission.

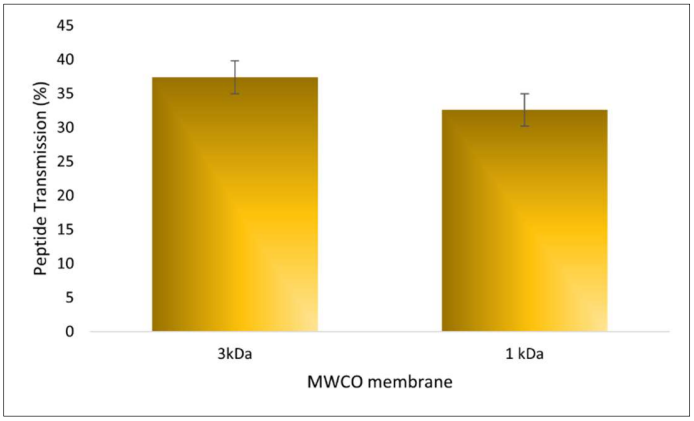

Figure 2. Effects of membrane pore size on peptide transmission

Effect of size towards potency of ACE-inhibitory activity

The 1 kDa possessed higher ACE-inhibitory activity compared to 3 kDa, which was 85.42% (Figure 3). Similar trends have been observed by Hua [4] and Ishak [35]. Hua [4] produced an antihypertensive peptide derived from tilapia collagen and the hydrolysate was separated using UF with two molecular sizes of <3 kDa and >3 kDa. The smaller fraction (<3 kDa) exhibited a higher percentage of ACE-inhibitory activity of 74.30% compared to >3 kDa, which was 58.5%. Ishak [35] studied the bioactive peptide derived from shortfin scads waste hydrolysate, (SWH), thus suggesting higher ACE-inhibitory activity of <3 kDa peptides with 81.50%. In this study, the IC_{50} value of 1 kDa RTBP hydrolysate was 0.41 mg mL^{-1}, which improved from 0.79 mg mL^{-1} (crude RTBP hydrolysate). The IC_{50} value of purified RTBP hydrolysate was comparable to the pepsin-hydrolysed tilapia frame <1 kDa protein hydrolysate [36]. The IC_{50} value was measured to assess bioactive peptide efficacy. It provides a measure of potency in pharmacological research by indicating the amount or concentration of a compound required to inhibit a biological process by 50% [37]. Therefore, the lower the IC_{50} value, the greater the potency.

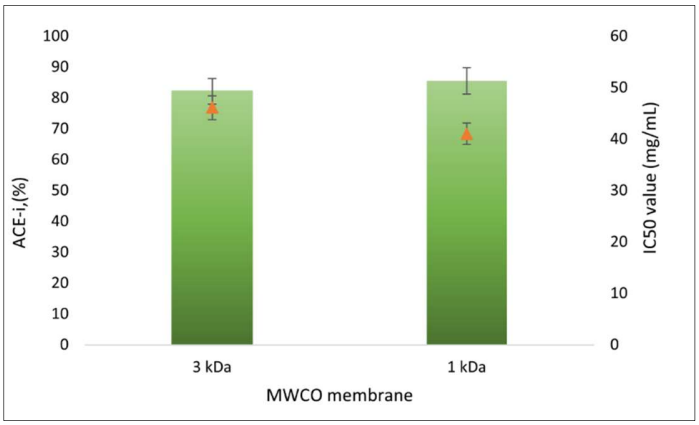

Figure 3. Effects of membrane pore size on ACE-inhibitory activity and IC_{50} value

The effect of peptides charges

In most cases, anion-exchange chromatography (AEX) can be used to separate molecules with negative charges from natural and basic molecules [38]. The peptide charged of RTBP hydrolysate was measured using Zeta potential. The electrostatic interactions between proteins and charged surfaces are also pH-dependent, as the charge of proteins depends on the pH of their surroundings [39].

Table 2. Zeta potential measurement of RTBPH

Sample	Zeta Potential (mV)
1 kDa	-8.75 ± 0.79
3 kDa	-4.82 ± 1.25

Both fractions (1 kDa and 3 kDa) were negatively charged (Table 2). Appropriate pH was used to maintain the surface charge of the RTBP hydrolysate and to avoid precipitation due to pH closer to its isoelectric point. The charges on protein molecules can change to accommodate other charged surfaces [39, 40]. The RTBP hydrolysate fraction must be negatively charged to allow the exchange of the peptides to the anionic exchange resin. The anionic exchangers could bind with the negatively charged counterions reversibly. An anion exchanger's counterion is often a weakly binding ion like Cl-, which can be changed out for stronger binding ions including negatively charged amino acids on a protein's surface. Thus, a high salt concentration buffer

was used to elute the trapped RTBP hydrolysate.

AEX of 1 kDa RTBP hydrolysate is shown in Figure 4. The absorption percentage of RTBP hydrolysate peptides to the resin was 93.99%. The non-adsorbed peptides consisted of positively charged peptides. The adsorbed peptides (negatively charged) were then eluted several times. ACE-inhibitory peptides can be observed in both the non-bound (non-absorbed) and bound (Elute 1 to 4) fractions. Meanwhile, the non-absorbed fraction (positively charged) has the highest ACE-inhibitory activity of 72.32%, whereas the elutes have the ACE-inhibitory activity from 6.07% to 52.55%. This is similar to the previous study done on Alaska pollack's frame hydrolysate by Je [41] and catfish skin hydrolysate by Sungperm [42], which has higher ACE-inhibitory activity on positively charged fraction. Daskaya-Dikmen [44] and Manoharan [43] suggested that the presence of positively charged on the side chain coupled with other aromatic amino acids would enhance the ACE-inhibitory activity effectiveness.

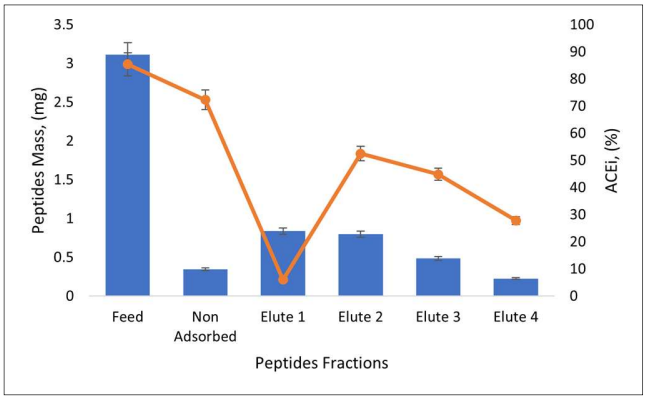

Figure 4. The peptide mass and ACE-inhibitory activity for absorption equilibrium

The effect of peptides hydrophobicity

Specific amino acids play a vital role in determining the type of bioactivity (Acquah, et al., 2018). ACE-inhibitory activity is inhibited more effectively by antihypertensive peptides, which typically have aromatic amino acid residues at the C-terminus and hydrophobic amino acid residues at the N-terminus [4], [23], [43–46]. The hydrophobic interaction chromatogram (HIC) was separated using RP-HPLC. The positively charged peptides fraction was further purified, and the fraction of chromatogram's peaks and its ACE-inhibitory activity is shown in Figure 5.

Both hydrophilic and hydrophobic chromatograms produced peaks at 0-5 minutes (Fraction 1) and 5-10 minutes (Fraction 2). The ACE-inhibitory activity of Fraction 1 and Fraction 2 from the hydrophobic fraction showed the highest bioactivity of 90.44% and 95.28%, respectively. However, hydrophilic peptides demonstrated inferior ACE-inhibitory activity in Fraction 1 (47.80%) and Fraction 2 (11.59%) (Figure 5). Ishak [35] observed similar ACE-inhibitory activity (87.99%) from a purified peptide fraction derived from shortfin scad applying RP-HPLC. Pa'ee [25] suggested that hydrophobic peptides tend to possess more ACE-inhibitory activity. In addition, the abundance of the hydrophobic fragment in the RTBP hydrolysate may be due to the enzymatic hydrolysis of Thermoase PC10F. The hydrophobicity of a peptide chain depends on several factors, including the extent to which it is hydrolysed, the processing conditions used, the type of protease employed, the average hydrophobicity value of the protein precursors and the sequence of hydrophobic amino acid residues in the peptide chain [47]. According to several studies, aliphatic amino acids at the N-terminus, positively charged amino acids in the central position, as well as proline, tyrosine, phenylalanine and tryptophan are the main structural components in the C-terminal of ACE inhibitory peptides with high ACE inhibitory action. Additionally, the amino ends of proteins tend to contain hydrophobic amino acids with

aliphatic side chains such as glycine, isoleucine, leucine and valine [4, 23, 40, 41, 44]. An ACE-inhibitory peptide that has proline residue at C-terminal tends to have competitive inhibition as mentioned above on *Clarias batrachus* [27], VAP derived from Grass crap [12] and LYPPP and YSMYPP, both of which were derived from snakehead fish [7].

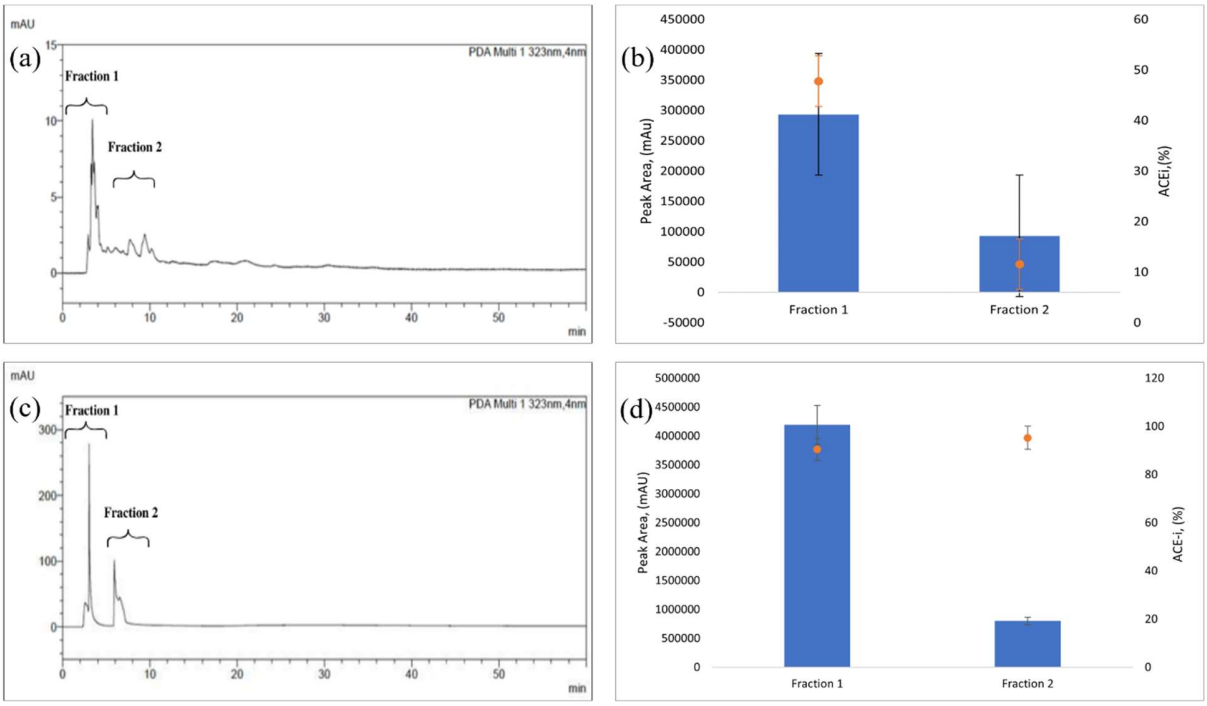

Figure 5. Chromatograms and the ACE-inhibitory activity of purified RTBP hydrolysate (a) Chromatogram fraction of hydrophilic peak (b) Hydrophilic fraction and its ACE-inhibitory activity (c) Chromatogram fraction of hydrophobic peak (d) Hydrophobic fraction and its ACE-inhibitory activity.

Conclusion

RTBP hydrolysate applying Thermoase PC10F liberated potent ACE-inhibiting peptides. Thermoase PC10F displayed high DH and ACE-inhibitory activity at 73.80% and 70.67%, respectively. 1 kDa RTBP hydrolysate has a stronger ACE-inhibitory activity of 85.42 %. The non-absorbed fraction yielded the highest ACE-inhibitory activity of 72.32%, indicating that it has positively charged characteristics. The purified RTBP hydrolysate yielded two fractions of high ACE-inhibitory activity (more than 90%) on the hydrophobic fraction. The reaction specificity of the Thermoase PC10F allowed the release of hydrophobic peptides. Furthermore, the determination of peptide sequence is crucial to decern its structure-activity relationship, molecular docking and dynamic studies, and other *in silico* studies.

Abstract

Silver nanoparticle (AgNP) synthesis can be produced by chemical, physical, and green synthesis methods. In this study, green synthesis of AgNPs was conducted by using *Euphorbia milii (E. milii)* leaf extract as the reducing agent. *E. milii*, also called crown-of-thorn or in Malay *'Mahkota duri'* was used as the targeted plant in this study due to its rich phytochemical contents. The leaves were extracted into six different solvents (hexane, chloroform, ethyl acetate, acetone, methanol and distilled water) by increasing polarities to extract different varieties of compounds that were applied as reducing agents in the synthesis of AgNPs. The crude extract was added to 1 mM $AgNO_3$ solution and kept in the dark at room temperature for 24 hours. The process was repeated for all crude extracts with different solvent polarities. The AgNPs solution obtained was analysed by using a UV-Vis spectrophotometer, Fourier-transform infrared spectroscopy (FTIR), and scanning electron microscope (SEM). The stability of the AgNPs was observed and compared between different extracts from different polarities. The wavelength of UV-Vis obtained for the 6 sets was between 415 nm and 485.5 nm. The formation of AgNPs based on the surface plasmon resonance band is proved by the peak that appeared around λ = ~450 nm. The FTIR spectroscopy of the various extracts indicated the presence of OH, C-H stretching, C=O stretching, C=C stretching and C-O stretching, respectively, as compared with the FTIR spectrum for AgNPs for the synthesis and stabilization of the AgNPs. SEM images showed the different sizes of AgNPs for different extracts, with a range of about 67 to 843 nm.

Keywords: green synthesis, reducing agent, green AgNPs, euphorbiaceae, *Euphorbia milii*

Abstrak

Sintesis nanopartikel perak (AgNPs) boleh dihasilkan melalui kaedah sintesis kimia, fizikal dan hijau. Dalam kajian ini, sintesis hijau AgNPs telah dijalankan menggunakan ekstrak daun *Euphorbia milii* (*E. milii*) yang bertindak sebagai agen penurunan. *E. milii* atau juga dipanggil mahkota duri atau dalam bahasa Melayunya 'Mahkota duri' telah digunakan sebagai tumbuhan sasaran

dalam kajian ini kerana kandungan fitokimia yang kaya. Daun diekstrak ke dalam enam pelarut berbeza (heksana, kloroform, etil asetat, aseton, metanol, dan air suling) dengan meningkatkan kekutuban untuk mengekstrak pelbagai sebatian yang berbeza yang digunakan sebagai agen pengurangan dalam sintesis AgNPs. Ekstrak mentah telah ditambah ke dalam larutan 1 mM $AgNO_3$ dan disimpan dalam gelap pada suhu bilik selama 24 jam. Proses ini diulang untuk semua ekstrak mentah dengan kekutuban pelarut yang berbeza. Penyelesaian AgNP yang diperolehi dianalisis dengan menggunakan spektrofotometer UV-Vis, spektroskopi inframerah transformasi Fourier (FTIR), dan mikroskop elektron pengimbasan (SEM). Kestabilan AgNP diperhatikan dan dibandingkan dari ekstrak yang berbeza kekutubannya. Panjang gelombang UV-Vis yang diperoleh untuk 6 set adalah antara julat 415-485.5 nm. Pembentukan AgNP berdasarkan jalur resonans plasmon permukaan dibuktikan oleh puncak yang muncul sekitar λ = ~450 nm. Spektroskopi FTIR bagi pelbagai ekstrak menunjukkan kehadiran OH, regangan CH, regangan C=O, regangan C=C dan regangan CO, masing-masing berbanding dengan spektrum FTIR untuk AgNP untuk sintesis dan penstabilan AgNPs. Imej SEM menunjukkan saiz AgNP yang berbeza untuk ekstrak berbeza dengan julat kira-kira 67 hingga 843 nm.

Kata kunci: sintesis hijau, agen penurun, AgNPs hijau, euphorbiaceae, *Euphorbia milii*

Introduction

Silver nanoparticles (AgNPs) are useful in various applications that have attracted much interest among researchers [1]. The production of AgNPs can involve chemical, physical, biological, and photochemical methods [2]. For the production of AgNPs, chemical and physical methods are usually used at the industrial level [3]. However, this method was a concern in biomedical applications because of the toxicity of reducing and capping agents, high temperature, and pressure in the protocol [4]. Capping agents such as alkylamines and alkanethiols had the function to stabilise the AgNPs from aggregation. The use of this capping agent and the reduction from this method can result in hazardous by-product formation that can affect the use of AgNPs in biomedical fields and chemical applications. To overcome this problem, green synthesis methods are used as a substitute for chemical and physical procedures [3] by using biological extracts such as plants, bacteria, or other potential natural reducing agents [5].

Plants provide a better platform for nanoparticle synthesis as they are free from toxic chemicals and natural capping agents [6]. In this study, *Euphorbia milii* (*E. milii*) was chosen as a targeted plant because it is rich in bioactive compounds and has high total flavonoid content [7]. Euphorbia is the largest genus, widely distributed primarily in tropical countries that acts as medicinal plants. *E. milii* is a flowering plant commonly known as the “Christ plant” or “Christ thrown” [8] and is widely used in folk medicine for the treatment of warts (South Brazil), cancer, and hepatitis (China). A previous study on *E. milii* was carried out on polar crude extract to isolate the active chemical components [7]. *E. milii* leaves act as reducing biological agents and bind together with silver metal ion solutions to form AgNPs. The reducing agents are widely distributed in the biological system [4]. The study presented here describes the effect of different polarities in the crude extract on the stability of the AgNPs.

Materials and Methods

Materials and instrumentation

Silver nitrate ($AgNO_3$) was purchased from Sigma Aldrich. The absorption spectra of synthesized AgNPs were recorded by using UV-visible spectroscopy from 300-800 nm (Shimadzu UV-1800). The Fourier Transform Infrared (FTIR) extracts and AgNPs were taken by Perkin Elmer Spectrum 100 by using the ATR method and recorded between 4000 and 400 cm^{-1}. The Scanning Electron Microscope (SEM) images were taken by JEOL 6360 LA with working distance and accelerating voltage, 15 mm and 15 kV, respectively. The sample for SEM was sonicated 3 times (15 minutes each) before it was mounted on an Indium tin oxide (ITO) substrate. Then, the sample was coated with metal gold.

Collection of the plant sample

The sample of *Euphorbia milii* leaves was collected from Kota Sarang Semut, Kedah (November 2020). The botanical identity of the plant specimen of *E. milii* leaves was confirmed by the Biological Laboratory, Universiti Malaysia Terengganu.

Preparation and extraction of *E. milii* leaves

E. milii leaves (70 g) were cleaned under running tap

water and dried at room temperature for seven days before grounded into powder form by using a grinder. Then, the powders were soaked with the first non-polar solvent, which is hexane and filtered to collect the hexane extract. The residue from hexane was repeated with different solvents by increasing the polarity (chloroform<ethyl acetate<acetone<methanol <distilled water) using the same method continuously at room temperature for 72 hours. Each extract was concentrated by using a rotary evaporator (Büchi Rotavap R-200 CH-9230, Switzerland) under reduced pressure (337-218 mbar) at 35-40 °C for 15-30 min. The six crude extracts obtained were weighed and stored in a chiller (4 °C) for further analysis.

Green synthesis of AgNPs

The green synthesis followed the method developed by Alsalhi, et al. with some modifications. To prepare AgNPs, 10 mg crude extract was added to 10 ml Mili-Q water. Then, it was filtered by using a syringe filter (0.2 µm). The mixture (5 ml) was added to 1 mM AgNPs solution (50 mL) [9]. The mixture was kept in the dark at room temperature for one day (until the color changed from colorless to brown). The process was repeated with different crude extracts, as shown in Figure 1.

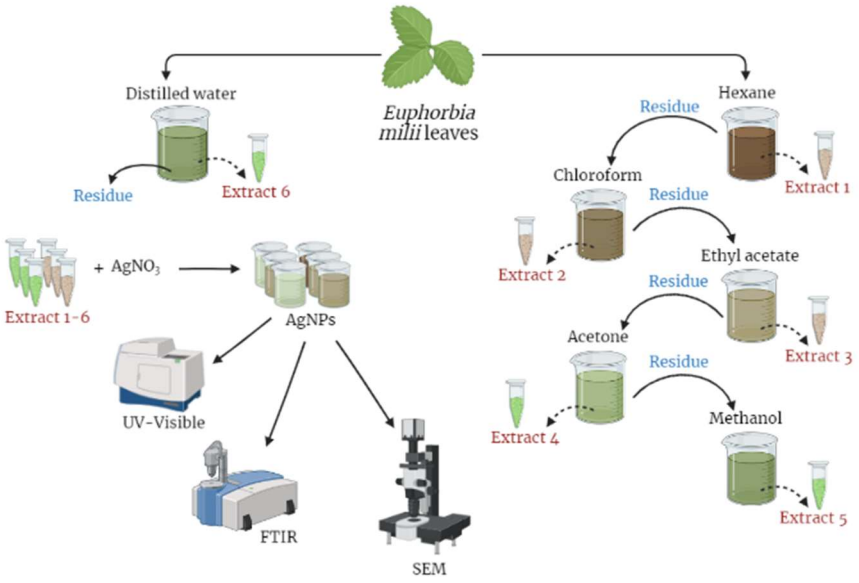

Figure 1. Overall experimental process

Results and Discussion

Green synthesis of AgNPs

The present study explored green synthesis of AgNPs was by using *E. milii* leaf extracts as a reducing agent. The reaction mixture turned from colorless to yellowish brown, which is the preliminary indication of the synthesis of AgNPs. Six conjugated AgNPs were made from $AgNO_3$ with different crude extracts. These conjugates were characterised as AgNPs-hexane extract (SH), AgNPs-chloroform extract (SC), AgNPs-ethyl acetate extract (SE), AgNPs-acetone extract (SA), AgNPs-methanol extract (SM) and AgNPs-distilled water extract (SDW-reference). AgNPs synthesis was confirmed with SEM analysis and discussed in a later section.

Characterization of AgNPs: Fourier-transform infrared spectroscopy (FTIR)

Fourier-Transform Infrared Spectroscopy (FTIR) analysis of the obtained crude extracts (Figure 2) revealed different characteristic peak values with various functional compounds. Table 1 shows the peak assignment for six extracts. The major bands at 3341 cm^{-1}, 3248 cm^{-1}, and 3333 cm^{-1} represented the O-H group of carboxylic acid. The absorption band observed at ~2926 cm^{-1} corresponded to the stretching vibration of

the C-H bond in the aliphatic hydrocarbon chains. The band at ~1636 cm^{-1} was attributed to C=C stretching vibrations of phenolic compounds such as polyphenols and flavonoids [10]. The C-H aliphatic band at approximately 1358-1396 cm^{-1} showed the presence of alkyl halides. The C-N bands at 1211 cm^{-1}, 1219 cm^{-1}, 1242 cm^{-1}, and 1258 cm^{-1} showed the presence of aliphatic amines. Lastly, the C-O bands at 1026 cm^{-1}, 1042 cm^{-1} and 1072 cm^{-1} showed the presence of alcohol, carboxylic acids, esters and ethers. The carboxyl and hydroxyl ions in the molecules develop a protective layer on the surface of AgNPs [9].

The FTIR spectra were carried out to recognize the existence of different functional groups. As shown in Figure 3, all conjugated samples compared to reference samples showed the formation of the O-H group (3333 cm^{-1}), C=C carbonyl-carbonyl group (1636 cm^{-1}), and C-H oop aromatic band (664 cm^{-1}).

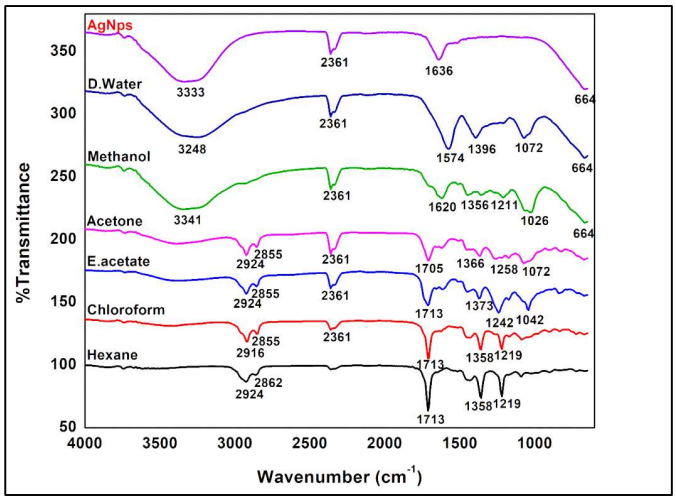

Figure 2. FTIR analysis for crude extracts

Table 1. Peak assignment for crude extracts

Peak Assignment	**Wavenumber (cm^{-1})**						
	Hexane	Chloroform	Ethyl Acetate	Acetone	Methanol	D. Water	AgNPs
O-H stretching	-	-	-	-	3341	3248	3333
C-H stretching	2926	2916	2924	2924	-	-	-
C=O stretching	1713	1713	1713	1705	-	-	-
C=C stretching	-	-	-	-	1620	1574	1636
C-H aliphatic	1358	1358	1373	1366	1356	1396	-
C-N	1219	1219	1242	1258	1211	-	-
C-O	-	-	1042	1072	1026	1072	-
C-H oop aromatic band	-	-	-	-	664	664	664

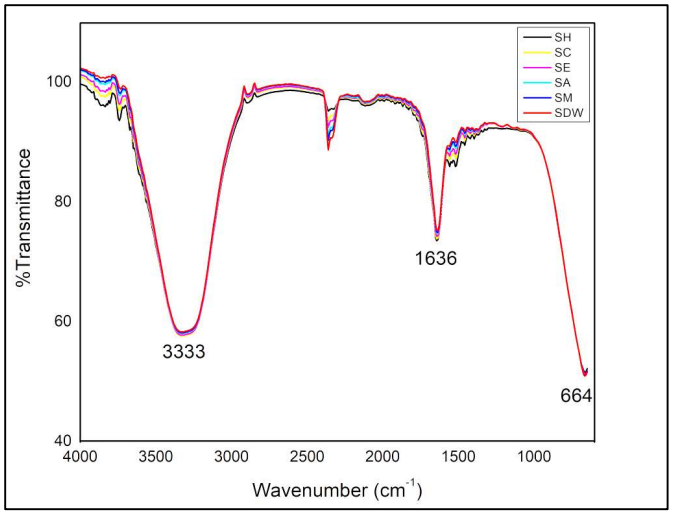

Figure 3. FTIR analysis for conjugated AgNPs

Ultraviolet-visible spectroscopy

The common phenomenon of surface plasmon resonance (SPR) in AgNPs has been studied in metal nanoparticles where electrons are excited by photons of incident light [2]. When excited by light, the induced charges characteristic of surface plasmons can propagate as an electromagnetic wave parallel to the metal surface. The most important factor in determining the frequency and intensity of plasmon resonance is their surface polarization. This is because it provides the main restoring force for electron oscillation [11]. All six conjugates were characterised by using UV-Vis spectroscopy to confirm the formation of the AgNPs. Based on all solvent systems, SH was the most unstable because the peak occurred only in 3 days. There was also no color change after the synthesis. While SC, SE, SA, SM, and SDW were more stable than SH because their peak occurred in 7, 42, 63, 63, and 64 days respectively (Figure 4 - Figure 8). As can be seen in UV-Vis spectra, the range of wavelength is from 401 to 456 nm. Table 2 shows the wavelength of AgNPs for each extract. The surface plasmon resonance band for spherical AgNPs was usually in the range of 390-450 nm [2] and 410-455 [12]. The optical properties of spherical AgNPs were highly dependent on the nanoparticle diameter. Smaller nanospheres primarily absorbed light and had peaks near 400 nm, while larger spheres had peaks that broadened and shifted towards longer wavelengths (known as red-shifting) [13]. Table 3 shows the references from other studies.

Table 2. Maximum peak for each AgNP

Conjugated AgNPs	Wavelength (nm)	Stability (Day)
AgNPs-hexane extract (SH)	427	3
AgNPs-chloroform extract (SC)	416	63
AgNPs-ethyl acetate extract (SE)	436	63
AgNPs-acetone extract (SA)	415	7
AgNPs-methanol extract (SM)	In-plane dipole: 401 In-plane quadrupole: 485	64
AgNPs-distilled water extract (SDW)	456	42

Table 3. References for the maximum peak from other studies

Plant	Solvent Extract	Wavelength (nm)	Stability (Day)	Reference
Ipomoea carnea Jacq.	Methanol	300-550	1	[14]

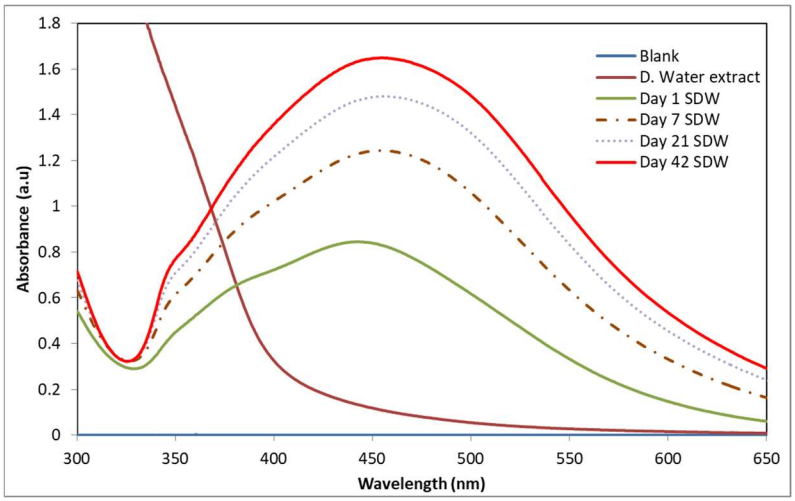

Figure 8. UV-Visible of SDW

Scanning electron microscope (SEM)

SEM technique was employed to visualise the size and shape of AgNPs. The SEM images of the AgNPs for each crude are shown in Figure 9. The smallest was from SE, which is 67-441 nm and the largest was from SH which is 771-843 nm (Table 4). The shape of all crude was mostly spherical. Compared to other studies using aqueous extract, *Euphorbia serpens* leaf had a spherical shape with particle sizes from 30 to80 nm [16], the spherical shape of *Euphorbia hirta* had a range of sizes between 50 and 80 nm [17], range sizes of *Boerhavia procumbens* was 20-80 nm with spherical shape [18], and Shireen, et al. stated that *A. americana, M. spicata, and M. indica* had mostly spherical and few triangular, rods and cubic shape [19].

Table 4. Range of size for AgNPs from various crude extract

AgNPs from Various Crude Extract	Size Range (nm)	Shape	References
(a) AgNps-hexane extract (SH)	771-843	Spherical	-
(b) AgNPs-chloroform extract (SC)	100-186	Spherical	-
(c) AgNPs-ethyl acetate extract (SE)	67-441	Spherical	-
(d) AgNPs-acetone extract (SA)	86-174	Spherical	-
(e) AgNPs-methanol extract (SM)	92-107	Spherical	-
(f) AgNPs-distilled water extract (SDW)	356	Spherical	-
Aqueous extract of *Euphorbia serpens* leaf	30-80	Spherical	[16]
Aqueous extract of *Euphorbia hirta* leaf	50-80	Spherical	[17]
Aqueous extract of *Boerhavia procumbens*	20-80	Spherical	[18]
Aqueous extract of *A. americana, M. spicata, and M. indica*	30-100	Mostly spherical Few triangular, rods and cubic	[19]

Conclusion

Six crude extracts of *E. milii* leaves were successfully utilized as capping and reducing agents for AgNP synthesis. The reaction conditions were optimized for approximate uniform dispersion of green synthesized AgNPs. The FTIR analysis suggested the presence of carboxylic acid, polyphenols, flavonoids, alkyl halides, aliphatic amines, alcohol, esters and ethers, responsible for the capping and stabilizing of AgNPs. UV-Vis spectroscopy confirmed the formation of AgNPs in all crude extracts by exhibiting the SPR band between 401 and 456 nm. SH was the most unstable AgNPs compared to other conjugated AgNPs. The shape for all conjugated AgNPs was spherical, with the sizes SH >SDW >SC >SM >SA >SE. Therefore, these studies concluded that six leaf extracts could be utilised for the green synthesis of AgNPs.

Abstract

Industrialization has a major impact on the ecosystem and the natural water composition particularly in places close to cities and manufacturing areas. Copper (Cu^{2+}) ion is one of the heavy metals present in the industrial effluent and is considered to be a toxic heavy-metal contaminant accounting to its extreme persistence and bioaccumulation. Current techniques for determining Cu^{2+} ions in water include atomic absorption spectrometry (AAS), X-ray fluorescence spectrometry (XRF) and electrochemical methods, which provide high precision but have high maintenance costs and complicated preparation. Thus, an inexpensive, nontoxic and rapid sensing system for copper detection is needed. Herein, a simple and effective route for designing a fluorescence detector for Cu^{2+} ions tracing was developed through a microwave-assisted rapid synthesis of carbon dots and nanosilica from Taal volcanic as its dopant. The parameters affecting the performance of the Taal Volcanic Ash Nanosilica-doped Carbon Dots (TVA/SiO_2-Cdots), such as silica dosage, agitation speed and contact time were investigated and optimized. Under optimized conditions, the TVA/SiO_2-Cdots showed the detection of Cu^{2+} ions in simulated wastewater. The optical properties of the synthesized TVA/SiO_2-Cdots were determined using Fourier transform infrared spectroscopy (FTIR) and UV-Visible spectrophotometer which explained the quenching of TVA/SiO_2-Cdots photoluminescence upon addition of Cu^{2+} ions. It has functional groups of Amine, C=C and C-O bonds. The mathematical correlation between photoluminescence (PL) intensity ratio of SiO_2-Cdots and Cu^{2+} ion concentration in simulated wastewater was found to be a Gaussian equation. The result showed that the model has no significant difference with the detected concentrations using ultraviolet spectrophotometric screening method.

Abstrak

Pembangunan industri memberi impak besar terhadap ekosistem dan komposisi air semulajadi terutamanya di kawasan-kawasan

berdekatan dengan bandar dan kawasan pembuatan. Ion kuprum (Cu^{2+}) adalah salah satu daripada logam berat yang terdapat dalam air sisa industri dan dianggap sebagai pencemar logam berat toksik kerana ketekalan dan bioakumulasi yang tinggi. Teknik semasa untuk menentukan ion Cu^{2+} dalam air termasuk spektrometri serapan atom (AAS), spektrometri sinar-X pendaflour (XRF) dan kaedah elektrokimia, yang memberikan ketepatan yang tinggi tetapi memerlukan kos penyelenggaraan yang tinggi dan persediaan yang rumit. Oleh itu, sistem pengesanan untuk penentuan kuprum yang murah, tidak toksik dan cepat diperlukan. Di sini, satu laluan yang mudah dan berkesan untuk reka bentuk pengesan pendaflour untuk pengesan ion Cu^{2+} telah dibangunkan melalui sintesis cepat bantuan gelombang mikro titik karbon dan nanosilika dari abu gunung berapi Taal sebagai bahan tambahannya. Parameter-parameter yang mempengaruhi prestasi abu gunung berapi Taal nanosilika-didop titik karbon (TVA/SiO2-Cdots), seperti dos silika, kelajuan pengadunan, dan masa sentuhan telah dikaji dan dioptimumkan. Di bawah keadaan yang dioptimumkan, TVA/SiO_2-Cdots menunjukkan pengesanan ion Cu^{2+} dalam simulasi air sisa. Sifat optik TVA/SiO_2-Cdots yang disintesis ditentukan menggunakan spektroskopi inframerah transformasi Fourier (FTIR) dan spektrofotometer UV-Cahaya Nampak yang menjelaskan pemelindapan fotoluminesens TVA/SiO_2-Cdots dengan penambahan ion Cu^{2+}. Ia mempunyai kumpulan berfungsi amina, C=C, dan C-O. Korelasi matematik antara nisbah intensiti fotoluminesen (PL) SiO_2-Cdots dan kepekatan ion Cu^{2+} dalam simulasi air sisa didapati sebagai persamaan Gauss. Keputusan menunjukkan bahawa model ini tidak mempunyai perbezaan yang signifikan dengan kepekatan yang dikesan menggunakan kaedah saringan spektrofotometri ultraungu.

Introduction

Heavy metal contamination is one of the prevailing issues detrimental to human health and environment. As a result of continuous industrialization, the heavy metals found in nature seep through municipal water supplies. Concentrations of copper, lead, cadmium, chromium, mercury and arsenic are the most concerning, mainly because of their relatively high concentrations in industrial wastewater. Copper exposure can have serious consequences for human health. At great amounts of exposure, copper attacks the internal organs and builds up in the brain to cause nausea, vomiting, coma, and even death. People who survive contact with high exposures of copper may be left with pruritic dermatitis, anemia, and muscular convulsions. Due to these complications, the regulation and detection of the amount of copper in municipal wastewaters is needed [1].

High performance liquid chromatography (HPLC) combined with electrochemical- or UV-Vis-detectors and atomic absorption spectroscopy (AAS) are the most used methods for the detection of heavy metal ions. Despite the high levels of sensitivity and precision achieved by these techniques, the majority of them need expensive, complicated equipment that must be operated by skilled personnel, making them challenging to employ in on-site measurements for portable detection [2]. This leads to the discovery of photometry, fluorescence analysis, electrochemical methods, phosphorescence analysis, and chemiluminescence. These methods are operationally simple, fast, and low cost. Therefore, the developments of simple, sensitive, and reliable spectral analytical methods are still greatly significant.

Due to their multiple intriguing features, carbon dots (CDs) have recently become a distinct class of fluorescent nanomaterials. They are thought to be superior to traditional fluorescent materials like semiconductor quantum dots and organic dyes due to their exceptional features like high aqueous solubility, low toxicity, great biocompatibility, functionalizability, and photostability [3]. Moreover, studies show that silica doping in carbon dots improves its efficiency and luminosity. These silicas are extracted either from wastes such as bricks, concrete, and other construction waste materials, or in nature including sand, gravel, clay, and volcanic ash. In bulk volcanic ash, the chemical composition is mainly determined by the magma from which it is generated. The mineral composition of volcanic ash consists of about 45–75 wt.% of silica [4].

Many studies prove how detrimental the emission of volcanic ash is for both human health and the surroundings. This ash is also a potential source of silica, which could be synthesized to nanosilica, and doped into metal detecting carbon dots. Previous studies proved that doping carbon dots had led to an improved quantum yield. Moreover, heteroatom dope escalates as a more

effective and general strategy to construct the optic and electron transfer properties of CDs. Hence, in this study, the researchers assessed the potentiality of utilizing nanosilica from Taal volcanic ash as a doping agent to carbon dots for Cu^{2+} ions tracing. The researchers also concentrated on the goal of developing a mathematical model that could be utilized to assess its applicability in determining copper ion pollutants with reasonable sensitivity and validity.

The nanosilica-doped dots were used for the detection of Copper (Cu^{2+}) ions in wastewater. Taal volcanic ash (TVA) underwent a series of processes to produce silica, and afterward was subjected for characterization. Taal volcanic ash silica-doped carbon dots (TVA/SiO_2-Cdots) served as a fluorescence detector that is limited to Cu^{2+} ions tracing only. In this study, its reactivity with other metals was no longer investigated. The effects of silica dosage, agitation and contact time in the PL intensity ratio of TVA/SiO_2-Cdots with Copper (Cu^{2+}) ions in simulated wastewater were determined in this study. Included also is the characterization of physicochemical properties of both carbon dots and TVA/SiO_2-Cdots. Moreover, the determination of the effects of PL intensity ratio of TVA/SiO_2-Cdots in simulated wastewater with an increasing amount of Cu^{2+} ions was conducted. The simulated wastewater was prepared for a practical application of Cu^{2+} tracing.

Materials and Methods

Production of nanosilica

Volcanic ash samples collected were subject to sieving to separate it according to particle size. A 40g sample of volcanic ash was prepared. This undergoes acid leaching particularly, 3M HCl solution to remove impurities. The sample was allowed to be soaked in the acid for three hours. Then washed until neutral (with pH ranging from 6.5 to 7.5) and dried in an oven at 100 °C for 6 hours. After drying, the sample went through reflux with 4M NaOH solution at 1:8 (w/v ratio) for four hours at 90-100 °C. The sample was left undisturbed overnight. Then, filtered using silica crucible and washed with warm water. After that, the HCl was added via burette. Note that there is a continuous addition of HCl until there is the formation of white gel, which is the Silica, and until the solution is acidic. Then, subjected it to further washing to be neutralized (with pH ranging from 6.5 to 7.5) and then dried in the oven for 6 hours at 120 °C.

To turn this silica into nanosilica, the dried sample was refluxed at 90-100 °C with 200 mL of 6M HCl solution for 5 hours. After 5 hours of reflux, HCl was decanted and added 160 mL 4M NaOH solution. This solution was subjected to constant stirring for about 4 hours before the addition of H_2SO_4. Note that there is a continuous addition of sulfuric acid until the formation of white precipitates and until the solution is acidic. The precipitates that will be formed is filtered and washed until neutral (with pH ranging from 6.5 to 7.5) and then, dried in the oven for 30 hours at 70 °C. The mass of the completely dried solid was recorded, which is the Nanosilica and the sample was prepared for the next stage of the study.

Preparation of carbon dots

The carbon dots were prepared by microwave-assisted rapid production. Under agitation, 0.57g of L-cysteine was dissolved in 10 mL of deionized water, and 1.5g of citric acid was then added. The resulting solution was heated in a microwave for 4 minutes after being subjected to ultrasonication for 10 minutes. After the reaction, the product was allowed to cool naturally to room temperature before being dissolved with agitation in 10 mL of deionized water to produce a brown solution. In order to eliminate the contaminant, it was centrifuged for 10 minutes at 4000 rpm before being filtered. The obtained solution was extracted by ethyl acetate and then kept in a refrigerator under 4 °C for later use [5].

Preparation of nanosilica-doped carbon dots

An amount 5 mL of carbon dots was mixed with various concentrations of silica (0.1, 0.3 and 0.5 g). It was then added to 25 mL of ethanol separately, and was stirred for 30 minutes at room temperature. After that, the reaction mixture was centrifuged at 3000-5000 rpm for 15-45 mins and the supernatant was discarded. The remaining pellets of silica-doped carbon dots were collected and washed three times with ethanol, and finally resuspended in ethanol with a concentration of 10 mg/mL.

Photoluminescence intensity metering of best TVA/SiO_2-Cdots

The prepared TVA/SiO_2-Cdots with varying parameters were mixed with copper-containing and non-copper-containing simulated wastewater. The simulated wastewater in this study was made using a standard preparation by Official Methods of Analysis of AOAC International. Simulated wastewater was prepared by dissolving 1.9645 g $CuSO_4 \cdot 5H_2O$ in H_2O and diluting it to 500 mL (1 mL = 1 mg Cu). After mixing thoroughly, the fluorescence spectra were recorded after 10 minutes at room temperature. Photos of the carbon dots were taken using an iPhone 11 Pro to collect light frequency, and the photographs were converted to luminous intensity using Image J Batch Software [6]. The fluorescence intensity ratio is measured at the excitation wavelength (λ_{ex}) of 365 nm using UV light [7].

Figure 1. Luminous intensity metering set up

The difference in the photoluminescence ratio of TVA/SiO_2-Cdots in simulated wastewater and copper-containing-simulated water was used to determine the reactivity of TVA/SiO_2-Cdots with Copper ions. Thus, the parameters having the highest photoluminescence intensity difference were considered to be the best parameters.

Preparation of simulated wastewater at increasing Cu^{2+} ions concentration

For Cu^{2+} detection, copper sulfate pentahydrate ($CuSO_4 \cdot 5H_2O$) was utilized as the source for Cu^{2+} ions. 20 mL of prepared TVA/SiO_2-Cdots was dissolved in 100 mL of simulated wastewater. 5 mL TVA/SiO_2-Cdots aqueous solution was added to a beaker and the $CuSO_4 \cdot 5H_2O$ solution was subsequently added along with increasing concentrations. The concentrations of Cu^{2+} ions are 0,1, 2, 3, 4, 5, 6, 7, 8, 9 and 10 ppm. Magnetic stirrer rotating at 3000 rpm facilitates uniform concentration at 20 °C.

Figure 2. Schematic Roadmap of Research Methodology

Characterization of nanosilica-doped carbon dots: Fourier transform infrared spectroscopy (FTIR)

Fourier transform infrared (FT-IR) spectrum was conducted to recognize the surface functional groups and conjugations existing on the TVA/SiO_2-Cdots' surface. Specific functional group of the molecule is read by its band association which gives the identification of the functional groups that constitute the material.

Dynamic light scattering (DLS)

To determine the particle size and particle size distribution of the sample, DLS was used. It determines the particle size distribution by measuring the random changes in the intensity of light scattered from a suspension or solution.

Formulation of mathematical model

In order to formulate a mathematical model that will describe the relationship between the photoluminescence intensity ratio of SiO_2-Cdots and Cu^{2+} ion concentration in simulated wastewater, Matlab R2011-A was used in calculating the desired parameters for the mathematical model. After analysis of different models, the Gaussian method of modeling was selected as the best fit to represent the effects of increasing heavy metal concentration in simulated wastewater to photoluminescence intensity of TVA/SiO_2-Cdots. This method was selected over the other five methods namely exponential of 2nd power, Fourier of 2nd power, linear model of 3rd power and rational. For all generated equations, P(C) is the photoluminescence intensity (RLU) as a function of heavy metal concentration, C in parts per million.

Validation of generated model using ultraviolet spectrophotometric screening method

To validate the degree of acceptability of the generated models, various concentrations of Cu^{2+} in simulated wastewater were prepared prior to ultraviolet spectrophotometric screening. A Shimadzu UV/VIS spectrophotometer, UV-2700 was used for measuring the absorbance and recording the spectra. Wavelength range for copper examination using UV-Vis spectrophotometry is 185-500 nm [8]. The results were used to plot a calibration graph which was used to determine the concentration of Cu^{2+} in produced water.

A 20 mL of prepared TVA/SiO_2-Cdots was dissolved in 100 mL of simulated wastewater. 5 mL TVA/SiO_2-Cdots aqueous solution was added to a 10 mL volumetric flask and the 5 mL of $CuSO_4 \cdot 5H_2O$ solution was subsequently added along with concentrations of 1 ppm to 10 ppm. The solutions were left to stand for 30 minutes and then analyzed using the UV-Vis spectrometer at a wavelength of 206 nm and the absorbance was taken.

Statistical treatment

For the determination of the effect of given parameters to the photoluminescence intensity of synthesized TVA/SiO_2-Cdots, Minitab and analysis of variance was used. The Taguchi orthogonal array design was utilized to determine the effect of TVA/SiO_2-Cdots with copper ions (Cu^{2+}) in photoluminescence (PL) intensity in terms of three factors including silica dosage, agitation rate, and contact time.

For the simulated wastewater with Cu^{2+}, empirical models and data curves relating the photoluminescence intensity and the increasing concentration Cu^{2+} ions were constructed using MATLAB R2011-A. One-way ANOVA was used to determine the effect PL Intensity of TVA/SiO_2-Cdots upon increasing Cu^{2+} Ion concentration in simulated wastewater. Two paired t-tests were employed to determine the degree of comparability between the concentrations obtained from the generated model from that of detected concentration using ultraviolet spectrophotometric screening method.

Results and Discussion

Parameters that affect the PL intensity of TVA/SiO_2-Cdots with copper (Cu^{2+}) ions in simulated wastewater

Using Image J batch software, the PL intensity of the synthesized carbon dots was recorded at 17.692. This intensity is low and suggests that doping carbon dots with other material is a must in order to increase its PL intensity. In this study, the effect of varying parameters including silica dosage, agitation rate and contact time to the photoluminescence (PL) intensity of TVA/SiO_2-Cdots copper ions (Cu^{2+}) in simulated wastewater was

evaluated using the 3^3 Taguchi design which has 3 levels and 3 factors. The difference in the PL intensity of TVA/SiO_2-Cdots in simulated wastewater and copper-containing water determined the reactivity of TVA/SiO_2-Cdots with copper ions.

Table 1. PL Intensities of TVA/SiO_2-Cdots with and without copper

Silica Dosage	Agitation Rate	Contact Time	PL Intensity (Without Cu^{2+})	PL Intensity (With Cu^{2+})
0.1	3000	15	41.509	49.276
0.1	4000	30	43.059	51.139
0.1	5000	45	45.198	52.808
0.3	3000	30	44.110	52.79
0.3	4000	45	46.694	55.445
0.3	5000	15	43.956	53.159
0.5	3000	45	51.529	64.677
0.5	4000	15	45.268	55.092
0.5	5000	30	45.682	55.498

Based on the experimental results, the highest PL intensity recorded from both with and without copper ions were under the operational conditions 0.5 g, 3000 rpm and 45 minutes.

Table 2. Response table for signal to noise ratios

	Level	Silica Dosage (g)	Agitation Rate (rpm)	Contact Time (min)
Without Copper	1	32.72	33.16	32.78
	2	33.05	33.06	32.92
	3	33.52	33.05	33.58
	Delta	0.80	0.11	0.80
	Rank	1	3	2
With Copper	1	34.16	34.84	34.39
	2	34.61	34.62	34.50
	3	35.31	34.62	35.18
	Delta	1.15	0.22	0.79
	Rank	1	3	2

According to the values of S/N ratios for with and without copper ions, level 3 is considered best for silica dosage, level 1 for agitation rate and level 3 for contact time. These findings relate to the optimized value for each parameter such as 0.5 grams silica dosage, 3000 rpm agitation rate and 45 minutes contact time. From the table, it was shown that the most significant factor in PL intensity for with and without copper ions is the silica dosage which has the highest S/N ratio followed by the contact time and lastly is the agitation rate.

The results obtained are likewise comparable to those observed in the S/N ratios. According to the data, level 3 had the highest value in silica dosage, level 1 is best for agitation rate, and level 3 for contact time both for with and without copper ions. These results are also related to the optimal value for each parameter, such as 0.5 grams silica dosage, 3000 rpm agitation rate and 45 minutes contact time. According to the table, the silica dosage is the most important parameter in PL intensity followed by the contact time and lastly is the agitation rate with respect to means.

Table 3. Response table for means

	Level	Silica Dosage (g)	Agitation Rate (rpm)	Contact Time (min)
Without Copper	1	43.26	45.72	43.58
	2	44.92	45.01	44.28
	3	47.49	44.95	47.81
	Delta	4.24	0.77	4.23
	Rank	1	3	2
With Copper	1	51.07	55.58	52.51
	2	53.79	53.89	53.14
	3	58.42	53.82	57.64
	Delta	7.35	1.76	5.14
	Rank	1	3	2

Analysis of Variance (ANOVA) is used to determine and evaluate the overall effect of the different parameters on the experiment response, which is the PL intensity of the TVA/SiO_2-Cdots. The *p*-values of silica dosage, agitation rate and contact time without copper ions are both 0.011, 0.048, and 0.011, respectively. With copper ions, the *p*-values of silica dosage and contact time are 0.011 and 0.042, respectively while the agitation rate is 0.393. The values of the parameters are all less than the significance level of 0.05, therefore it indicates that there is a significant effect between the response (PL intensity) and factors (silica dosage, agitation rate and contact time).

The *F*-value is the test statistic that also determines the association of the response variable to the factors. The large *F*-value of silica dosage from with and without Copper ions compared to other parameters implies that it is statistically significant. The value of sum of squares (SS) is crucial as it influences the effectiveness of the response. The greater the SS value, the more effective it is. The SS values of each parameter are 26.9367 for silica dosage, 0.8909 for agitation rate and 26.8309 for contact time without copper ions and 80.990, 4.660, and 39.593 respectively for copper ions. The percentage contribution of silica dosage, agitation rate, and contact time are 42.44%, 1.41% and 42.28%, respectively without copper ions. On the other hand, the percent contribution for the TVA/SiO_2 with copper ions are 53.29% for silica dosage, 3.07 for agitation rate and 26.04% for contact time. The silica dosage for both the TVA/SiO_2 with and without copper ions has the highest SS value and % contribution which indicates that the silica dosage heavily impacted the absorption process. On the other hand, the agitation rate had the lowest % contribution. As can be observed, the results of ANOVA analysis for PL intensity of TVA/SiO_2-Cdots is similar to those of the results from S/N ratios.

In addition, using *t*-test, the *p*-value of TVA/SiO_2-Cdots with and without the addition of copper ions is 6.86E-0.5, it is found out that there is a significant difference in PL intensity ratio of TVA/SiO_2-Cdots upon the addition of Cu^{2+} ions in simulated wastewater.

Characterization of the best TVA/SiO_2-Cdots particle size and particle size distribution

The synthesized Cdots presented an average particle size diameter of 6.37 nm. After doping with nanosilica particles, the average diameter of the obtained TVA/SiO_2-Cdots increased to about 17.46 nm, suggesting the successful doping of nanosilica on the surface of carbon dots.

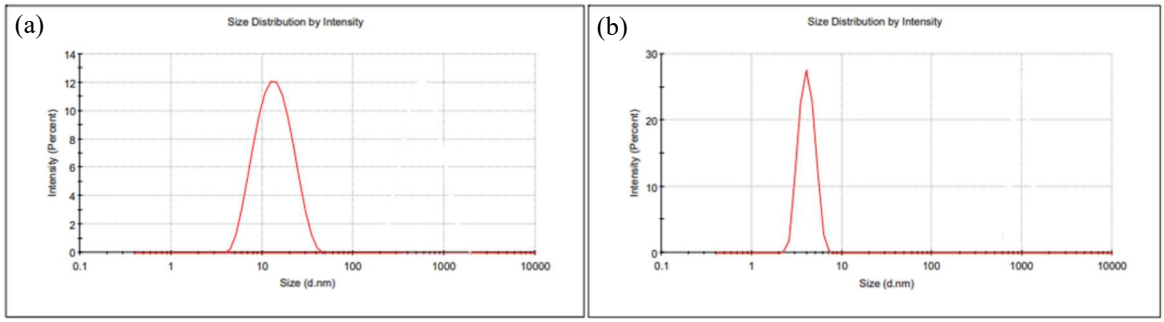

Figure 3. Particle size distribution of (a) Cdots and (b) TVA/SiO_2-Cdots

Table 4. Particle Size Distribution of Cdots and TVA/SiO_2 – Cdots

Sample	Z – Average (d.nm)	Peak	Size	Intensity	St. Dev. (d.nm)
Cdots	6.37 nm	Peak 1	7.63	100.0	2.797
TVA/SiO_2 – Cdots	17.46 nm	Peak 1	14.92	100.0	19.62

Particle size distribution is determined through dynamic light scattering (DLS) by measuring the random changes in the intensity of light scattered from a suspension or solution. The synthesized Cdots presented an average particle size diameter of 6.37 nm. A stable nanometric solution must have a size diameter of 1 to 100 nm. This confirms that the Cdots are nanometric. Particle size distribution of Cdots were shown in Figure 3 and Table 4. After doping with nanosilica particles, the average diameter of the obtained TVA/SiO_2-Cdots increased to about 17.46 nm, suggesting the successful doping of nanosilica on the surface of carbon dots.

Functional group and its conjugation

The distinct absorption peaks that defined the optical properties of Cdots were 3319.79, 1732.54, 1625.16, 1398.57, 1243.27 and 1013.58 cm^{-1}. The functional groups determined were N-H group, C=O group, C=C bond having an olefinic conjugated diene [9], C-H group, C-O group respectively. Typical conjugations with other double bond structures such as the C=C, C=O or aromatic rings will reduce the intensity frequency with strong or intense absorption bands [2].

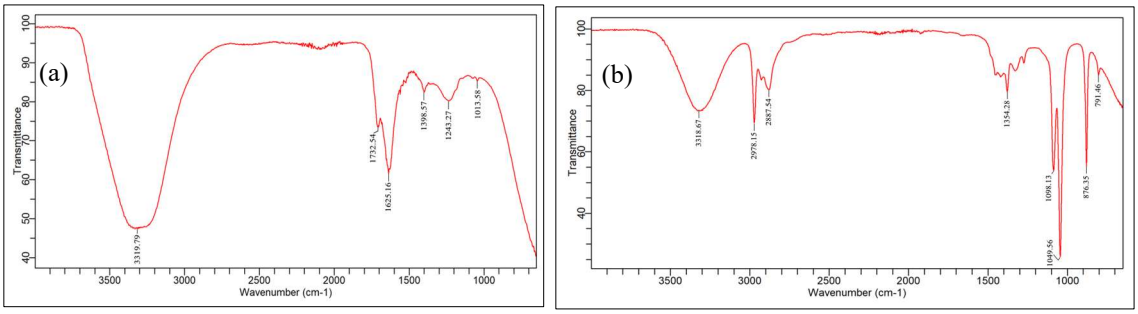

Figure 4. FTIR spectra of Cdots (a); TVA/SiO_2Cdots (b)

As for synthesized TVA/SiO_2-Cdots, the distinct peaks that determined their optical properties were observed at 3318.67, 2978.15, 1354.28, 1098.13, 1049.56, 876.35 and 791.46 cm^{-1}. The functional groups determined were N-H group, O-H group, sulfoxide group, C-O bond, strong Si-O-C bond, and strong C-Cl bond, respectively. The participation of the carbon dots in the synthesis of TVA/SiO_2-Cdots is determined because all the bands

were shifted. The broad bands at 2978.15-2887.54 and 3318.67 cm^{-1} in the synthesized TVA/SiO_2-Cdots which are assigned to the O-H and N-H functional groups accounts to the solubility and stability of the synthesized TVA/SiO_2-Cdots [9]. The presence of the said functional also plays a major factor in the color tuning of the synthesized TVA/SiO_2-Cdots. The blue shift in the emission wavelength of the TVA/SiO_2-CDots can be attributed to an amine state, which can emit shorter wavelengths under UV excitation [2]. The presence of functional groups such as hydroxyl group containing medium emission, and sulfoxide and C-Cl bond which both contain strong emission proves the higher strength of emission of TVA/SiO_2-Cdots compared to the synthesized carbon dots. In addition, the greater number of chemical bonds present in the TVA/SiO_2-Cdots indicates its high reactivity to heavy metals [10].

Determination of PL Intensity TVA/SiO_2-Cdots upon increasing Cu^{2+} ion concentration in simulated wastewater

The detection of Cu^{2+} ions using TVA/SiO_2-Cdots was conducted at different concentrations between a range of 0 to 10 ppm. The results revealed that there was a drastic reduction in the PL intensity at 365 nm as the Cu^{2+} concentration increased, demonstrating excellent sensing of the metal ion in the system. The PL intensity is significantly reduced and the emission wavelength of the fluorescent material along with a quencher do not change. As the concentration of Cu^{2+} increases from 0 ppm to 10 ppm, the PL intensity of TVA/SiO_2-Cdots decreases from 245.9760 to 58.7867. Thus, the PL intensity of synthesized TVA/SiO_2-Cdots is Cu^{2+} metal-ion-concentration-dependent.

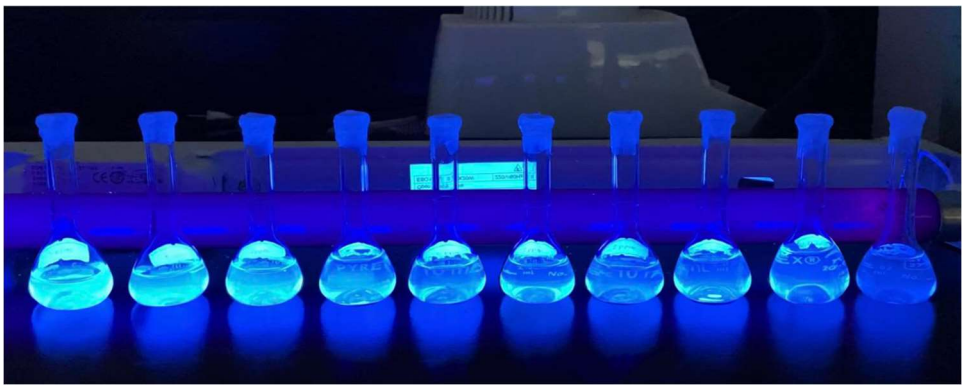

Figure 5. PL intensity of TVA/SiO_2-Cdots with the increasing Cu^{2+} ion concentration in simulated wastewater

Table 6. PL Intensities of TVA/SiO_2-Cdots with the increasing Cu^{2+} ion concentration in simulated wastewater

$CuSO_4 \cdot 5H_2O$ Concentration (ppm)	**Photoluminescence Intensity (Simulated Wastewater)**
0	245.9760
1	162.4328
2	134.9339
3	128.6127
4	125.5015
5	119.3487
6	108.4712
7	98.4624
8	86.7122
9	72.5457
10	58.7867

The fluorescence-quenching mechanism of normal CDs can be attributed to several factors such as inner filter effects, non-radiative recombination pathways, electron transfer and ion-binding interaction [11]. The fluorescence-quenching mechanism of TVA/SiO_2-Cdots was assessed using the UV–visible spectroscopy. The broad absorption band of TVA/SiO_2-Cdots around 185 and 400 nm showed definite reduction upon increasing Cu^{2+} metal ion concentrations, therefore indicating the formation of complexations between the functional groups of TVA/SiO_2-Cdots and Cu^{2+} ions.

On the basis of this observation, the researchers propose that the formation of complexation between TVA/SiO_2-Cdots and Cu^{2+} results in electron transfer between Cu^{2+} ions and TVA/SiO_2-Cdots (nonradiative energy), which plays a major role in quenching the PL intensity of TVA/SiO_2-Cdots. The figure below shows the fluorescence-quenching mechanism of TVA/SiO_2-Cdots by Cu^{2+} metal ions. In fact, the main reason for the decrease of PL intensity of such quantum dots is the defects that existed in their structures that led to trap electrons and hence decrease the PL intensity. By surface modification of the quantum dots, the defects centers were significantly decreased and therefore the PL intensity is increased. Due to the high PL intensity of the synthesized carbon quantum dots, we used them to the detection of Cu^{2+} ions. The results showed Cu^{2+} can quench PL intensity of carbon dots due to the bonding between of N functional groups of CQD and Cu^{2+}.

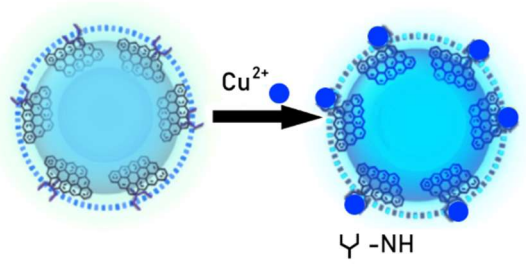

Figure 6. Quenching mechanism of carbon dots

A one-way ANOVA was performed to compare the effect of increasing Cu^{2+} ion concentration in simulated wastewater and TVA/SiO_2-Cdots PL intensity. Since the data obtained had a p-value of 2.34E-07, which is less than 0.05, it meant that increasing Cu^{2+} ion concentration in simulated wastewater has a high effect on the PL intensity of TVA/SiO_2-Cdots. The obtained F-stat value (58.41) is greater than the *F*-critical value (4.35) which is equivalent to a *p*-value less than alpha. Both of these mean that the PL intensity of TVA/SiO_2-Cdots was significantly affected by an increase in Cu^{2+} ion concentration in simulated wastewater.

Table 7. Statistical result for the effect in PL intensity of TVA/SiO_2-Cdots upon increasing Cu^{2+} ion concentration in simulated wastewater

Medium	Mean Square	Sum of Squares	*F*-Stat	*p* - value	*F*-critical
Simulated Wastewater	1288.45	25769.08	58.41	2.34E-07	4.35

Mathematical model on the effect of Cu^{2+} ion concentrations on the PL intensity of TVA/SiO_2-Cdots in simulated wastewater

After analysis of different models, the Gaussian method of modeling was selected as the best fit to represent the effects of increasing heavy metal concentration in simulated wastewater to photoluminescence intensity of TVA/SiO_2-Cdots. This method was selected over the other five methods namely exponential of 2nd power, Fourier of 2nd power, linear model of 3rd, power and rational.

Table 8. Generated model curves describing the effect of Cu^{2+} ion concentrations to PL intensity of TVA/SiO_2-Cdots in simulated wastewater

Types of Models Fit	Method	Equations Generated	SSE	R^2	Adjusted R^2	RMSE
Exponential (2nd Power)	Non-linear Squares	$P(C)= 73.73e^{-3.105C} + 172.3e^{-0.08933C}$	489.32	0.9811	0.9730	8.361
Fourier (2nd Power)	Non-linear Squares	$P(C)= 1.791x10^{14} - 2.387x10^{14}\cos(0.0002733*C) - 3.831x10^{11}\sin(0.0002733*C) + 5.969x10^{13}\cos(5.466x10^{-4}*C) + 1.915x10^{11}\sin(5.466x10^{-4}*C)$	127.86	0.9951	0.9901	5.0569
Gaussian (2 terms)	**Non-linear Squares**	$\boldsymbol{P(C)= 501.7e^{(\frac{-2.658-C}{2.308})^2} + 127.5e^{(\frac{2.839-C}{2.099})^2}}$	**12.908**	**0.9995**	**0.9990**	**1.1067**
Linear Model (Poly 3)	Linear Squares	$P(C)= -0.5801C^3 + 9.983C^2 - 59.85C + 230.9$	1268.2	0.9676	0.9230	13.46
Power	Non-linear Squares	$P(C)= -7.128C^{1.1239} + 160$	1007.4	0.9798	0.9771	7.9349
Rational	Linear Squares	$P(C)= \frac{-56.35C^3 - 7.285C^2 + 277C + 28}{C^2 + 2.889C + 2.382}$	22.598	0.9991	0.9983	2.126

In selecting the best mathematical model from the generated equation shown above, the equation's fitness must be measured in terms of SSE, adjusted, and root mean squared error. Similarly, the model with the lowest SSE and RMSE is the best fit because these assess the errors from the data points. The model that is closest to one in terms of R^2 is the most suitable [12]. Based on the generated models, the Gaussian equation has the lowest SSE and RMSE and it also has the closest value of 1 in terms of the R^2 and adjusted R^2 values.

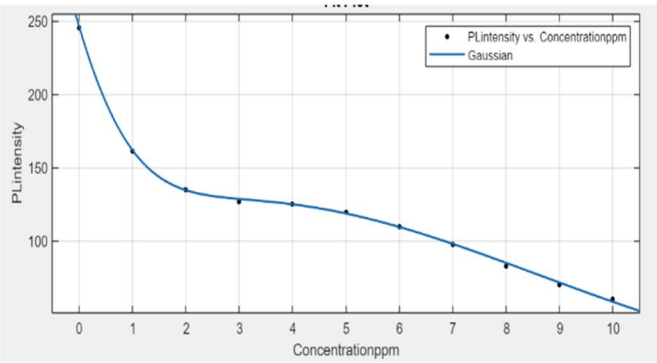

Figure 7. Curve fit of Gaussian method for Cu^{2+}

This model is best described by the equation for Cu^{2+}:

$$P(C) = 501.7\, e^{-(\frac{C+2.658}{2.308})^2} + 127.5\, e^{(\frac{2.839-C}{2.099})^2} \quad (1)$$

where P(C) is the PL intensity in RLU as the function of heavy metal concentration, C in ppm.

Comparison of the Cu^{2+} ion concentration calculated from the generated model with the detected concentrations using ultraviolet spectrophotometric screening method

In the table above, the amount of calculated concentration from the selected model is shown. The photoluminescence intensity of TVA/SiO_2-Cdots decreases along with increasing formulated concentration of Cu^{2+} ions. The calculated concentration using the model provides values that are approximately the same as the detected concentration using the ultraviolet spectrophotometric screening method, with a maximum deviation (by virtue of difference) of 0.2587 and minimum deviation of 0.0013. Furthermore, the model fits more effectively at low to moderate concentrations.

Table 8. Concentration of Cu^{2+} ion based on calculated and detected values

Formulated $CuSO_4 \cdot 5H_2O$ Concentration (ppm)	Photoluminescence Intensity	Calculated Concentration using the Model (ppm)	Detected Concentration
1	162.4328	0.9869	0.9974
2	134.9339	1.9787	1.9653
3	128.6127	3.0212	2.9876
4	125.5015	3.8967	4.0259
5	119.3487	4.9221	4.9208
6	108.4712	6.0951	5.8364
7	98.4624	6.9563	7.0113
8	86.7122	7.8677	7.9274
9	72.5457	8.9208	9.0692
10	58.7867	9.9652	9.9865

Table 9. Statistical result for the comparison of calculated and detected concentration of Cu^{2+} ion in simulated wastewater

Mean Difference	Standard Deviation	Standard Error Mean	*t* -Value	*p* - value	*t*-Critical Value
0.01171	-	-	-0.331	7.48E-01	2.262

Note. p – value depicts a value greater than α = 0.05 has no significant effect

The p-value calculated is greater than 0.05 which denotes the acceptance of the null hypothesis. Thus, there is no significant difference between Cu^{2+} concentrations calculated from the generated mathematical model with that detected from the UV-Vis screening method.

Conclusion

The following conclusions were based on the mathematical analysis of the data using the appropriate computer software and the in-depth interpretation of the results and findings. Varying parameters such as silica dosage, agitation rate, and contact time play significant roles in copper detection. There is the presence of amine N-H, carbonyl C=O, C=C, C-H, and C-O groups in the Cdots, whereas the presence of N-H, O-H, and sulfoxide groups as well as C-O, strong C=C, and strong C-Cl bonds in TVA/SiO_2-Cdots, which are responsible for their color emission, stability, and reactivity. Moreover, the results of dynamic light scattering measurements indicated that upon silica doping, the average diameter of CDs in ethanol had increased, indicating a success in the doping process. The photoluminescence intensity at 365 nm decreased significantly along with the increasing Cu^{2+} ion concentration in the range of 0 to 10 ppm in simulated wastewater, which indicated that the photoluminescence intensity of TVA/SiO_2-Cdots was quenched by Cu^{2+} ions. The generated mathematical model in equation 1, can be used to determine Cu^{2+} concentrations at specific ranges having no significant

difference with the ultraviolet spectrophotometric screening method.

Abstract

In this work we report crystal structure and Hirshfeld surface analysis of compound di[2-((1*E*)-{2-(2-methylbenzylsulfanyl)methylidene- hydrazin-1-ylidene}methyl)-6-methoxy- phenol] (**HL**), which has a dimeric dithiocarbazate backbone. **HL** has a non-planar structure due to strong intra-bonds that create two S(6) graph-set motifs, preventing free rotation by locking its atoms in a nearly planar arrangement. The crystal packing involves intermolecular C—H···S and C—H···π interactions that form a two-dimensional sheet parallel to the *ac*-plane which extends into a three-dimensional network arrangement via π···π interactions involving the centroid of the phenyl ring. Hirshfeld surface analysis describes that the major contribution to the overall crystal packing is from H···H contacts, followed by H···C/C···H contacts, which signify the presence of C—H···π interactions. The presence of intermolecular C—H···S interactions can be confirmed through the involvement of S···H/H···S contacts.

Keywords: dithiocarbazate, dimeric, crystal structure, Hirshfeld surface analysis

Abstrak

Dalam kajian ini, kami melaporkan struktur hablur dan analisis permukaan Hirshfeld bagi sebatian di[2-((1E)-{2-(2-metilbenzilsulfanil)metilidena-hidrazin-1-ilidena}metil)-6-metoksi-fenol] (**HL**), yang mempunyai rangkaian dithiocarbazat berbentuk dimerik. **HL** mempunyai struktur tidak rata disebabkan oleh ikatan dalaman yang kuat yang membentuk dua motif set-

graf S(6), menghalang putaran bebas dan mengunci atom-atomnya dalam susunan hampir rata. Penempatan hablur melibatkan interaksi intermolekul antara C—H···S dan C—H···π yang membentuk satu lapisan dua dimensi sejajar dengan satah *ac* dan meluas ke susunan rangkaian tiga dimensi melalui interaksi π···π yang melibatkan pusat gelang fenil. Analisis permukaan Hirshfeld menjelaskan bahawa sumbangan utama kepada penempatan kristal secara keseluruhan adalah daripada sentuhan H···H, diikuti oleh sentuhan H···C/C···H, yang menunjukkan kewujudan interaksi C—H···π. Kewujudan interaksi intermolekul antara C—H···S dapat disahkan melalui keterlibatan sentuhan S···H/H···S.

Introduction

Dithiocarbazate Schiff bases have gained significant attention due to their diverse range of biological and pharmacological activities [1–5]. These compounds consist of a dithiocarbazate moiety (depicted in Figure 1), which is formed by condensing a primary amine with carbon disulfide and subsequently reacting it with an aldehyde or ketone to create the Schiff base. These ligands bear structural similarities to thiosemicarbazone and hydrazone ligands. Even minor modifications in the molecular structure of dithiocarbazate derivatives can result in intriguing biological properties [2, 6]. Moreover, these ligands possess both soft sulfur and hard nitrogen donor atoms, enabling them to coordinate with various metal ions to form metal complexes that exhibit fascinating physicochemical and enhanced biological characteristics. In this study, our focus lies on synthesizing di[2-((1E)-{2-(2-methylbenzylsulfanyl)methylidene- hydrazin-1-ylidene}methyl)-6-methoxy- phenol] (**HL**) and performing a single crystal X-ray diffraction (XRD) analysis to determine the crystal characteristics of **HL**. In addition, the significant intermolecular interactions have been studied using Hirshfeld surface analysis.

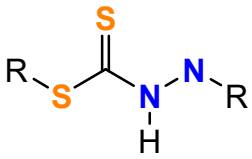

Figure 1. Dithiocarbazate backbone (R = alkyl/aryl/H)

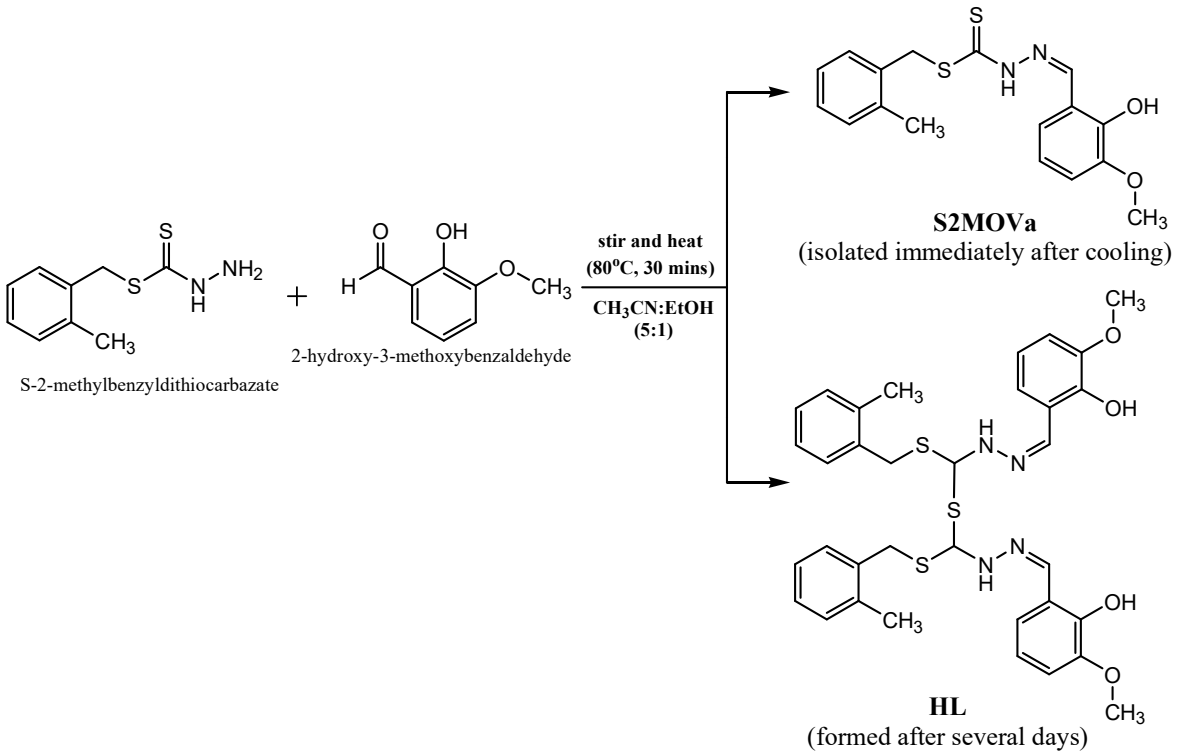

Materials and Methods

Materials

Analytical reagent grade solvents and reagents were utilized without additional purification. The following chemicals were employed: Hydrazine hydrate (Fluka), 2-methylbenzyl chloride (ACROS), potassium hydroxide (HmbG), carbon disulfide (BDH), and 2-hydroxy-3-methoxybenzaldehyde (Merck). The solvents used were acetonitrile (Baker) and absolute ethanol with a purity of 99.8% (Scharlau).

Synthesis and crystallization of di[2-((1E)-{2-(2-methylbenzylsulfanyl)methylidene- hydrazin-1-ylidene} methyl)-6-methoxy- phenol] (HL)

The formation of the **HL** was synthesized using established literature procedures [4,7]. To initiate the synthesis, S-2-methylbenzyldithiocarbazate (2.12 g, 10 mmol) was dissolved in 100 mL of hot acetonitrile. This solution was then combined with an equimolar amount of 2-hydroxy-3-methoxybenzaldehyde (1.52 g, 10 mmol) dissolved in 20 mL of absolute ethanol. The resulting mixture was stirred at 80 °C for 30 minutes and allowed to sit at room temperature overnight. The completion of the reaction was checked using thin layer chromatography (TLC) plate. Following this, light yellow crystalline solid, 2-((1E)-{2-(2-methylbenzyl sulfanyl)methylidene-hydrazin-1-ylidene}methyl)-6-methoxy-phenol was obtained. The yellow crystalline solid was then recrystallized from a mixture of CH_3CN and EtOH in a 1:1 ratio. After several days of allowing the recrystallization solution to sit at room temperature, yellow plate-shaped crystals of the compound were formed. The single crystal X-ray diffraction analysis confirmed the unexpected product of di[2-((1E)-{2-(2-methylbenzylsulfanyl)methylidene- hydrazin-1-ylidene}methyl)-6-methoxy- phenol] (**HL**). The synthetic scheme for the formation of **HL** is shown in Scheme 1.

Scheme 1. Synthetic pathway for the formation of **HL**

X-ray crystallography refinement

X-ray analysis was conducted on a single crystal suitable for analysis using a CCD area-detector. CuKα radiation with a wavelength of 1.54178 Å was used. A high-quality crystal, clear and light yellow in color, measuring 0.58 × 0.31 × 0.15 mm, was carefully extracted and observed under a microscope for data collection. The APEX2 software was utilized for data collection, while cell refinement and data reduction were carried out using the SAINT software [8]. The crystal structure was solved using the Direct Method in the SHELXTL program and refined using its' full-matrix least squares technique on F^2 with anisotropic displacement parameters. Absorption correction was applied to the final crystal data using the SADABS software [8]. All geometric calculations were performed using the PLATON program [9]. Molecular graphics were generated using SHELXTL [10]. The non-hydrogen atoms were refined anisotropically, while the hydrogen atoms were positioned geometrically [C—H = 0.93, 0.96 or 0.97 Å] and refined using a riding model with isotropic displacement parameters set to 1.2 (for C) or 1.5 (for C_{methyl}) times the equivalent isotropic U values of the parent carbon atoms. The methyl groups were modelled using a rotating groups model. Additionally, hydrogen atoms bonded to oxygen atoms were located and distinguished through the differences observed through overlapping Fourier maps and freely refined [O-H = 0.76(4) and 0.81(4) Å]. In the final refinement, three outliers (991, 913, and 912) were omitted for clarity. Table 1 provides a summary of the crystal data and relevant refinement parameters for the **HL**.

Hirshfeld surface analysis

Hirshfeld surface and 2D-fingerprint plots calculations were carried out using CrystalExplorer 17.5 [11] on crystal structure imported from CIF file. The Hirshfeld Surfaces for **HL** were mapped with normalized contact distances (d_{norm}), shape index and curvedness functions.

Results and Discussion

Molecular structure and crystal packing of HL

The molecular structure of the compound **HL** with assigned atom-numbering scheme are presented in Figure 2. The molecular structure of **HL** is crystallized in Triclinic crystal system with *P*-1 space group. All selected bond lengths and angles listed in Table 2 are found within the normal ranges. **HL** consist of dimeric dithiocarbazate backbone with two terminal toluene and 2-methoxyphenol moieties. Intramolecular O1—H1O1···N2 and O3—H1O3···N4 hydrogen bonds are observed with the non-bonding distances (O···N) and the angles (O—H···N) of the intramolecular hydrogen bond of 2.642(3 Å) Å, 159(5)° and 2.679(3) Å, 151(5)°, respectively. Subsequently, these bonds create two *S*(6) graph-set motif, preventing any free rotation of atom, hence locking them (O1/N2/C9-C11 and O3/N4/ C24-C26) in a nearly planar arrangement. Both sulphur and nitrogen bond lengths are found within the normal range where S1—S3 bond length is 2.0411 (9) Å and the N1—N2 as well as N3—N4 bond lengths are 1.406 (3) Å and 1.408 (3) Å, respectively. Figure 2 shows the non-planar

structure of **HL** where the terminal methyl substituted benzene rings are twisted at C1—S2—C2—C3 and C16—S4—C17—C18 torsion angles of −151.6 (2)° and −159.8 (2)°, respectively. Moreover, the terminal 2-methyl phenol rings are likewise observed to be twisted at C1—N1—N2—C9 torsion angle of −156.7 (2)° whereas on the other side of the molecule, the ring is observed to be slightly twisted with C16—N3—N4—C24 torsion angle of −173.9 (2)°. Additionally, the dihedral angles between the phenyl rings (Table 3) are also compared whereby the angles are in the range of 20°-72°, which further confirms the non-planar structure of **HL**.

In the arrangement of the crystal structure as shown in Figure 3 and Table 4, the molecules of **HL** are connected in a one-dimensional chain along the *a*-axis through intermolecular C7—H7···S3 hydrogen bonding. These intermolecular C—H···S interactions are further reinforced by intermolecular C—H···π interactions, specifically C19—H19···*Cg*2 (as indicated in Table 4), where *Cg*2 represents the centroid of the C25-C30 phenyl rings. These interactions result in the formation of a two-dimensional sheet parallel to the *ac*-plane. Furthermore, the crystal structure is strengthened by π···π interactions involving the centroid of the phenyl ring, *Cg*2 (C10-C15),where the centroid to centroid distance is 3.6423(16) Å. These π···π interactions results into extending the two-dimensional *ac*-sheets into a three-dimensional network arrangement.

Hirshfeld surface analysis

Hirshfeld surface analysis was employed to conduct a thorough investigation of the intermolecular interactions within compound **HL**. This technique is highly valuable for visualizing and quantifying the diverse intermolecular interactions within the crystal structure. In Figure 4, the Hirshfeld surface is plotted using d_{norm}, enabling the visualization of intermolecular interactions through color codes (red, white, and blue). The red color signifies the closest or strongest contacts, indicating the sum of d_i (distance from a point on the surface to the nearest nucleus internal to the surface) and d_e (distance from a point on the surface to the nearest nucleus external to the surface), with de being shorter than the sum of the relevant Van der Waals radii. Conversely, weak intermolecular interactions are represented by white and blue color codes [12]. Notably, the dark red region surrounding each molecule corresponds to significant C—H···S interactions within the crystal packing. Additionally, the mapping of shape index and its curvature helps visualize π···π and C—H···π interactions involving phenyl rings. In Figure 5(a), the red concave regions exhibiting 'bow-tie' patterns on the shape index surface indicate the presence of aromatic stacking (π···π) interactions involving *Cg*1···*Cg*1, as well as the occurrence of C—H···π (C19—H19···*Cg*2) interactions. Figure 5(b) displays the Hirshfeld surface mapped over curvedness, highlighting flat surface patches characteristic of planar stacking involving *Cg*1···*Cg*1.

Furthermore, two-dimensional (2D) fingerprint plots are generated to provide quantitative information related to the type of intermolecular contacts present within the crystal [12,13]. The 2D fingerprint plots of Hirshfeld surfaces were successfully outlined into H···H, H···C/C···H, S···H/H···S, O···H/ H···O, H···N/N···H, C···C, N···C/C···N, O···C/C···O, S···N/N···S, N···N, S···C/C···S, and O···O contacts. The 2D fingerprint plots of the intermolecular contacts with their respective percentage contribution are presented in Figure 6. The H···H contacts contribute to the overall crystal packing at 42.6%. These dominant contacts may have attributed to the large hydrogen content of the molecule as observed through the exhibition of the two tips at $d_e + d_i$ = 2.3 Å. A pair of characteristic wings of H···C/C···H (22.3%) contacts at $d_e + d_i$ = 2.7 Å signifies the presence of C—H···π interactions in the compound. The existence of intermolecular C—H···S interactions can be confirmed through the involvement of 12.5% of S···H/H···S contacts as characterized by a pair of sharp peaks with spikes at $d_e + d_i$ = 2.7 Å. The H···N/N···H contacts contributing to about 3.7% in the Hirshfeld surface analysis is represented by a pair of diffuse spikes at $d_e + d_i$ = 2.8 Å. However, the weak C···C, N···C/C···N, O···C/C···O, S···N/N···S, N···N, S ···C/C···S, and O···O contacts minorly contributes in the **HL** compound with 2.7%, 1.7%, 0.9%, 0.6%, 0.4%, 0.3%, and 0.1%, respectively. All these intermolecular interactions aids in the stabilization of the **HL** molecular assembly [14].

Database survey

There are three similar crystallographic literatures when compared to **HL** in the database, and the details are compiled in Table 5. Among them, Derivative (I) closely resembles **HL**, with the only difference being the S-bound R group. In Derivative (I), the S-bound R group is a S-methylbenzyl ester with a methyl group in the para position, and it has a 2-hydroxylbenzene ring bound to the imine-C. Figure 7 illustrates the close similarity between (I) and (II), where the only distinction lies in the S-bound R group, with R = *p*-methylbenzyl (GUPDAZ [15]) and R = H (LUGLUD [16]). Both (I) and (III) exhibit complete molecules generated by crystallographically imposed twofold symmetry, similar to **HL**. The S—S bond length of **HL** falls within the experimental range of 2.0373 (4) Å in (II) and 2.0504 (7) Å in (III). Similarly, the C—S—S—C torsion angle of **HL** exhibits the lowest angle compared to 90.70 (8) (I), (91.54 (6) (II), and 96.2 (1) (III). By comparing all the data, all four molecules mentioned in Table 5 adopt a similar conformation.

Table 5. Comparison of key geometric parameters (Å, °) in structures related to **HL**

Compound	Symmetry	S-S	C-S-S-C	Refcode	Reference
HL	2	2.0411 (9)	89.2(1)	-	This work
(I)	2	2.0439 (8)	90.70 (8)	GUPDAZ	[15]
(II)	-	2.0373 (4)	91.54 (6)	LUGLUD	[16]
(III)	2	2.0504 (7)	96.2 (1)	CUHHET	[17]

Conclusions

A new structure of **HL** was synthesized and confirmed by single crystal X-ray diffraction analysis. The crystal system of the molecule was found to be triclinic, with the space group *P*-1. Furthermore, the Hirshfeld surface analysis revealed the existence of intriguing C—H···S intermolecular interactions within the crystal structure. Notably, the two-dimensional fingerprint plots emphasized the significance of H–H contacts, which accounted for the majority (42.6%) of the total Hirshfeld surface area. These findings shed light on the unique molecular arrangement and bonding patterns of **HL**, paving the way for further investigations into its properties and potential applications.

Abstract

Photocatalytic degradation appeared as a future alternative for the removal of many organic contaminants with high efficiency and energy-saving technology. As a photocatalyst, molybdenum disulphide (MoS_2) exhibits good photocatalytic properties due to great potential for organic contaminant degradation. It is ascribed that various approaches for MoS_2 preparation serve a diverse number of exposed active sites that facilitate MoS_2 efficiency for photocatalytic reaction. Several methods have been extensively applied to improve MoS_2 photocatalytic efficiency, including synthesized different surface morphology and heterojunction formation with other semiconductors. Therefore, it will increase the photocatalytic activities of the composites by combining MoS_2 with other semiconductor photocatalyst materials. Integration of MoS_2 as a binary or ternary photocatalyst will produce a synergic effect that hinders the recombination process and enhancement of the surface areas. On the other hand, it improved on conductivity of the nanosheets, whereby it is believed to be able to deal with photocatalytic material challenges and provide efficient solutions to deal with degradation of organic contaminants.

Keywords: conducting polymer, metal disulphide, organic pollutants, photocatalytic degradation, sustainable water management

Abstrak

Degradasi fotokatalitik muncul sebagai alternatif masa depan untuk penyingkiran banyak bahan cemar organik dengan kecekapan tinggi dan teknologi penjimatan tenaga. Molibdenum disulfida (MoS_2) sebagai fotomangkin mempamerkan sifat fotokatalitik yang baik kerana potensi besar untuk degradasi bahan cemar organik. Disifatkan bahawa pelbagai pendekatan penyediaan MoS_2 menyediakan bilangan tapak aktif terdedah yang berbeza yang memudahkan kecekapan MoS_2 untuk tindak balas fotokatalitik. Beberapa kaedah telah digunakan secara meluas untuk meningkatkan kecekapan fotokatalitik MoS_2, termasuk morfologi permukaan yang berbeza yang disintesis dan pembentukan heterojunction dengan semikonduktor lain. Oleh itu, dengan menggabungkan MoS_2 dengan bahan semikonduktor fotomangkin lain, ia akan meningkatkan aktiviti fotomangkin komposit. Penyepaduan MoS_2 sebagai fotomangkin binari atau ternari akan menghasilkan kesan sinergik yang menghalang proses

penggabungan semula dan peningkatan kawasan permukaan. Sebaliknya, ia bertambah baik dalam kekonduksian helaian nano di mana ia dipercayai mampu menangani cabaran bahan fotokatalitik dan menyediakan penyelesaian yang cekap untuk menangani degradasi bahan cemar organik

Kata kunci: pengalir polimer, logam disulfida, bahan pencemar organik, degradasi fotokatalitik, pengurusan air yang mampan

Introduction

Photocatalytic from semiconductors are more desirable and simpler to be used for environmental remediation, whereby it emphasizes on green energy technology. The semiconductor materials performance depends on the photocatalysts potential to absorb split and transport photogenerated electrons and holes for the absorption of light energy in the available region. Molybdenum disulphide (MoS_2) shows considerable absorption in the solar spectrum visible region or sunlight, which is the renewable source with a lower bandgap [1]. MoS_2 consists of sulfur with *p* and molybdenum with *d* atomic orbitals. The presence of *d* electrons in the conduction and valance bands indicated an interaction with the *p* orbital in the sulfur. As a *d*-block element, molybdenum acts as a catalyst due to its ability to modify oxidation or to absorb and activate other substances on its surface in the case of metals. Besides, the molybdenum experienced a strong spin-orbital coupling at 4*d* electrons that reduced the degenerated energy level [2].

However, various methods have been used to develop the photocatalytic ability of MoS_2 that include photocatalyst combination, surface morphology modification, heterojunction integration with other semiconductors and doping process [3]. The mechanical and chemical approaches allow to obtain a single layer of MoS_2. The thin layered MoS_2 is prepared using different synthesis techniques, such as hydrothermal, exfoliation, solvothermal and chemical vapor deposition techniques.

Single and bulk layer of MoS_2 as photocatalyst in the photodegradation approach is widely used to degrade organic pollutants. Furthermore, MoS_2 as a semiconductor photocatalyst demonstrates active surface sites and small band gaps, which are efficient in the aqueous solution for reactive species generation. Despite its distinct chemical, electrical and physical characteristics, MoS_2 inherits semiconductors characteristics for water purification due to its excellent potential in light response. MoS_2 monolayer sites are considerably more resistant to photocatalytic degradation. Furthermore, Saha et al. (2019) stated that the integration of MoS_2 with conducting polymer as a binary photocatalyst would improve the photocatalytic activity [4]. For instance, MoS_2 with polyaniline will be able to solve the problems of current photocatalytic structures. Moreover, it provides an ideal solution for the separation of contaminants from wastewater for water purification, as polyaniline generates a highly charged carrier to assist the photocatalytic degradation processes. Recently, Feng et al. showed $MoS_2/TiO_2/ZnS/CdS$-Mn as the ternary photocatalyst with high photocatalytic efficiency and degradation for azo dye under sunlight irradiation at a removal rate of 98% in 100 min [5].

The development of photocatalytic method with the aid of MoS_2 is important to assist valued industries in ensuring organic contaminants can be removed from the environment. Additionally, MoS_2 can conduct the semiconductors characteristics for water purification due to its excellent light response capability. Therefore, by identifying the best approach for preparation of MoS_2, its excellent physical, chemical and electrical properties at maximum level can be sustained for high-performance photocatalytic reactions. Moreover, integrating MoS_2 with other photocatalysts will solve the problems of current photocatalytic structures and provide an ideal solution for separation of organic contaminants. Consequently, the most excellent interaction, either as a single, binary, or ternary photocatalyst can be pointed out to assist in photocatalytic activities. The execution using MoS_2 with other photocatalysts will come up with a great deal in the improvement of energy efficiency.

.

Fundamental of photocatalytic degradation

A substantial amount of studies was performed in recent years with advanced oxidation processes (AOPs) and as a result, different types of AOPs were discovered. AOPs

tend to be a potential research area that has been shown to be efficient for the removal of water and soil soluble organic pollutants that cause almost complete degradation. Several AOPs include photolysis, ozonolysis and photocatalysis. Amongst the AOPs, photocatalytic activity was proven to be a viable tool for the degradation of organic compounds. Besides, the approach is more effective than other AOPs, since it can easily neutralize different organic pollutants [6].

Photocatalytic degradation is a chemical response under the action of light and photocatalyst. Additionally, photocatalytic activity is a molecular degradation caused by photon absorption that has an identical light absorption range with the wavelengths in sunlight. It is the best method for water treatment since it relies on the range of light intensity and wavelengths [7]. It is often used in organic pollutant degradation due to its effectiveness, flexibility, reproducibility and simplicity. Photocatalysts are the foundation of the photocatalytic method. A photocatalyst is a compound triggered by adsorbing a photon and can activate a reaction without being utilized. Therefore, semiconductor photocatalyst is globally used in photocatalytic approaches [8].

Mechanism of action for photocatalytic degradation

Photocatalytic degradation mechanism has been frequently used to remove organic contaminants due to environmental operating pressure and temperature, total mineralization and intermediate products without secondary emission and low operating expenses. The mechanism of the photocatalytic reaction is complex and has many intermediate steps [9]. The theory of photocatalytic is to transform the light energy under light irradiation into chemical energy and to create a corresponding free group of radicals with a redox capability. In a previous study by Mirza Hedayat et al., photocatalytic was observed as an effective approach for removal of organic pollutants in wastewater purification [10]. However, a study conducted by Ajmal et al. stated that heterogeneous AOPs, involving photocatalytic dye degradation with semiconductor nanoparticles were assumed to be an effective treatment for dye contamination [11]. The indirect heterogeneous method of the photocatalytic oxidation using semiconductive compounds could be summed up, as shown in Figure 1.

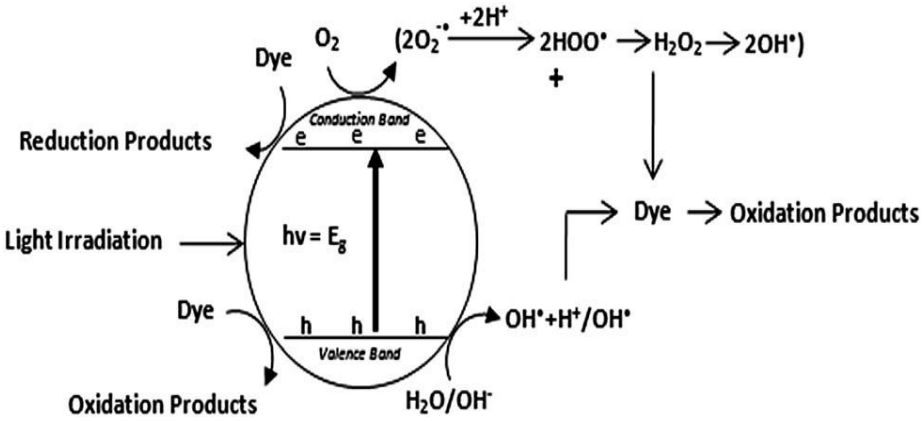

Figure 1. Pictorial illustrated the direct dye removal process [11]

The photocatalytic reaction was caused by the recruitment of a photoelectron of a photocatalytic semiconductor from the occupied valence band. From the result of irradiation, the metal oxides filled the empty conduction band. The absorbed photon had energy (*hv*) equal to or higher than the bandgap of the photocatalyst. The excitation phase in the valence band left behind a hole and produced the electron and hole pair. Then, the photogenerated holes reacted with water in the valence band to create OH radical by ionization of water. Next, as the photogenerated hole binds with OH to produce radical hydroxyl, the oxygen induced electron was used to produce anionic radical superoxides. The superoxide ions prevented electron-hole recombination. Lastly, the

superoxide created the radical hydroperoxyl and dissociated H_2O_2 into highly reactive hydroxyl radicals. The oxidation and reduction processes happened frequently on the surface of the photoexcited semiconductor photocatalyst.

Preparation of molybdenum disulfide

MoS_2 is a layered transition metal dichalcogenide formed by loading the slightly interacted 2D S-Mo-S layer like graphite that demonstrates many useful applications. This includes hydrogen generation, solid-state lubricants and as a photocatalyst for pollutant degradation or hydrogen production. It has excellent anti-friction efficiency and resistance to abrasion process. Various morphologies of MoS_2 (Figure 2) were successfully prepared, including nanowires, nanotubes, nanorods, inorganic fullerene structures, nanospheres, hollow spheres and nanoflowers [12]. However, there were concerns in the limited reproducibility, low production efficiency and photocatalytic performance of the molybdenum disulphide. Therefore, a robust synthetic method was developed to overcome the issues [13].

Hydrothermal process

The hydrothermal procedure requires crystallizing the substance in aqueous solution at high pressure and The hydrothermal procedure requires crystallising the substance in aqueous solution at high pressure and temperature in a sealed vessel known as an autoclave, which can sustain a high temperature of 600°C to 700°C [14]. Moreover, it is an affordable and standardised process for MoS_2 synthesising. Hydrothermal synthesis is a promising way to develop nanostructures composites, especially for MoS_2 with various morphologies. Additionally, more MoS_2 layers that were exposed to the environment with higher chemical activities could be produced [15]. A study by Li et al. examined the morphology, structure and photocatalytic properties of MoS_2, which were prepared by hydrothermal process [16]. MoS_2 samples with four different morphologies, hollow MoS_2 (H-MoS_2), flowerlike MoS_2 (F-MoS_2), spherical MoS_2 (S-Mo-S_2) and coil MoS_2 (C-MoS_2) were analysed through the scanning electron microscope (SEM). Figure 2(a) reveals H-MoS_2 morphology with small holes on the surfaces of primary nanoparticles and microspheres. The size and number of primary particles were impacted directly by the hydrothermal reaction temperature. Figure 2(b) shows F-MoS_2 at approximately 600 nm in diameter. The MoS_2 surface consisted of a small-sized 2D-curl MoS_2 layer and the structure was uniform. Figure 2(c) shows S-MoS_2 that consisted mainly of nanoparticles of about 120 nm in diameter and with significantly lower wrinkles and a smoother surface. Figure 2(d) displays C-MoS_2 with a uniform diameter of 280 nm. F-MoS_2, with the smallest surface area, had the highest degradation rate, while H-MoS_2, with the greatest surface area, had the lowest degradation rate of MB.

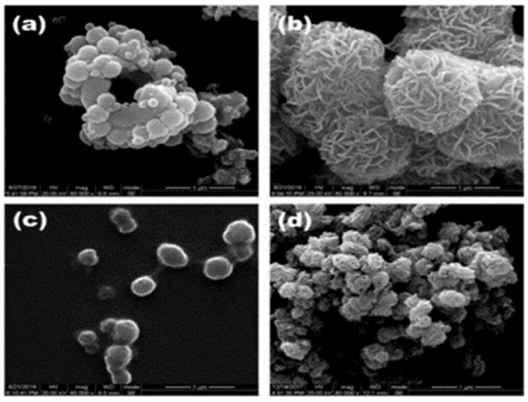

Figure 2. SEM images of (a) H-MoS_2; (b) F-MoS_2; (c) S-MoS_2; (d) C-MoS_2 [16]

Solvothermal method

Solvothermal process is a method of producing single crystals at high temperature and pressure from a non-aqueous solution in an autoclave. It was developed using the hydrothermal process and the major difference between solvothermal method and the latter is the organic solvent rather than water used for preparation [1]. A study by Vattikuti et al. analysed the X-ray diffraction (XRD) patterns, as shown in Figure 3. Both samples, the nanosheets and nanospheres, exhibited crystallite nature of MoS_2 materials with a XRD pattern indexed at 14˚, 32˚, 39.5˚ and 58˚, corresponding to (002), (100), (103) and (110) crystal planes of the MoS_2 structure [3]. The research stated that solvothermal synthesised MoS_2 nanocomposites could be modelled into nanorods using different sulphur sources, such as sodium sulphide and hydrogen sulphide (H_2S) in acidic media with different conditions and concentrations of citric acid to enhance specific textural and structural morphologies.

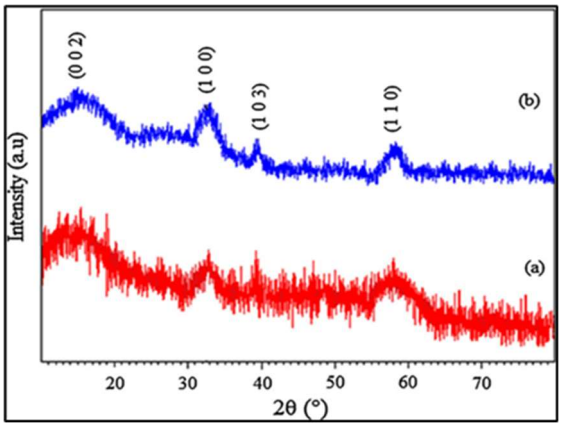

Figure 3. XRD patterns of MoS_2 a) nanospheres and b) nanosheets [3]

Another research by Sun et al. disclosed the formation influence of F-MoS_2 , with the effects of various reaction time. The samples were collected in solvothermal conditions at 190°C for 6 hr, 12 hr, 18 hr and 24 hr. Then, the samples were annealed for 5 hr at 500°C in a nitrogen atmosphere. However, after 6 hr, 12 hr and 18 hr, the products showed diffraction peaks due to MoO_2 as an impurity. It was also observed that the diffraction peak intensity, due to MoS_2, continued to rise and the diffraction peak intensity of MoO_2 dropped significantly (Figure 4). The diffraction peaks of MoO_2 faded when the reaction time was 24 hr and some diffraction peaks at 2θ = 13.9°, 34.5° and 60.4° were indexed using 2H-MoS_2. Therefore, it was suggested that hydroxylamine hydrochloride, which served as a reducing agent, reacted with a portion of sodium molybdate at an early stage of the reaction, giving MoO_2. This MoO_2 then reacted with S^{2-} that was obtained from the thiourea reaction that transformed MoO_2 into MoS_2 and was later applied for photocatalytic degradation [17].

Exfoliation method

The process of exfoliation involves electrochemical, chemical and liquid-phase exfoliations [18]. A study by Bai et al. reported that exfoliation approach could be used to extract monolayer and MoS_2 nanosheets in layered structures [19]. Alternatively, 1T metallic MoS_2, also known as metallic octahedral type could be obtained by ion intercalation. The most common method of intercalating alkali metal ions is particularly by lithium-ion intercalation [20]. MoS_2 exfoliation is a possible large-scale route for the production of semiconductor material with a controllable band gap that is capable of absorbing photons in the visible range [21]. In the same vein, Khan et al. concluded that the prepared composites of MoS_2/TiO_2 by in situ addition of exfoliated MoS_2 demonstrated higher output of photogenerated electron-hole pairs and accelerated charging transfer, as more active edges were available in MoS_2 that resulted in increased photocatalytic activity [22]. Figure 5 proved that the loading of exfoliated MoS_2 resulted in enhanced photodegradation activity due to

greater separation of the load carrier from the visible light. The absorption bands showed a red change when loaded with MoS_2. This was linked to the nanosized MoS_2 sheets, which provided more active surface area and optimal energy levels to increase the chemical activity. Therefore, in the presence of sunlight, the photocatalytic reaction significantly increased.

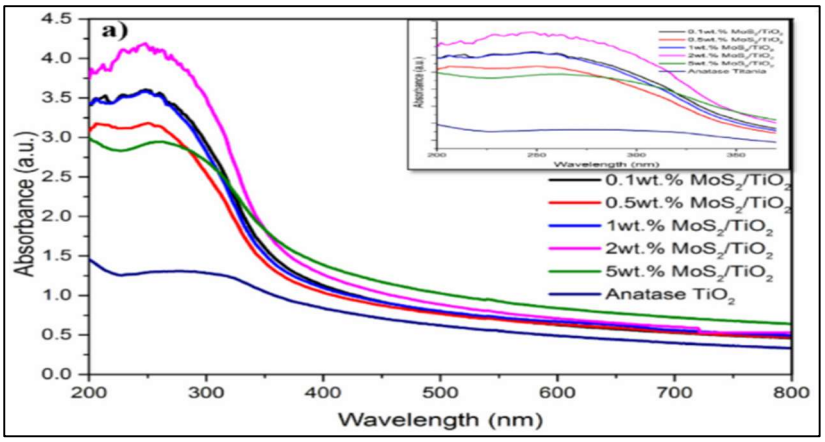

Figure 5. UV-Vis absorption spectrum of pure anatase TiO_2 and prepared photocatalysts [22]

Chemical vapor deposition method

Chemical vapour deposition (CVD) is a mechanism that produces great-quality MoS_2 layers. It has controllable size and uniform morphology by the chemical reaction at a specific temperature and gas flow between molybdenum and sulphur sources. CVD is an effective method for the synthesis of large single-layer MoS_2 film and can be categorised roughly into two types; the one-step and two-step procedures. One-step CVD generates MoS_2 by evaporating the sources of molybdenum and sulphur. Through sputtering procedure, molybdenum is dispersed onto a substrate in the two-step method. Then, it is placed in a sulphur atmosphere and reduced to graphite-like MoS_2 at a higher temperature [23]. The X-ray photoelectron spectroscopy (XPS) measurements were performed to investigate the stoichiometry ratio of the free thin films, which was prepared by CVD method using MoS_2. The peaks at 232.2 eV, 229.0 eV, 226.2 eV, 162.9 eV and 161.7 eV corresponded to Mo^{4+} $3d_{3/2}$, Mo^{4+} $3d_{5/2}$, S 2S, S $2p_{1/2}$ and S $2p_{3/2}$, respectively. Furthermore, the $3d_{5/2}$ peak of Mo and $2p_{3/2}$ peak of S were placed at binding energies that corresponded to the

Mo-S crystal. The peaks referred to a synthesised 2H structure of MoS_2. The Mo and S atomic ratios were 1:2.2, 1:2.35, 1:2.31 and 1:2.44, respectively, for concentrations of 0.0500 M, 0.0250 M, 0.0125 M and 0.007 M. All peaks were aligned without significant deviation. MoS_2 was synthesised and characterised successfully and the result showed that the CVD process was effective [24]. On the contrary, Najmaei et al. (2013) stated that other procedures to synthesise MoS_2 were by direct sulphurisation of films that contained molybdenum with CVD method [25]. Conversely, by this synthetic route, the inefficient consistency happened, which was caused by their low carrier mobility at 0.004 $cm^2 V^{-1} s^{-1}$ to 0.04 $cm^2 V^{-1} s^{-1}$. This process carries a considerable degree of difficulty in the preparation of precursors and in achieving adequate efficiency, which has limited effectiveness. Table 1 shows a summary of the synthesis method for MoS_2 composite.

Table 1. Summary of synthesis of MoS_2

Method of Synthesis	Type of Catalyst	Organic Pollutant	Type of Light	% Degradation	Ref.
Hydrothermal	MoS_2/PANI	4-chlorophenol (4-CP)	UV	75	[4]
	TiO_2-MoS_2	Rhodamine (RB)	Visible	90	[26]
Solvothermal	MoS_2/Cds	Methylene Orange (MO)	Visible	85	[27]

Exfoliation	$BiOIO_3$/g-C_3N_4/MoS_2	Mercury	Visible	70	[28]
	WS_2/MoS_2	RhB	Xe lamp	85	[29]
Chemical vapor	MoS_2/ZnO	MB	UV-Vis	81	[30]

MoS_2 as photocatalyst in photodegradation of organic contaminants

MoS_2 has become one of the most effective photocatalysts with the introduction of two-dimensional functional materials based on a high photocatalytic ability, good adsorption, low cost and non-toxicity. Furthermore, MoS_2-based composites are known as potential photocatalysts for the removal of environmental pollutant, as it accelerates photo-induced electron transportation and reduces levels of electron recombination. Various photocatalysts took advantage of semiconductor properties of MoS_2 constructing composite catalysts and showed favourable photocatalytic performance over organic compounds. Table 2 shows MoS_2 as a photocatalyst in the degradation of organic contaminants. The photodegradation efficiency (E%) was calculated using the following equation [31].

$$E\% = (C_0\text{-}Ct)/C_0 \times 100\% \quad (1)$$

Where C_0 is the whole amount of organic pollutants in the solution before illumination; Ct is the concentration of organic pollutants in solution at time t. There are two ways to determine residual concentrations after pollutants have been degraded. One method is to measure the linear relationship between the precise concentration of contaminants and the absorbance by an ultraviolet-visible (UV-Vis) spectrophotometer. Another option is to use high-performance liquid chromatography to quantify pollutants in aqueous solutions (HPLC).

MoS_2 as a single photocatalyst

A single photocatalyst consists of only one component in a composite. For example, metal oxides or metal sulphides, such as ZnO and MoS_2. Single photocatalyst operates based on its own unique and distinctive properties [32]. Vattikuti et al. highlighted that shape and size control was crucial during the production of single MoS_2 for obtaining well-defined structures with distinct features. MoS_2 morphology and scale are pivotal in sensors and catalysis [33]. Besides, the photocatalytic

activity can be tuned and enhanced by using appropriate doping. Moreover, MoS_2 has a benefit over other semiconductor photocatalyst materials, such as SnO_2, TiO_2 and ZnO for photocatalytic degradation due to its lower bandgap of ~1.9 eV. Therefore, MoS_2 is able to absorb both UV and visible solar spectrum [34]. It is reported that the single layer of MoS_2 with p-type doping has an acceptable band structure, high thermal conductivity and electrostatic integrity, which can be used as an effective single layer for self-consistent photocatalyst. The dielectric constant measures the material ability to absorb light. The peaks are mainly within 350 nm to 700 nm, which is in visible light range. Consequently, MoS_2 exhibited great sunlight absorption and optimal to be used as photocatalysts, which originated from the electronic structure of the MoS_2 single layer [35].

MoS_2 based composites of semiconductor as binary photocatalyst

Saha et al. traced the drawbacks of MoS_2, such as agglomeration between the composites and low electronic conductivity. It could be overcome by inserting 2D MoS_2 layers with 1D conducting polymer [4]. Therefore, photocatalytic response could be boosted by the integration of a single photocatalyst into composites. A binary photocatalyst is the hybridisation between two photocatalysts with different bands and electronic structures, which can resolve photocatalyst limitations. According to Norsham et al., the reaction of MoS_2/rGO resulted in synergic effects that hindered the recombination process and enhancement of the surface areas [36]. A research by Kasim et al. proved that MoS_2/PPy nanocomposite as a binary photocatalyst produced better visible light absorption compared to polypyrrole and pure MoS_2 under the same condition. The introduction of small quantities of polypyrrole coated with MoS_2 boosted the photodegradation of 2-chlorophenol because molybdenum had a narrow bandgap and produced reaction species in an aqueous solution, as confirmed in Figure 6. Moreover, polypyrrole could absorb visible light, whereby photogenerated electrons were efficiently transferred from the excited state into the conductive band of MoS_2 particles [37].

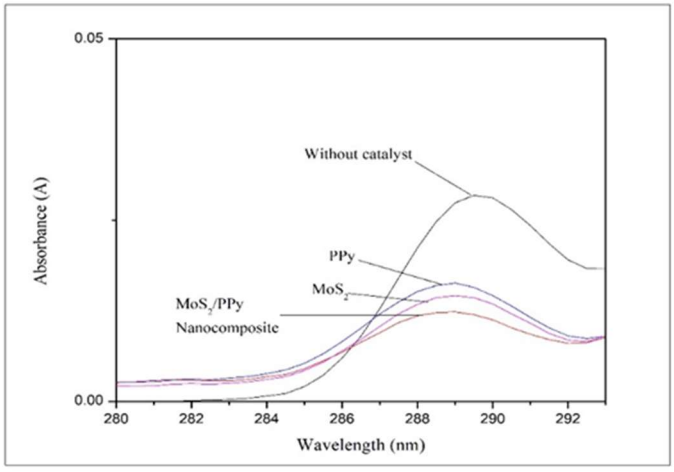

Figure 6. Different absorbance for different catalysts (condition: 0.01 g nanocomposite, 5mL of 50 mg/L of 2-chlorophenol at pH 5 and exposed to the sunlight for 3 hours) [37]

Ren et al. synthesized a novel 3D heterojunction composed of flowerlike nanosheets of MoS_2 stacked with $CoFe_2O_4$ nanorods. Particularly, as a binary photocatalyst, MoS_2/$CoFe_2O_4$ exhibited higher photocatalytic reactions under visible light irradiation to degrade organic dyes. The lower efficiency of pure $CoFe_2O_4$ nanorods for photodegradation signified that F-MoS_2 could be classified as the dominant active component for removing Congo red (CR) particles. The photodegradation efficiency of MoS_2/$CoFe_2O_4$

heterojunctions increased gradually as the MoS_2 content rose [38].

MoS_2 based composites and semiconductor as ternary photocatalyst

A previous study reported that ternary photocatalyst would assist to improve separation and photocatalytic stability of charge carriers. This was extensively used in the development of photocatalysts to optimise the performance. Ternary photocatalyst is the integration of three photocatalysts in a composite. Zhang et al. stated that hybrid photocatalysts had attracted intense attention by combining a set of conjugated polymers with an inorganic semiconductor [39]. Conjugated polymers could improve light production and promote separation of photogenerated carriers, leading to improvement for photocatalytic composites. Furthermore, loading noble metals to the composites as the ternary photocatalyst provided another useful inhibiting solution recombination of electron-hole pairs. A novel ternary photocatalyst, g-C_3N_4/Ag/MoS_2 was synthesised by attaching Ag nanoparticles on MoS_2 microsphere and g-C_3N_4, which provided high photocatalytic efficiency for respective single and binary photocatalysts, such as MoS_2, g-C_3N_4 and Ag/MoS_2. The pure g-C_3N_4 (Figure 7) showed two major peaks at about 27.3° and 13.1°, respectively, indexed as (002) and (100) reflections. Besides, g-C_3N_4/MoS_2, Ag/MoS_2 and g-C_3N_4/Ag/MoS_2 showed identical XRD structures, suggesting that the formation of g-C_3N_4 or Ag nanoparticles did not change their crystalline structure. The primary cause for this was the low concentration of Ag nanoparticles in the composite and overlap of the g-C_3N_4 (100) with the main (113) MoS_2 diffraction peak [40]. Recently, Zhang et al. proved that the ternary composite of MoS_2/Au/TiO_2 with optimal composition had degraded over 89.73% of methylene blue solution within 100 min under visible light [41]. The composite band alignment had strictly limited the formation of electron-hole pairs under visible light irradiation. Therefore, the integration of MoS_2 with Au and TiO_2 would increase the degradation of methylene blue percentage and significantly improve its catalytic activity by creating efficient use of their unique properties (Figure 8). The ternary composites exhibited a faster degradation rate attributed to the presence of synergistic effect of the materials. The results from a study by Pant et al. stated that the ternary composite of MoS_2/CdS/TiO_2 increased visible light activity in the composite compared to pure TiO_2 nanofibres [42]. This data illustrated the importance of carbon nanofibre absorption capacity together with the interaction of MoS_2 and CdS. The lower bandgap of CdS compared to TiO_2 was beneficial to absorb visible light at a wavelength of <510 nm. The photogenerated electrons in the CdS activated TiO_2 photocatalyst to transfer from CdS to TiO_2, leaving the photogenerated holes in CdS behind. However, this charge carrier separation restrained the rapid charge formation, resulting in the increment of the photocatalytic activity of TiO_2. Therefore, by loading the MoS_2 into the composite, it enhanced the separation of electron-hole pairs and promoted the separation and transfer of photogenerated electrons. Photocatalysts are the foundation of the photocatalytic method. A photocatalyst is a compound that is triggered by adsorbing a photon and can activate a reaction without being utilised [47]. Nevertheless, some research has proven that there are some limitations in semiconductor photocatalysts, whereby the electrons and holes are readily recombined, leading to a drop in quantum elimination of the processes. Next, small photocatalyst surface area leading to a low organic pollutant degradation level and weak visible light absorption limits its application. Multiple approaches have been developed to maximise the concentration of charge carriers and to inhibit recombination of the electron-hole photocatalysts in semiconductors [48].

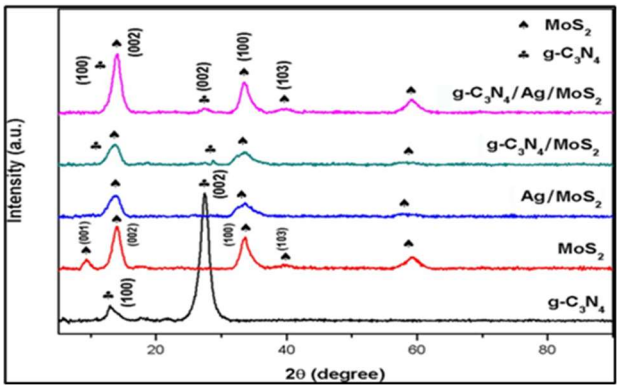

Figure 7. XRD patterns of the g-C_3N_4, MoS_2, Ag/MoS_2, g-C_3N_4/ MoS_2, and g-C_3N_4/Ag/MoS_2 samples

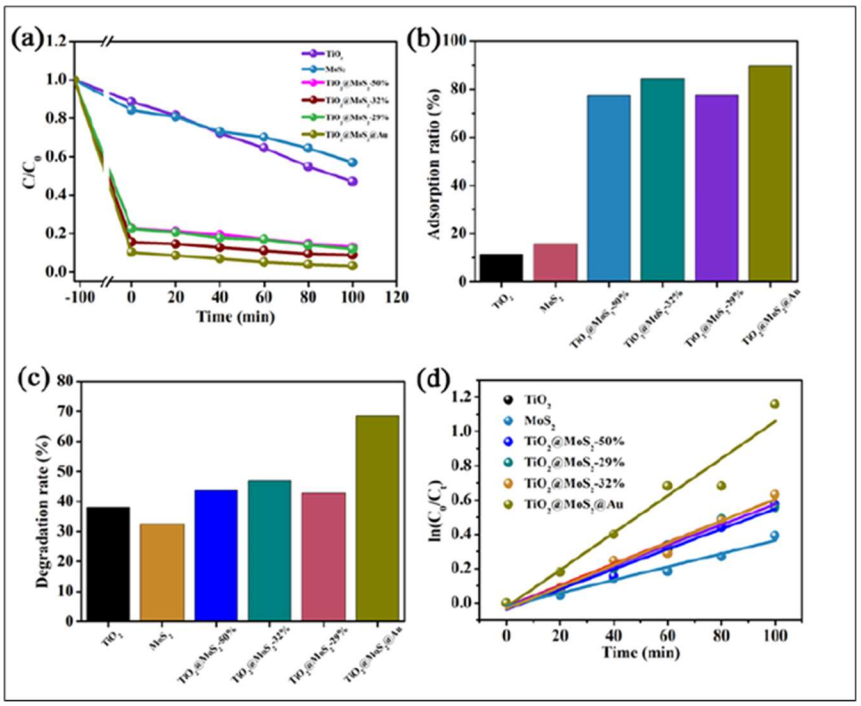

Figure 8. (a) Adsorption performance (b) methylene blue adsorption rate after stirring (dark condition), (c, d) photocatalytic degradation of methylene blue under visible light irradiation [41]

The obtained results from a study by Pant et al. stated that the ternary composite of MoS_2/CdS/TiO_2 increased the visible light activity in the composite compared to pure TiO_2 nanofibers [42]. This data illustrated the important carbon nanofiber absorption capacity together with the interaction of MoS_2 and CdS. The lower bandgap of CdS compared to TiO_2 is beneficial to absorb visible light at a wavelength of <510 nm. The photogenerated electrons in the CdS activated TiO_2 photocatalyst to transfer from CdS to TiO_2, leaving the photogenerated holes in CdS behind. However, this charge carrier separation restrains the rapid charge formation, resulting in the increment of the photocatalytic activity of TiO_2. Thus, by loading the MoS_2 into the composite, it enhanced the separation of the electron-hole pairs and promoted the separation and transfer of photogenerated electrons.

Table 2 Summarize MoS_2 composites or semiconductor as photocatalyst

Type of Catalyst	Example	Organic Pollutant	Light Source	% Degradation	Ref
Single Photocatalyst	MoS_2	Thiobencarb (TBC)	Visible light	95	[43]
Binary Photocatalyst	MoS_2/ZnO	Methylene blue (MB)	UV–vis light	85	[30]
	MoS_2-PPY	2-Chlorophenol	Visible light	79.59	[37]
	MoS_2/RGO	MB	UV–Vis	98	[44]
Tertiary Photocatalyst	n-BiVO4@p-MoS_2 with core-shell structure	Chromium	Visible light	85	[31]
	BiOBr/MoS_2/graphene oxide	Tetracycline antibiotics	Visible light	98	[45]
	MoS_2/ graphitic-C_3N_4@TiO_2	MB	visible light	97.5	[46]

Photocatalysts are the foundation of the photocatalytic method. A photocatalyst is known as a compound that is triggered by adsorbing a photon and can activate a reaction without being utilized [47]. Nevertheless, some research has proved that there are some limitations in semiconductor photocatalysts in which the electrons and holes are readily recombine leading to a drop in quantum elimination of the processes. Next, small photocatalyst surface area leading to a low organic pollutant degradation level and weak visible light absorption limits its application. Multiple approaches have been developed to maximize the concentration of charge carriers and to inhibit the recombination of the electron-hole photocatalysts in semiconductors [48].

Conclusion

Based on the literature data, it can be concluded that different MoS_2 composites with different morphology and photocatalyst combination undergo different mechanisms of preparation based on their suitability and condition. Besides, the photocatalytic performance of a single semiconductor is limited due to the recombination of charge carriers. Therefore, heterojunction is an effective method to improve charging carriers separation. The ternary semiconductor composites could be expected to provide a great opportunity for multiphoton excitation of photoactive materials with lower energy photons.

Abstract

This study describes the role of magnetite nanoparticle (MNP) or Fe_3O_4, which are magnetic nanomaterials (MNMs), as adsorbents for the removal of a synthetic azo dye called sunset yellow FCF (SY) from aqueous samples. Improper release of the SY dye into water can have significant adverse effects on the environmental, including disruption of photosynthesis, obstructs sunlight penetration, and risks to aquatic life and human health. Therefore, it is crucial to develop effective methods for removing the SY dye from water sources. This research aims to investigate the potential of Fe_3O_4 magnetic nanoparticles in removing the SY dye from water samples. By analyzing the effects of Fe_3O_4 nanoparticles, this study aims to provide insights into their efficiency and effectiveness as a potential solution for the removal of the SY dye, contributing to the development of sustainable water treatment strategies. The adsorbents was prepared using co-precipitation method, and their characteristics were analyzed using various instruments. Furthermore, the study investigated the adsorption conditions, including the optimization of pH, adsorbent dosage, and contact time using the Taguchi optimization method. The optimization for the effect of temperature and initial concentration of dye was conducted separately. The results of this study showed that the interaction between the homogenous surface of the adsorbents and the adsorbates or analytes molecules involved chemisorption and monolayer adsorption. The adsorption was found to be feasible, spontaneous, increased randomness, and endothermic. Additionally, the prepared adsorbents were validated by applying to remove the SY dye from three actual wastewater samples. The removal percentage ranged approximately from 30% to 85% with a low relative standard deviation (RSD% < 9.2%). This demonstrated that the adsorbents remained reliable for removing the dye from real samples were spiked with a high concentration of analytes. Overall, this study presents a promising approach for removing the SY dye from wastewater samples. It shows that even the bare form of MNMs base can be extensively developed for analyte removal from real aqueous samples.

Keywords: magnetic nanoparticles, sunset yellow dye FCF, Taguchi optimization, adsorption, wastewater

Abstrak

Artikel ini menerangkan peranan zarah nano magnetit (MNP) atau Fe_3O_4, yang merupakan bahan nano magnetik (MNMs), sebagai bahan jerap untuk menyingkirkan pewarna azo sintetik yang dipanggil kuning matahari terbenam FCF (SY) daripada sampel berakua. Pembebasan pewarna SY yang tidak betul ke dalam air boleh memberi kesan buruk yang ketara kepada alam sekitar, termasuk gangguan fotosintesis, menghalang penembusan cahaya matahari, dan risiko kepada hidupan akuatik serta kesihatan manusia. Oleh itu, adalah penting untuk membangunkan kaedah yang berkesan untuk mengeluarkan pewarna SY daripada sumber air. Penyelidikan ini bertujuan untuk menyiasat potensi nanopartikel magnet Fe_3O_4 dalam menyingkirkan pewarna SY daripada sampel air. Dengan menganalisis kesan nanopartikel Fe_3O_4, kajian ini bertujuan untuk memberikan pandangan tentang kecekapan dan keberkesanannya sebagai penyelesaian yang berpotensi untuk penyingkiran pewarna SY, menyumbang kepada pembangunan strategi rawatan air yang mampan. Bahan jerap telah disediakan menggunakan kaedah pemendakan bersama, dan ciri-cirinya dianalisis dengan menggunakan pelbagai instrumen. Tambahan pula, kajian ini menyiasat keadaan penjerapan, termasuk pengoptimuman pH, dos penjerap, dan masa sentuhan menggunakan kaedah pengoptimuman Taguchi. Pengoptimuman untuk kesan suhu dan kepekatan awal pewarna dijalankan secara berasingan. Hasil kajian ini menunjukkan bahawa interaksi antara permukaan homogen bahan jerap dan bahan dijerap atau molekul analit melibatkan penjerapan kimia dan monolapisan. Penjerapan didapati tersaur, spontan, peningkatan kerawakan, dan endoterma. Tambahan pula, bahan jerap yang disediakan telah disahkan potensinya dengan menggunakannya untuk menyingkirkan pewarna SY daripada tiga sampel air buangan sebenar. Peratusan penyingkiran berjulat kira-kira dari 30% hingga 85% dengan sisihan piawai relatif rendah (RSD% < 9.2%). Ini menunjukkan bahawa bahan jerap kekal boleh dipercayai untuk menyingkirkan pewarna daripada sampel sebenar yang telah dicemari dengan kepekatan analit yang tinggi. Secara keseluruhan, kajian ini membentangkan pendekatan yang menjanjikan dalam mengeluarkan pewarna SY daripada sampel air buangan. Ia menunjukkan bahawa walaupun bentuk yang asas MNMs dapat dibangunkan secara meluas untuk penyingkiran analit daripada sampel berakua sebenar.

Kata kunci: zarah nano magnetit, pewarna kuning matahari terbenam FCF, pengoptimuman Taguchi, penjerapan, air kumbahan

Introduction

In this modern world, rapid industrialization has led to a gradual increase in environmental pollution [1]. Among the various types of pollution, water pollution is particularly concerning. Water is not only essential for human body, it is also crucial for human daily activities such as agriculture, industrial production, and drinking water [2, 3, 4]. Unfortunately, the scarcity of clean water caused by pollution erodes all these benefits. Water pollution occurs mainly due to the discharge of emerging contaminants (EC) from various industries, such as heavy metals, pesticides, polyaromatic hydrocarbons, and dyes, as highlighted Belachew et al. [5]. This problem needs to be addressed urgently to ensure that the water sources can be preserved and the maintained for healthy environment. Through the implementation of stringent regulations and effective strategies, water pollution can be prevented and its quality can be restored.

Dyes, as one type of EC, are colorants that can be transferred from a liquid onto numerous substrates and are usually used in industries such as printing, textile, plastics, rubbers, and foodstuffs [6, 7]. They are also popular as food colorants in the food industry to enhance taste and to improve the appearance of food. Food colorants are broadly classified into two categories which are natural colorants and synthetic colorants. Due to their excellent stability, effectiveness, and low-cost production, synthetic colorants are extensively used in the industry [8]. Natural dyes are produced from various sources, such as animal, plant, and mineral deposits. The commonly used natural dyes include brown (caramel), yellow (turmeric), and red (beet juice). On the other hand, the synthetic dyes, which are produced through chemical processes, offer a wider variety of colors. Some of these dyes include Sunset Yellow, Allura Red, Brilliant Blue, and Tartrazine[9].

One specific synthetic azo dye, Sunset Yellow FCF (SY), known as CI Food Yellow 3, INS No.110 and Orange Yellow S, has the chemical name disodium 2-hydroxy-1-(4-sulphonatophenylazo)naphtha-lene-6-sulphonate [8]. SY in the form of powder present as orange-red colour and is soluble in water. It used in pharmaceuticals, cosmetics, and food products [10]. In the food industry, SY is commonly used to produce apricot jam, lemon curd, sweets, beverage mixes, custard powders, and instant noodles [11]. Apparently,

this type of synthetic dye is beneficial in many fields, especially in the food industry.

However, despite its usefulness in various fields, it still has limitations, especially when released abundantly into water without pre-treatment. This can affect the water ecosystem and human beings, as they are interconnected through the food chain and food web. Nwuzor et al. mentioned that some dyes are lost in streams during the industrial colouring process, and these dyes are toxic and can disrupt the water's nature state by hindering sunlight penetration, disrupting photosynthesis, and causing aesthetic issues. Furthermore, they can cause allergies and affect neurobehavioral and reproductive parameters, leading to symptoms such as diarrhea and allergies [11]. Therefore, the presence of dyes like SY as water effluents without proper treatment could have a negative impact on aquatic organisms and human health.

Therefore, remedies should be outlined to curb this issue. According to a previous study by Villar Blanco et al., three forms of techniques can be implemented including physicochemical, physical, and biological. Several actions such as oxidation, ion exchange, flocculation, filtration, ozonation, membrane separation, precipitation, and adsorption have been employed to treat the issue. However, most of these processes encountered some limiting factors, such as high operating costs, difficulties in timing and implementation, and the generation of toxic by-products and sludges [14, 15]. As a result, many of them cannot be efficiently utilized. However, Jeeva et al. stated that adsorption is the most efficient method to treat effluents due to its simplicity, cost-effectiveness, and directness. It is extensively applied to remove pollutants from wastewater as it exhibits high removal efficiency [16].

Adsorption is a process that involves the accumulation of molecules on the surface or at the interface between two phases [17]. It is also known as a separation process in which molecules tend to accumulate on the surface of the adsorbent due to the presence of attractive forces, such as the Van der Waals force. This accumulation creates an adsorbate film on the adsorbent's surface [18]. Thus, it is evident that the adsorbate and adsorbent are essential elements in an adsorption process, highlighting the importance of choosing a suitable adsorbent to ensure the effective adsorption of the targeted analyte (adsorbate) [19].

Recently, magnetic nanoparticles, such as iron oxide (Fe_3O_4), have been recognized as effective adsorbents for pollutants' removal in recent years. Previous studies have validated the use of Fe_3O_4 in developing a simple, inexpensive, and efficient adsorption method [20]. Fe_3O_4, also known as magnetite or magnetic nanoparticles (MNPs), is derived from nanomaterials (NMs). NMs are generally small-sized materials ranging from 1 to 100 nm [21]. These characteristics contributed to their larger surface area and unique properties, making them ideal sorbents.

Furthermore, the use of MNPs derived from NMs is favored due to their susceptibility to external magnetic fields. This property eliminates the need for cumbersome processes like centrifugation and filtration, as the sorbents can be easily and quickly separated from the liquid reaction system using a magnet [22]. As a result, the adsorption or removal of analytes (such as dyes) from water samples becomes more straightforward and accessible. Importantly, the aforementioned benefits highlight that Fe_3O_4 can be implemented to enhance the adsorption process of various analytes, including dyes.

Based on the preceding discussion, the main objective of this study was to investigate the performance of Fe_3O_4 in removing a synthetic azo dye, sunset yellow FCF (SY), from water samples. The study involved optimizing several parameters that influenced the removal performance of SY, such as pH, contact period, temperature, adsorbent dosage, and initial concentration of SY. The application of the Taguchi method in designing the optimization study was also examined. Furthermore, the study explored the kinetics reaction and isotherm adsorption of Fe_3O_4 in removing SY from an aqueous solution to understand the adsorption mechanism. Additionally, a thermodynamics study was conducted to assess the viability and spontaneity of the process. Finally, the optimized values were applied to

real water to validate the performance of the proposed method for practical sample analysis.

Materials and Methods

Chemicals and reagents

Ferrous chloride tetrahydrate ($FeCl_2.4H_2O$) and ferric chloride hexahydrate ($FeCl_3.6H_2O$) from R&M Chemicals (Edmonton, Canada) were used to synthesize the MNPs, Fe_3O_4. Methanol was supplied by HmbG Chemicals (Cologne, Germany), and a 25% ammonia solution (NH_3) utilized was from Merck, Darmstadt, Germany. The Sunset Yellow FCF powder was purchased from R&M Marketing (Essex, U.K.). All reagents and chemicals were used without further purification.

Instrumentation

The experiments were conducted using deionized water obtained from the Sartorius Stedim deionized water dispenser, Milli–Q® system (Arium 611 DI). A pH meter (BP3001 Trans Instruments) was utilized for measuring and adjusting the pH value. A UV-vis spectrophotometer (Perkin Elmer Lambda25) was employed to determine residual concentrations of the Sunset Yellow FCF at λ_{max} = 480.9 nm. An incubator shaker (IKA, KS4000 control) was used to shake the sample solution at 300 rpm with adjustable temperature and time, while mechanical shaker (Orbitron) was used to shake the solution at a similar speed and at room temperature with adjustable time.

Synthesis of Fe_3O_4

In this study, Fe_3O_4 was prepared using a conventional co-precipitation method with slight modification [23]. Firstly, $FeCl_2.4H_2O$ and $FeCl_3.6H_2O$ were mixed and dissolved in 50 mL of deionized water. Then, the mixture was stirred under nitrogen gas at 50°C for 30 min. Subsequently, ammonia solution (25%) was added into the mixture solution to allow the magnetization process, and the mixture was agitated for an hour at 90°C under nitrogen gas before the final products were collected by an external magnet, followed by washing step using 50 mL methanol and 50 mL deionized water alternately for several times. Afterward, the products were dried in an oven overnight. Finally, the dried products were crushed and ground using a pestle and mortar, before stored for further use.

Characterization of the synthesized Fe_3O_4

For the characterization process, several instruments were employed to examine the physical characteristics of the synthesized Fe_3O_4. A vibrating sample magnetometer (VSM, model Lake Shore/7404, McCourkle Boulevard, WO, USA) was used to investigate the magnetic properties of the adsorbent. Fourier transform-infrared spectroscopy (FT-IR) with the KBr technique from model Thermo Nicolet model in Waltham, USA, and thermogravimetric analysis (TGA, model Perkin Elmer) was utilized to identify the functional groups and the thermal stability of Fe_3O_4, respectively. The morphology of the synthesized Fe_3O_4 was examined using a transmission electron microscope (TEM, Phillips CM12 Version 3.2 model, Hillsboro, USA) and a scanning electron microscope (SEM, QUANTA FEG650 model, Hillsboro, Oregon, USA). X-ray diffractometer (XRD) from Siemens D5000 model (Frimley, UK) was applied for the phase identification of adsorbent crystallinity and unit cell dimension. Additionally, Brunauer-Emmet-Teller (BET) analysis was conducted using Quantachrome model (Boynton Beach, FL, USA) to measure the surface area of the adsorbent and determine the physical adsorption of gas particles on a solid surface. Prior to BET analysis, the prepared adsorbent was degassed at 80°C for 2 h to remove moisture.

Adsorption experiments

All the adsorption experiments were conducted using a 20 mL glass vial containing a specific amount of Fe_3O_4 adsorbent mixed with 10 mL of a sample solution containing a predetermined concentration of SY dye as the analyte. The vials were then placed on an incubator or a mechanical shaker at designated temperature for a specific duration at a consistent speed of 300 rpm. The adsorption experiments were carried out by varying different parameters, including pH (2.0, 3.0, 4.0, and 5.0), contact period (10, 20, 30, and 40 min), adsorbent dosage (5, 10, 15, and 20 mg), temperature (298, 313, and 333 K) and initial concentration of SY dye (5, 10, 20, 40, and 60 ppm).

During the experiment, the pH of the solution was

adjusted by adding hydrochloric acid, HCl (0.1 M), or sodium hydroxide, NaOH (0.1 M). After adsorption, Fe_3O_4 adsorbents were separated using an external magnet, and the remaining solutions were analyzed using a UV-vis spectrophotometer at λ_{max}= 480.9 nm. All the experiments were conducted in triplicate. Finally, the percentage removal (R%) of each run was calculated by using equation (1):

$$R\ (\%) = \frac{Co-Ce}{Co} \times 100\% \quad (1)$$

where C_o refers to the initial concentration of the dye and C_e refers to the equilibrium concentration of the SY FCF dye (ppm).

Optimization for adsorption experiments

In this study, two methods were employed to conduct the optimization. The optimization for the effects of pH, contact period, and adsorbent dosage was performed using the Taguchi Orthogonal Array design. Several values were selected for each factor (pH, contact period, and adsorbent dosage), and the experiments were conducted based on the pre-designed data. Additionally, the values for the initial concentration of SY and temperature were predetermined and kept constant for the Taguchi experiment.

Subsequently, separate procedures were conducted at various initial concentrations of SY and different temperatures to optimize the effect of initial concentration and temperature. During these runs, the pH value, adsorbent dosage, and contact period were maintained constant at pH 3, 10 mg, and 10 min, respectively. These values were then optimized based on the outcomes of the Taguchi experiment.

Taguchi method for optimization

The Taguchi method is an effective strategy for designing an experiment to obtain the optimum process results, which was proposed by Dr. Genichi Taguchi [24]. It is a method that combines multiple factors at various levels while ensuring equal consideration of all levels of each factor, thereby reducing the number of experimental runs. To conduct the Taguchi method, several procedures were adopted during the process. According to Nandhini et al. (2014), the three main procedures adopted in designing parameters using the Taguchi method are as follows: (1) experimental planning, which involves the selection of factors (*P),* their values (levels, *L*) and the appropriate Taguchi orthogonal array design, (2) implementation of the experimental design based on the designed table, and (3) analysis of results using Analysis of Variance (ANOVA), main effect plot of signal-to-noise (S/N) ratio, and means to determine the optimum value for the control factors [25].

In this study, the three main procedures were adopted. The Taguchi method was conducted at varying ranges of controllable factors, namely pH (2.0, 3.0, 4.0, and 5.0), contact period (10, 20, 30, and 40 min), and adsorbent dosage (5, 10, 15, and 20 mg). Simultaneously, the initial concentration and temperature were fixed at 10 ppm (10 mL) and room temperature, respectively. Since there were three factors (*P)* with four testing conditions values (*L*) for each factor, the Taguchi experiment was conducted by implementing Taguchi design: L_{16} (*P*= 3, *L*= 4). Table 1 below shows the selected parameters for this study. Meanwhile, Table 2 shows the experimental plan based on L_{16} (*P*= 3, *L*= 4) design, and Table 3 depicts the experimental runs with the actual values of testing conditions for each run. Signal to noise ratio and the implementation of ANOVA were also observed to determine the optimum conditions and assess the contribution of each factor sequentially.

Optimization for the effect of temperature and initial concentration

This study was conducted using various initial concentrations of SY (5, 10, 20, 40, and 60 ppm) in 10 mL of sample solution at different temperatures of 298, 313, and 333 K, separately. Meanwhile, other factors such as pH value, contact period, and adsorbent dosage were fixed at their optimized values obtained from the Taguchi experiment: pH 3, 10 min, and 10 mg, respectively.

Adsorption isotherm, kinetic, and thermodynamic study

To further investigate the reaction mechanism and adsorbent behaviour toward the analyte, detailed evaluation of kinetic, isotherm, and adsorption thermodynamics were conducted. The behaviour of Fe_3O_4 toward SY dye was studied using several well-known models. The thermodynamic study was then investigated using entropy (ΔS°), enthalpy (ΔH°), and free Gibbs energy (ΔG°).

Adsorption kinetics study

The use of kinetic model in a study can evaluate the sorption mechanism and potential rate-determining steps [23, 26]. In this study, two models were utilized to investigate the kinetic behavior of Fe_3O_4 toward SY dye: the pseudo-first order and pseudo-second order. The pseudo-first order model is a kinetic model that was proposed Lagergren in 1898, and it is the most commonly employed kinetic model for liquid-solid adsorption systems [15, 27]. To pursue this study on SY adsorption onto Fe_3O_4 adsorbent, the pseudo-first order model was described based on pseudo-first order linear equation, equation (2):

$$\log (q_e - q_t) = \log q_e - \frac{k1}{2.303} t \quad (2)$$

The pseudo-second order model is another well-known kinetic model. This model has been implemented in several sorption systems to successfully examine chemisorption interactions, which includes the exchange of electrons and valance sharing between the adsorbent and analyte [23, 28]. For this study, the determination of kinetic behavior using the pseudo-second order model was expressed by the following linear equation, equation (3):

$$\frac{t}{q_t} = \frac{1}{k_2 q_e^2} + \frac{t}{q_e} \quad (3)$$

where q_e and q_t (mg/g) represent the amount of SY FCF dye adsorbed at equilibrium and at time t (min), respectively. k_1 (min^{-1}) is the rate constant for the first order adsorption, and k_2 (g/mg.min) is rate constant for the second order adsorption.

Furthermore, the suitability of the model to determine adsorption kinetics was also assessed by calculating the normalized standard deviation Δq (%) and relative error (%) based on equations (4) and (5), respectively:

$$\Delta q\ (\%) = \sqrt{\frac{((q_{exp} - q_{cal})/ q_{exp})^2}{N-1}} \times 100 \quad (4)$$

$$\text{Relative error } (\%) = \left(\frac{q_{exp} - q_{cal}}{q_{exp}}\right) \quad (5)$$

where N represents the number of data points, while q_{exp} and q_{cal} represent the experimental and calculated adsorption capacities, respectively.

Adsorption isotherms study

Adsorption isotherm models are crucial for predicting and comparing the performance of an adsorption process [29]. In this study, five isotherm models were implemented to investigate the adsorption of SY dye onto Fe_3O_4. The models used were Langmuir, Freundlich, Dubinin-Radusckich, Halsey, and Temkin isotherm models.

$$\frac{C_e}{q_e} = \frac{1}{q_m}.C_e + \frac{1}{b.q_m} \quad (6)$$

$$\log q_e = \frac{1}{n} \log C_e + \log K_F \quad (7)$$

C_e ($mg.L^{-1}$) represents the initial concentration of the adsorbate according to the Langmuir model and the concentration at equilibrium according to the Freundlich model. q_e ($mg.g^{-1}$) represents the amount of adsorbate adsorbed at equilibrium. The Langmuir model is characterized by the parameters q_m ($mg.g^{-1}$) and b ($L.mg^{-1}$), which represent the maximum adsorption capacity and the rate of adsorption, respectively. The Freundlich model is characterized by the parameters K_F ($mg.g^{-1}$) and n, which represent the adsorption capacity and intensity, respectively.

The Dubinin-Radusckich model is generally used to express the adsorption mechanism with Gaussian energy

$$\ln q_e = \ln q_m - \beta E^2 \quad (8)$$

$$E = RT \ln \left[1 + \frac{1}{C_e}\right] \quad (9)$$

$$\ln q_e = \left[\frac{1}{n} \ln K_H\right] - \frac{1}{n} \ln C_e \quad (10)$$

$$q_e = \beta \ln K_T + \beta \ln C_e \quad (11)$$

The adsorption energy constant, denoted by β, can be calculated using the Dubinin-Radusckich equation. Additionally, β is equal to RT/b_τ at a given temperature (T in Kelvin), which corresponds to the Temkin equation. The universal gas constant, represented by R, is measured in units of $kJ.mol^{-1}$. The Halsey isotherm constants, denoted as K_H and n, are obtained from the slope and intercept of the ln q_e against ln C_e, respectively. The Temkin constant, KT, is related to the equilibrium binding energy, and b_τ is associated with the heat of adsorption.

The Langmuir model is an empirical model that assumes a homogenous surface of the adsorbent and involves monolayer adsorption, with the adsorbed layer having a thickness of one molecule [23, 29], while the Freundlich isotherm model is an empirical model which generally used to illustrate heterogeneous adsorbents data. In this study, the Langmuir and Freundlich model parameters were described through their linear equations (6) and (7), respectively.

onto heterogeneous surfaces [30], while the Halsey model is suitable for multilayer adsorption and illustrates the heterosporous nature of a material [31]. Additionally, the Temkin is an empirical isotherm model that considers the interactions between adsorbent and adsorbate while neglecting the concentration values, which are extremely high or low [30].

This study determined the parameters of the Dubinin-Radusckich, Halsey, and Temkin isotherm models using linear equations. Equations (8) and (9) corresponded to the Dubinin-Radusckich isotherm model, while equations (10) and (11) are for the Halsey and Temkin isotherm models, respectively.

Adsorption thermodynamic

Thermodynamics must be considered in adsorption

experiments to demonstrate the viability and spontaneity of the process [23]. Thermodynamic parameters can be determined in an adsorption process as they are temperature-dependent [32]. In this research, the effects of temperature on the thermodynamic parameters such as ΔH°, ΔS°, and ΔG° were investigated at three different temperatures (298, 313, and 333 K). Subsequently, the Van Hoff plot was obtained by plotting ln k_d against 1/T based on equation (12). The slope of the curve was used to calculate ΔH°, while ΔS° was determined the y-intercept.

$$\ln k_d = -\frac{\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R} \quad (12)$$

The equilibrium constant, which represents the ratio of the forward and reverse reaction rates at equilibrium, is denoted by k_d.

Pre-treatment of real samples

Wastewater samples were randomly collected from various industrial areas around the Kepala Batas area (5.5172° N, 100.4315° E). All samples were filtered using a nylon filter and stored in appropriate containers before use.

Method validation and real sample analysis

To validate the proposed method, linearity, and repeatability (intra-day and inter-day) were evaluated under optimized conditions. The linearity of SY in water samples was assessed by constructing a calibration curve ranging from 2 to 80 ppm. The coefficient of determination (R^2) value was obtained from a linear plot of absorbance (A) versus analyte concentration (ppm).

Accuracy (removal) and precision (relative standard deviation, RSD%) were assessed by analyzing effluent wastewater samples with a spiked standard solution at three different concentration levels (5, 20, and 60 ppm). Equation (1) was used to calculate accuracy, while equations (13) and (14) were employed to calculate the precision.

$$SD = \sqrt{\frac{\sum(\bar{x}-x)^2}{n-1}} \quad (13)$$

$$RSD = \frac{SD}{\bar{x}} \times 100 \quad (14)$$

In a set of measurements with a sample size of n, where $\bar{x}$ represents the mean and x represents the result of each individual run, the standard deviation (SD) is a measure of the spread or variability of the data.

To assess the reliability of the proposed method, three real samples were spiked with three different analyte concentrations and analyzed using a UV-vis spectrophotometer. The analysis aimed to investigate the matrix effect on the removal of SY by Fe_3O_4.

Results and Discussion

Characterization of the adsorbent

FTIR analysis was conducted to identify the vibration of functional groups present on the surface of the prepared Fe_3O_4. The FTIR spectrum of Fe_3O_4 is shown in Figure 1, and the data are presented in Table 4. Based on the figure, two prominent peaks were in the spectrum of Fe_3O_4. A strong and broad peak was identified at 3417.6 cm^{-1}, corresponding to O-H stretching due to the presence of the O-H bond in the structure. Additionally, a strong peak related to Fe-O stretching was observed at a wavenumber of approximately 587.0 cm^{-1} in the FTIR spectrum. This peak indicates the successfully synthesized of Fe_3O_4.

Then, the thermal stability of the adsorbents was assessed using TGA analysis, and the results are shown in Figure 2. Based on the TGA curve, significant weight loss was observed in the temperature range of 31-120℃, gradually increasing from 120-390℃, due to the evaporation and loss of water content from Fe_3O_4

structure. This observation is consistent with the findings reported by Mokadem et al. [33]. Furthermore, the results indicated that no significant weight loss occurred at higher temperature (>390°C). Similar trends were reported by Cao et al., where no significant changes were observed in the TGA results near 400°C [34]. Therefore, it can be concluded that Fe_3O_4 exhibits excellent stability, as only 7% of the weight was decomposed at elevated temperatures[35].

Moreover, VSM was used to investigate the magnetic behavior of the synthesized Fe_3O_4. The hysteresis loop of the adsorbents is shown in Figure 3. The Fe_3O_4 particles exhibited a maximum saturation (Ms) of 135.26 emu/g, indicating a high magnetic strength that falls within the acceptable range for the adsorption process. Additionally, the adsorbents exhibited a superparamagnetic characteristic [20] as evidenced by the S-shaped curved in the hysteresis loop.

Table 4. FTIR frequencies of adsorbents

Characteristics	**Fe_3O_4**
Assignments	**Wavenumbers (cm^{-1})**
Fe-O stretch	587.0
O-H stretch	3417.6

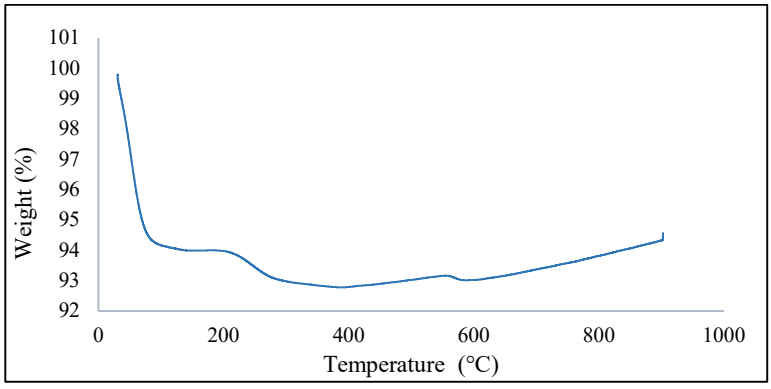

Figure 2. TGA curve of Fe_3O_4

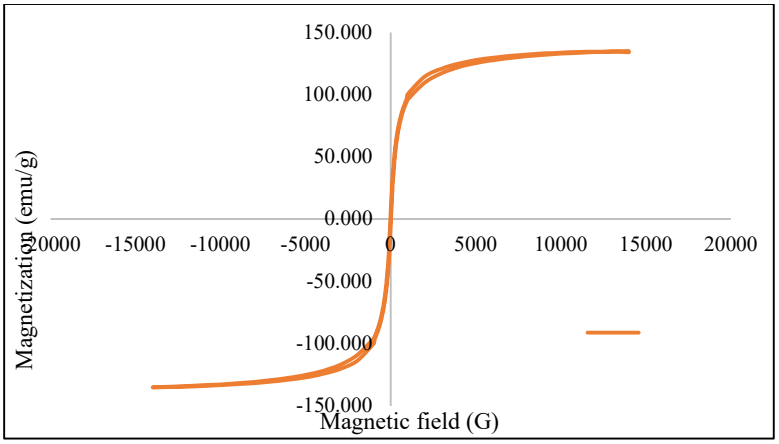

Figure 3. VSM analysis of Fe_3O_4

Microscopic morphological analysis of the prepared adsorbents was conducted using TEM and SEM techniques to examine their surface features. TEM images, shown in Figure 4 (a-i), revealed that the particles had an average diameter of approximately 10.42 nm. The Fe_3O_4 particles were observed to be spherical and uniform in size [36] when captured at various scales ranging from 50 to 500 nm. The images also displayed the aggregation of these small spherical particles into larger aggregates. On the other hand, the SEM image of Fe_3O_4, depicted in Figure 5, exbibited a beaded, rough, and agglomerated surface structure.

Crystallinity identification was performed using XRD, and the results are plotted in Figure 6. The diffraction peaks of the Fe_3O_4 exhibited good crystallinity [37]. The solid samples showed diffraction peaks at the 2θ values of 30.50, 35.73, 43.51, 54.30, 57.30, and 63.04, corresponding to the (220), (311), (400), (422), (511) and (440) cubic spinel planes of Fe_3O_4 particles, respectively. These values correspond to the joint committee on powder diffraction standard card number (88-0866 and 19-0629) [36, 37].

The BET surface area of Fe_3O_4 was found to be 44.6795 m^2/g. The nitrogen adsorption-desorption isotherm, depicted in Figure 7, indicated that the samples followed a type IV isotherm and exhibited a H3 hysteresis loop. This finding confirmed the mesoporosity of the adsorbents, with pores in the range of 1.5-100 nm [36, 38]. Furthermore, the pore diameters for Fe_3O_4, calculated to be approximately 14.44 nm using the Barret–Joyner–Halenda model (BJH), further supported the existence of the adsorbents as mesoporous materials. Mesoporous materials have pore sizes between microporous (< 2 nm) and macroporous (> 50 nm) materials. They offer numerous advantages, such as high surface area, stability, and pore volume. Therefore, Fe_3O_4, being in the mesoporous region, exhibited its mesoporosity characteristics, which are beneficial for adsorbate adsorption.

Optimization for adsorption experiment: Taguchi optimization, the main effect plot for the S/N ratio, and implementation of ANOVA

As mentioned earlier, the Taguchi method was used to optimize three controllable factors: pH, contact period, and adsorbent dosages, with four levels for each factor (testing conditions). Table 5 shows the L_{16} orthogonal array design used in this study and the results obtained after each run. The significance order of the controllable factors was determined and is presented in Table 6. The significance order was determined by analyzing the rank of S/N ratio and considering the delta values, which represent the relative magnitude of effects by comparing the highest and lowest average characteristics for each controllable factor [26, 39].

The results show that the average removal percentage of SY dye (Table 5) ranged from 62.1% to 91.9%, depending on the combination of controllable factors. Additionally, it was observed (Table 6) that the contact period had the most significant variation in the S/N ratio, followed by the adsorbent dosage, and pH. In other words, the contact period had the most significant influence on the adsorption process, while the pH value had the least significant contribution. The optimal conditions for each factor in the adsorption process are also indicated in Table 6.

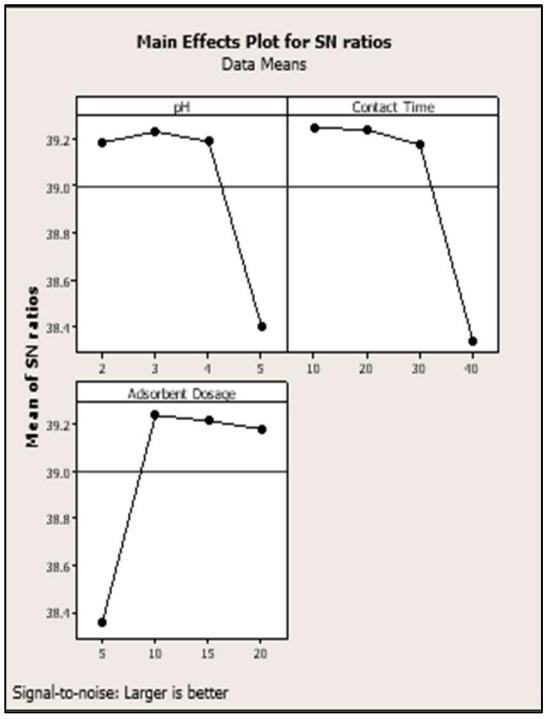

Figure 8. The response curves for the individual effects of SY dye adsorption parameters on S/N ratio

Moreover, the comparative response curves for the independent effects (main effect plot) of the adsorption parameters on the SY removal efficiency can be referred to in Figure 8. Based on the figure, it can be observed that the removal of SY dye increased as the pH increased from 2 to 3. However, the removal trend decreased when the pH value was further increased to 5. The decrease in dye removal can be attributed to the negative charge on adsorbent surface at higher pH [40], which reduces the electrostatic interaction between the dye and the adsorbent surface.

This decrease in removal efficiency is a result of the presence of SY dye as anionic ions ($D\text{-}SO_3^-$) in an aqueous solution, where the sulfonate groups ($D\text{-}SO_3Na$) of the dye dissociate upon dissolution [41]. Under basic conditions at higher pH value, the adsorbent surface becomes deprotonated and acquires a negative charge. As a result, electrostatic repulsion occurs between the analyte and the adsorbent, leading to a lower removal percentage [20].

A similar study conducted by Rajabi et al. (2015) revealed that the optimal pH for removing SY is 3 because the surface of APTES-modified MNPs has a positive charge in acidic media, which facilitates easier adsorption compared to alkaline pH [42]. This occurs because the surface of modified MNPs tends to attract negatively charged anionic dye molecules. Another study by Bagheri et al. found that the optimal pH for removing SY is 4. The accumulation of SY onto the surface of Fe3O4-MNPs loaded on activated carbon (Fe3O4-MNPs-AC) at a mild pH level can be enhanced by the combination of hydrogen and electrostatic attraction. However, at higher pH levels, the negative and repulsive forces between the anionic dye and the negatively charged adsorbent can hinder the further accumulation of SY on the adsorbent [43]. The trend observed in both studies is similar to the trend observed in our study, where removal of SY is favored at lower pH levels.

Furthermore, a higher pH value resulting from the presence of OH^- ions from NaOH would also lead to competition with the anionic dye for the active sites of the adsorbent. As a result, the electrostatic interaction between the dye and the adsorbent is reduced due to this competition. In contrast, a lower pH value generates H^+

ions on the external sites of the adsorbent. This increased the electrostatic interaction between the dye and the nano adsorbents [40], such as Fe_3O_4, because the negatively charged dye is attracted to the protonated (positively charged) surface of the adsorbent. Consequently, this enhances their interaction and facilitates the removal process.

However, a slight decrease in dye adsorption was observed below pH 3, which may be attributed to the dissolution of the metal oxide structure. Metal oxides are typically stable over a wide range of pH value, but in extremely acidic solutions, some metal oxides dissolution may occur [2]. This explains the trend line observed in Figure 8, indicating that pH 3 was determined to be the optimal pH condition.

Furthermore, the adsorbent dosage plot exhibited a similar trend line to the pH plot. A significant increase in removal capability was observed when the adsorbent dosage increased from 5 to 10 mg. However, the removal percentage decreased consistently as the adsorbent dosage increased to 20 mg. The initial increase in removal percentage was attributed to the accessibility of active sites, but it eventually became saturated, leading to reduced removal. At higher dosage, the overlapping particles blocked the binding sites, contributing to the decrease in removal ability [40]. Therefore, the trend line observed in Figure 8 indicated that the optimum dosage should be 10 mg. This trend is consistent with studies conducted by Chukwuemeka-Okorie et al. and Sartape et al. for the removal of sunset yellow and malachite green, respectively [45, 44].

The contact time trend was also crucial in determining the removal of SY by Fe_3O_4. Based on Figure 8, it can be observed that the removal of SY dye decreased as the contact time increased from 10 to 40 min. This result indicates that the shorter shaking times resulted in more efficient removal due to saturation of the binding sites on Fe_3O_4, rendering them unavailable for further adsorption of SY and ultimately reducing the removal rate of the dye. A similar trend was reported in a study by Aziz et el., where the percentage recovery of the analyte decreased with increasing contact time [46].

Moreover, the aqueous suspensions of Fe_3O_4 are generally unstable and can quickly aggregate, limiting their effectiveness [22, 47]. Therefore, the decrease in removal rate with increasing contact time can also attributed to the instability of Fe_3O_4 in the aqueous solution and the subsequently agglomeration of the adsorbent. This hinders the effective of SY dye. Consequently, the trendline would decrease, and in this study, and a contact time 10 min was considered the optimal value, which is adequate for the adsorption process.

Next, ANOVA analysis was conducted to evaluate the contribution of each factor to the efficiency of SY dye removal and to gain a better understanding of the obtained findings and their acceptability within the controllable factors [26, 48]. The ANOVA results are tabulated in Table 7. Based on the results, it can be concluded that the experiments were performed under controlled conditions, as the error value is below 50% contribution [26]. Additionally, the contribution percentage in Table 7 indicate that the contact period had the most significant effect, with the highest contribution percentage, while pH had the least significant effect on SY dye removal by Fe_3O_4.

Effect of temperature and initial concentration of SY dye

Moving on the effect of temperature and initial concentration on SY removal by Fe_3O_4, Figure 9 illustrates the binding. In can be observed that the removal percentage increased from 5 ppm to 20 ppm and then decreased as the initial concentration increased to 60 ppm, for all temperatures (298, 313, and 333 K). The initial increase in SY can be attributed to the availability of adsorption sites on the adsorbent and fewer collision between SY molecules, allowing for greater adsorption of analytes at low concentration [49, 50]. However, at higher initial concentrations, the surface area and available adsorption sites available on Fe_3O_4 became limited compared to the number of dye molecules present [20]. A similar finding was obtained by Aziz et al. for the adsorption of copper (II) onto palm oil boiler mill fly ash (POFA) at different initial concentration [46]. In this study, an initial concentration of 20 ppm was chosen as the optimum concentration for SY dye.

Table 5. Removal of SY dye for each run and S/N ratios

Run	pH	Contact Time (min)	Adsorbent Dosage (mg)	Removal (%)			Average Removal (%)	S/N Ratio
				R1	R2	R3		
1	2	10	5	91.8768	91.8349	91.8554	91.8557	39.2621

Error	6	4.133	0.6888			39.10
Total	15	10.572				100.00

Regarding the effect of temperature, it was observed that all three temperatures showed nearly identical removal ability. The removal percentage at 298 K, 313 K, and 333 K, as shown in Figure 9, were consistent for each SY concentration. However, at the highest concentration of 60 ppm, the removal percentage at 333 K was slightly higher than the other two temperatures. This result is consistent with thermodynamics considerations, indicating that the adsorption process is endothermic. Therefore, a temperature 298 K, corresponding to room temperature, was selected as the optimum temperature.

	5ppm	10ppm	20ppm	40ppm	60ppm
298 K	83.3019	91.7604	93.9681	74.4128	53.0517
313 K	83.8214	91.4532	94.0400	74.4196	55.0891

Adsorption kinetic study

The kinetic study was conducted, and the obtained data was used to plot the y against x curves based on the linear equations of the pseudo-first order (Equation 2) and pseudo-second order (Equation 3). It was observed that the data for the pseudo-second order exhibited the highest R^2 value, approaching one (R^2= 0.9812). Based on this result, it can be concluded that the adsorption behavior of SY dye onto Fe_3O_4 followed the pseudo-second order kinetic model. The pseudo-second order curve, along with the linear equation and the R^2 value, can be seen in Figure 10. Additionally, the kinetic parameters associated with this kinetic model are presented in Table 8.

Furthermore, the validity of the result was confirmed by the close agreement between the calculated q_e (7.905 mg/g) and the experimental q_e (9.732 mg/g). The low values of standard deviation and relative error (%) also indicate a better fit of this model to the data. Moreover, the data fitting well with the pseudo-second order suggests that the rate-limiting step involve chemisorption [26], which occurs between the dye and the adsorbent.

Table 8. Pseudo-second order model parameters

Kinetic model	Parameters	Value
	q_e exp (mg/ g)	**9.732**
Pseudo-second order	q_e cal (mg/g)	7.905
	K_2 (g/mg min)	0.041
	h (mg/g min)	2.587
	$t^{0.5}$(min)	0.005
	R^2	0.9812
	Δq(%)	10.839
	Relative error (%)	18.773

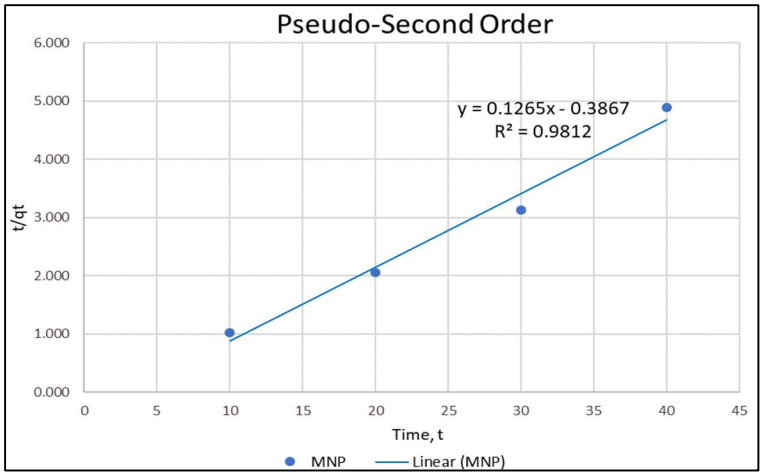

Figure 10. Adsorption kinetic of Sunset Yellow FCF based on pseudo-second order model

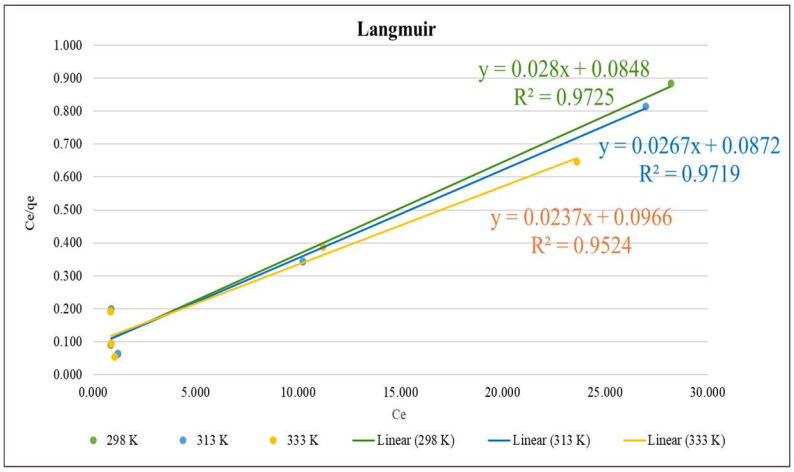

Figure 11. Adsorption isotherm of Sunset Yellow FCF based on Langmuir model

Adsorption isotherm study

Furthermore, the isotherm experiment was conducted using several models, and the data obtained was used to plot linear curves based on Equations (6), (7), (8), (10), and (11) for Langmuir, Freundlich, Dubinin-Radusckich, Halsey and Temkin models, respectively. Based on the obtained curved, the Langmuir model exhibited the highest R^2 value, approaching 1. Therefore, it could be concluded that the Langmuir model best fits the data from this study. The curve of this model, along with the calculated parameters, is shown in Figure 11 and Table 9, respectively.

Based on the observed results indicating adherence to the Langmuir model, it suggests that monolayer adsorption occurred, forming a single molecule thickness of adsorbates. Additionally, it validates the homogeneity of the Fe_3O_4 adsorbent used in this study. Furthermore, the calculated R_L values in Table 9, obtained using equation (15), indicate that the isotherm adsorption was favorable as all the calculated values between 0 and 1. Thus, it confirmed that Fe_3O_4 is suitable for the adsorption of SY dye under the conditions employed in this study.

$$R_L = \frac{1}{1 + bC_0} \quad (15)$$

Where b = Langmuir constant, and C_0 = initial concentration of sunset yellow (ppm)

Table 9. Langmuir isotherm model parameters

Isotherm Model	Parameters	Temperature		
		298 K	313 K	333 K

	R_L	0.0481	0.0517	0.0636

Adsorption thermodynamic

Table 10 presents the thermodynamic parameters for the removal of SY dye by Fe_3O_4. Based on the results, the calculated ΔG° (J/mol) values in this study were negative. This indicates the spontaneous nature and thermodynamic feasibility [19, 40] of the process at all temperatures. Additionally, the positive value of enthalpy, ΔH° (J/mol), suggest that the adsorption process is endothermic. In contrast, the positive entropy value, ΔS° (J/Kmol), indicates an increase in randomness at the solid/liquid interface during the adsorption process [40, 51]. Furthermore, it suggests a favorable affinity between the adsorbent and the dye [39].

Table 10. Thermodynamic parameters of SY adsorption onto Fe_3O_4

Temperature (K)	ΔG° (J/mol)	ΔH° (J/mol)	ΔS° (J/Kmol)
298	-302.759		
313	-531.646	9.988	42.628
333	-1210.139		

Method validation and real sample

To validate the proposed method, the calibration curve of A versus analyte concentration (ranging from 2 to 80 ppm) yielded an R^2 value of 0.9933. The removal percentage and RSD% for inter-day (n=5) and intra-day (n=7) are presented in Table 11. The removal (%) for inter- and intra-day ranged from 34.02% to 82.87% and 33.67% to 82.92%, respectively, while the RSD% for inter-day and intra-day ranged from 2.45% to 6.91% and 2.49% to 6.70%, respectively.

Furthermore, when three real wastewater samples from different locations were spiked with analyte initial concentrations of 5, 20, and 60 ppm, and analyzed using UV–Vis spectrophotometer, the sample removal (%) ranged from 30.10% to 84.43%, with RSD% ranging from 1.18% to 9.12%, as shown in Table 12. The results indicated that these real wastewater samples had a slightly complicated matrix, as the removal performance was somewhat affected and reduced compared to deionized water, especially at high initial concentrations of the analyte. However, the majority of removal performances achieved high removal percentage, indicating that the Fe_3O_4 adsorbent was still capable of removing the SY dye from real water samples despite the matrix effect. This suggests that the adsorbent is practical for the removal of sunset yellow dye from wastewater samples. The method can be further developed in the future to improve analyte removal performance.

Table 11. Linearity, repeatability, and precision of the SY dye removal method

Calibration Equation	R^2	Spiked Concentration (ppm)	Inter-day (n=5)		Intra-day (n=7)

Conclusion

In this study, magnetite or magnetic nanoparticles (MNPs) with the chemical formula Fe_3O_4, a basic form of magnetic nanomaterials (MNMs), were successfully synthesized using co-precipitation method. These MNPs were employed as an adsorbent for the removal of sunset yellow FCF dye from aqueous samples. Various instruments such as VSM, TGA, FTIR, SEM, TEM, XRD, and BET were utilized to investigate the physical characteristics of the prepared adsorbents, including their properties, structures, surface areas, and functional groups.

To determine the optimized conditions for the removal of SY dye by Fe_3O_4, an adsorption study was conducted. The Taguchi method was employed for the optimization experiments, and the optimal testing conditions were found to be pH 3, 10 mg adsorbent dose, and 10 min contact time. Additionally, when the optimization for the effect of temperature and initial concentration of the dye was carried out separately, the optimum initial concentration of the dye was observed to be 20 ppm. Furthermore, room temperature was chosen as the optimum temperature, as consistent results were obtained across the all-tested temperatures. The application of these optimized conditions in further adsorption studies revealed that the kinetics behavior of the adsorbents towards SY dye followed the pseudo-second order model, while the isotherm study showed good fit with the Langmuir model. This indicates a chemical interaction or chemisorption between the adsorbents and adsorbate molecules, forming a monolayer adsorption. Moreover, the adsorption study demonstrated feasibility, endothermic nature, and spontaneous occurrence with increasing randomness.

Subsequently, the real wastewater samples from three different areas were used for method validation and real sample analysis. These samples were spiked with three different concentrations of analytes. The removal percentage ranged from 30% to 85%, with a low range of RSD% (1.8% to 9.2%). This suggests that the proposed adsorbent could effectively remove SY dye from real wastewater samples, albeit with slight influence from the matrix effect. Therefore, this study provides valuable insights into the nature of Fe3O4 and confirms the validity and practicality of the proposed method for removing SY dye from real wastewater samples. Further comprehensive studies can be conducted to enhance the removal performance.

Acknowledgements

The authors would like to express their gratitude to the Ministry of Higher Education, Malaysia for providing funding for this project through the Fundamental Research Grant Scheme (FRGS) with reference code FRGS/1/2021/STG04/USM/02/8 and account code 203.CIPPT.6711974. The authors are also thankful to the Advanced Medical and Dental Institute, Universiti Sains Malaysia, for providing the necessary resources to complete this project.

Abstract

This study involved the development and validation of a high-performance liquid chromatography (HPLC) assay for the determination of delphinidin-3-O-glucoside chloride, specifically to be applied in future pharmacokinetic and bioavailability studies in rats supplemented with roselle extract. The HPLC method was validated following solid-phase extraction, with six validation parameters (linearity, recovery, precision, accuracy, limit of detection (LOD), and limit of quantification (LOQ) assessed according to Food and Drug Administration guidelines. Chromatographic separations were performed using Agilent Reverse Phase EC-C18 (4.6×150 mm; 2.7 µm particle size) and mobile phase acetonitrile with 0.1% trifluoracetic acid in an aqueous solution (81:19, v/v). The calibration curve of delphinidin-3-O-glucoside chloride had a coefficient determination (R^2) of ≥95.0% and recovery percentage of 80.37%. It also showed good precision and accuracy, and its method detection and quantification limits were 47 ng/mL and 213 ng/mL, respectively. In conclusion, the validated HPLC method in this study can be used to determine the pharmacokinetic of delphinidin-3-O-glucoside chloride or other type of anthocyanins in the future.

Keywords: delphinidin-3-o-glucoside chloride, rat plasma, high-performance liquid chromatography, method validation

Abstrak

Kajian ini melibatkan pembangunan dan pengesahan kaedah kromatografi cecair berprestasi tinggi (KCPT) bagi pengesanan sejenis antosianin, iaitu delfinidin-3-O-glukosida klorida, khususnya bertujuan untuk digunakan dalam kajian lanjutan untuk farmakokinetik dan bioavailibiliti antosianin di dalam tikus yang disuplementasi dengan ekstrak rosel. Kaedah KCPT ini disahkan menggunakan kaedah pengekstrakan fasa pepejal dan enam parameter pengesahan dinilai mengikut garis panduan Pentadbiran Makanan dan Dadah iaitu kelinearan, pemulihan, ketepatan, kejituan, had pengesanan, dan had kuantifikasi. Pengasingan kromatografik dilakukan menggunakan Agilent Fasa Berbalik EC-C18 (4.6×150 mm; 2.7µm saiz partikel) manakala fasa gerak

adalah asetonitril bersama 0.1% trifluoroasetik asid di dalam air (81:19, v/v). Lengkung penentukuran delfinidin-3-0-glukosida klorida mempunyai penentuan pekali (R^2) ≥95.0% dan peratusan pemulihan delfinidin-3-0-glukosida klorida adalah 80.37%. Delfinidin-3-0-glukosida klorida juga menunjukkan ketepatan dan kejituan yang baik dan had pengesanan dan kuantifikasi kaedah untuk delfinidin-3-0-glukosida klorida masing-masing adalah 47 ng/mL dan 213 ng/mL. Kesimpulannya, kaedah HPLC yang disahkan dalam kajian ini boleh digunakan untuk menentukan tahap antosianin dalam kajian farmakokinetik pada masa depan.

Kata kunci: delfinidin-3-o-glukosida klorida, plasma tikus, kromatografi cecair berprestasi tinggi, pengesahan kaedah

Introduction

In recent years, anthocyanins have come into the interest of researchers from various fields due to their health-promoting properties. One major health benefit associated with anthocyanin intake is a reduced risk of coronary heart disease [1]. Anthocyanins are naturally occurring, water-soluble pigments found in the vacuoles of vascular plants that serve multiple functions, such as aiding in pollinating plants by luring insects and animals with their color and potent UV absorbance [2]. Anthocyanins give out red, purple, and blue pigments, resulting from the conjugated bonds in flowers, tubers, and fruits. They are classified under the flavonoid class and phenolic photochemical subclass [3]. While water-soluble, their stability varies according to pH, temperature, light, and structure [4]. As a result, anthocyanins appear red in acidic environments and blue in alkaline environments. Accordingly, they are commonly found in plants and the most prevalent anthocyanins in nature are cyanidin, delphinidin, and pelargonidin, which are present in 50% of flowers, 69% of fruits, and 80% of colored leaves [5]. However, in current study, we choose to focus on delphinidin since it is one of the most abundant types of anthocyanin found in roselle calyx extract, which is the interest of our research team.

To date, several analytical methods, especially liquid chromatography, are available for the detection of anthocyanins in biological fluid and tissue [6-10]. Liquid chromatography, including high-performance liquid chromatography (HPLC), allows the effective separation and identification of compounds in various biological samples, suitable for both qualitative and quantitative analysis. However, variability in experimental condition factors, such as extraction method, quantification, and parameter analysis, hinders the reproducibility of this method for obtaining the most efficient recovery of anthocyanins. Additionally, large sample volumes are required for the detection of anthocyanins, as shown in past studies [7, 11]. Although these protocols have been demonstrated to be efficient, none specifically focus on the anthocyanin delphinidin-3-O-glucoside chloride.

Despite these shortcomings, prior validation of HPLC provides documented evidence of a reliable analytical method for the sensitive quantification of compounds present in samples, thus providing valuable data. Therefore, the development and validation of a new HPLC protocol for the determination of anthocyanin, specifically delphinidin-3-O-glucoside chloride, is much needed as a potential reference protocol to be applied in future pharmacokinetic and bioavailability studies in rats supplemented with roselle extract. By employing six validation parameters according to FDA guidelines (linearity, recovery, precision, accuracy, limit of detection (LOD), and limit of quantification (LOQ), this study describes a rapid, sensitive, and specific HPLC protocol for the detection of delphinidin-3-O-glucoside chloride in small volumes of rat plasma.

Materials and Methods

Chemicals and reagent

Delphinidin-3-O-glucoside chloride (catalog no. CFN92038) and its internal standard, cyanidin-3-5-0-diglucoside chloride (catalog no. CFN92138) were purchased from ChemFaces (Wuhan China) (Figure 1). Acetonitrile (ACN), and methanol were of HPLC grade from Merck (Darmstadt, Germany) while sulfosalicyclic acid, trifluoroacetic acid (TFA) and formic acid (FA) were of analytical grade from Sigma-Aldrich (St Louis, USA). Water used was deionized and distilled using the Water Prodigy System (Labconco, MO, USA).

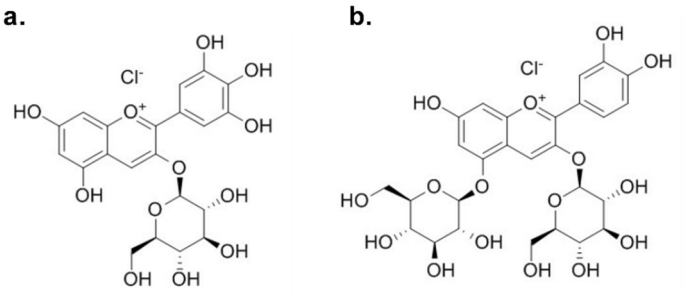

Figure 1 . Chemical structure for a. delphinidin-3-O-glucoside chloride with molecular formula of $C_{21}H_{21}ClO_{12}$, and b. cyanidin-3-5-O-diglucoside chloride with the molecular formula of $C_{27}H_{31}O_{16}C_l$

Chromatographic condition

The HPLC system consisted of a pump (Gilson 307), a column heater, an autosampler (Gilson GX-271) and detector (UV/VIS-155) from Gilson (Wisconsin, USA). Gilson Trilution® LC software was used for data acquisition. Chromatographic separations were performed on Agilent Reverse Phase EC-C18 (4.6 × 150 mm I.D, particle size 2.7 µm) (Agilent Technologies, California, USA) with flow rate of 0.5 mL/min, injection volume of 10 µL and detected at 525 nm. The mobile phase is composed of ACN with 0.1% of TFA in aqueous solution (81:19, v/v) and degassed in an ultrasonic bath (FB15063) from Fisher Scientific (USA). All solutions were filtered through a 0.45 µm membrane (Sartorious, Germany) prior to use.

Preparation of stock, standard working solutions and plasma samples

Standard stock solutions of delphinidin-3-O-glucoside chloride (100 µg/mL) and its internal standard (100 µg/mL) were prepared by dissolving 1 mg of each in 10 mL methanol, respectively. A working solution of the internal standard was prepared by diluting the stock solution of cyanidin-3-5-0-diglucoside chloride with mobile phase to give a final concentration of 500 ng/mL. Five selected delphinidin-3-0-glucoside chloride concentrations of 250, 500, 1000, and 2000, 3000 ng/mL in buffer were prepared by further dilution of the stock solution with appropriate volumes of mobile phase accordingly.

Blank plasma was obtained from untreated rats and 500 µL of plasma spiked with delphinidin-3-O-glucoside chloride to achieve five concentrations of 250, 500, 1000, and 2000, 3000 ng/mL for calibration curve. Quality control (QC) samples of low, medium, and high concentration (350, 1500, 2500 ng/mL) were prepared similarly to the standard calibration. All stock solutions were stored at 4 °C and all working solutions were freshly prepared daily.

Solid phase extraction

The plasma samples spiked with delphinidin-3-O-glucoside chloride and its internal standard were subjected to solid phase extraction to remove unwanted analytes or impurities using Water Sep-Pak tC18 cartridge (Massachusetts, USA). Protein precipitation of plasma sample was done by adding 500 µL of 0.1 % TFA aqueous solution and 100 µL of 20 % sulfosalicylic acid aqueous solution in 500 µL of plasma, vortex mixed and centrifuged at 4000 × *g* for 20 mins at 4˚C and supernatant was kept for further separation. Following that, the cartridge was first pre-conditioned with 2 mL of methanol followed by 2 mL of 0.1% TFA in aqueous solution. The supernatant plasma sample was then loaded into the cartridge and then eluted with 1 mL of methanol. Eluted sample was then centrifuged at 5000 rpm for 10 minutes using an Ultrafree®-MC centrifugal filter (Merck, Germany) and the supernatant was evaporated to dryness using nitrogen gas. Dried residue then was reconstituted with 100 µL of mobile phase and then injected into HPLC for analysis.

Method validation

Plasma calibration curves were prepared and analyzed in triplicate for intra-day and inter-day to assess the linearity, precision, accuracy, recovery, LOD, LOQ, selectivity, sensitivity, and stability according to the

CDER [12].

Results and Discussion

Chromatographic condition

Based on our team's previous optimization study [13], for this study, we chose a composition of ACN with 0.1% TFA in an aqueous solution (81:19, v/v) as a mobile phase. Although in prior research rapid resolution liquid chromatography analysis was conducted for the identification of another type of anthocyanin (cyanidin-3-O-glucoside), this protocol still produced a good peak of delphinidin-3-0-glucoside chloride content and effectively separated it from its internal standard (cyanidin-3-5-0-glucoside chloride).

Solid-phase extraction

Several parameters, such as percentage of recoveries, chromatographic peak shape obtained, and peak tailing, were some of the factors that needed to be considered when choosing a suitable extraction method. In this experiment, we thus chose solid-phase extraction rather than liquid-liquid extraction based on our team's previous optimization study [13]. Furthermore, as Sep-Pak tC18 cartridges are widely employed to purify anthocyanin due to their simplicity and efficiency [14-17], we incorporated Sep-Pak tC18 cartridges into our SPE extraction method.

Recovery

In this study, we obtained delphinidin-3-O-glucoside chloride recoveries using two different methods: area ratio and slope ratio. We quantified recovery by finding the ratio of the slopes of the calibration curve for the extracted (in plasma) to non-extracted (in buffer) samples. The recovery of delphinidin-3-O-glucoside chloride revealed the mean recovery percentage to be 80.377%, while the slope ratio was 71.43%. Generally, recovery need not be 100% when 80–90% recovery is considered optimal. Tables 1 and 2 summarize the percentage recoveries and their standard deviations (SD) at different extract concentrations.

The assay sample was calculated from the following equation 1:

$$\text{Recovery (\%)} = (\text{mean area ratio extracted} / \text{mean area ratio non-extracted}) \times 100 \quad (1)$$

Table 1. Recovery of delphinidin-3-O-glucoside chloride by area ratio

Concentration (ng/mL)	Mean Area Ratio (Non-Extracted)	SD	Mean Area Ratio (Extracted)	SD	Percentage Recovery (%)
3000	2.068	0.246	1.514	0.161	73.199
2000	1.387	0.275	1.035	0.258	74.662
1000	0.776	0.050	0.507	0.259	65.365
500	0.294	0.065	0.277	0.175	94.350
250	0.203	0.052	0.191	0.046	94.311
Mean					80.377 ±11.823

Table 2. Recovery of delphinidin-3-O-glucoside chloride by ratio of slopes

	Combined Standard Curve (Non-Extracted)	Combined Standard Curve (Extracted)
Intercept, a	-0.0097	0.0437
Slope, b	0.0007	0.0005
R^2	0.9648	0.9653
Recovery by the ratio of slope	0.0005/0.0007 = 71.43 %	

Calibration curve, precision, accuracy, and linearity

The concentration of a drug in an unknown sample can be determined using calibration curves to compare the unknown concentration to a set of standard samples with known concentrations [18]. The calibration curve of delphinidin-3-O-glucoside chloride was linear in the concentration range (250 ng/mL, 500 ng/mL, 1000 ng/mL, 2000 ng/mL, and 3000 ng/mL) in rat plasma. Five concentrations were selected to produce a calibration curve for delphinidin-3-O-glucoside on intraday (Figure 2) and inter-days (Figure 3). Five to eight points should make up the calibration curve to cover the expected analyte concentration range in the test samples [19-20].

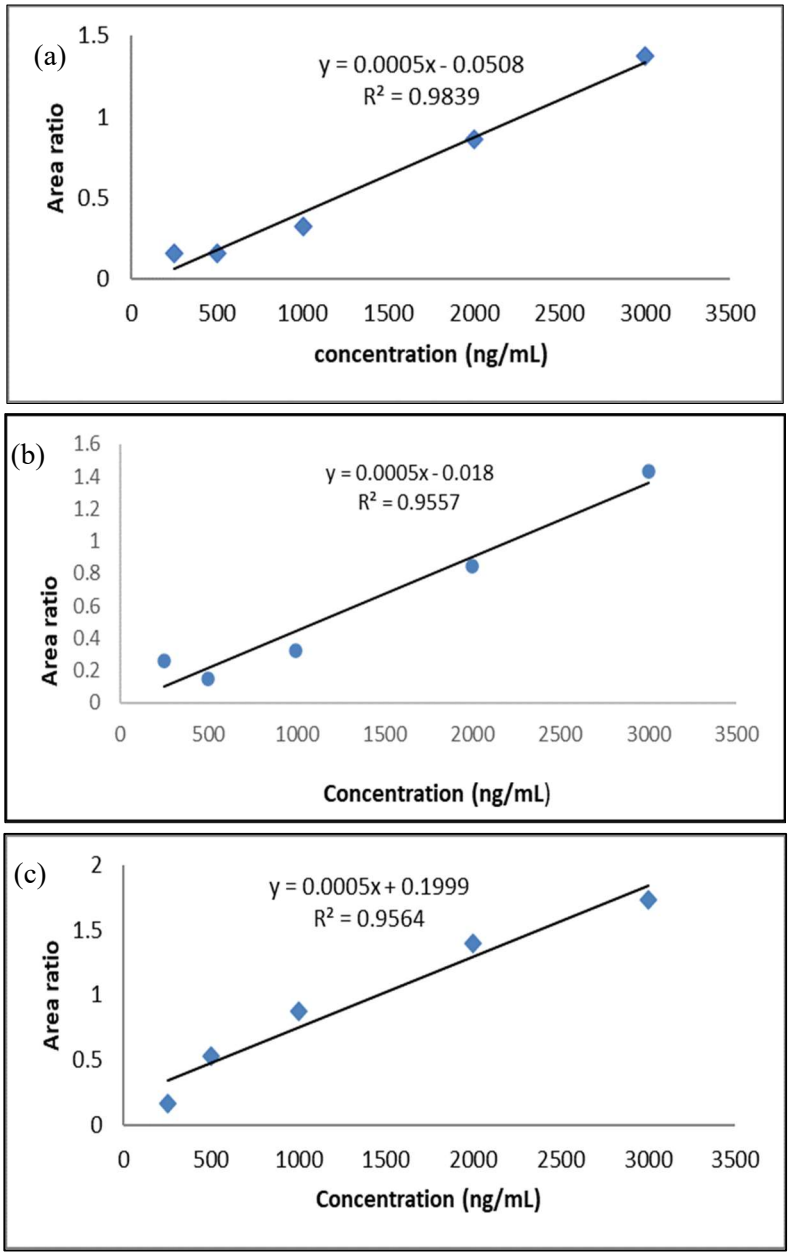

Figure 2. Intra-day validation: calibration curves of the area ratio of delphinidin-3-O-glucoside chloride to cyanidin-3-5-0-glucoside chloride versus delphinidin-3-O-glucoside chloride's concentrations a) validation 1, b) validation 2, and c) validation 3.

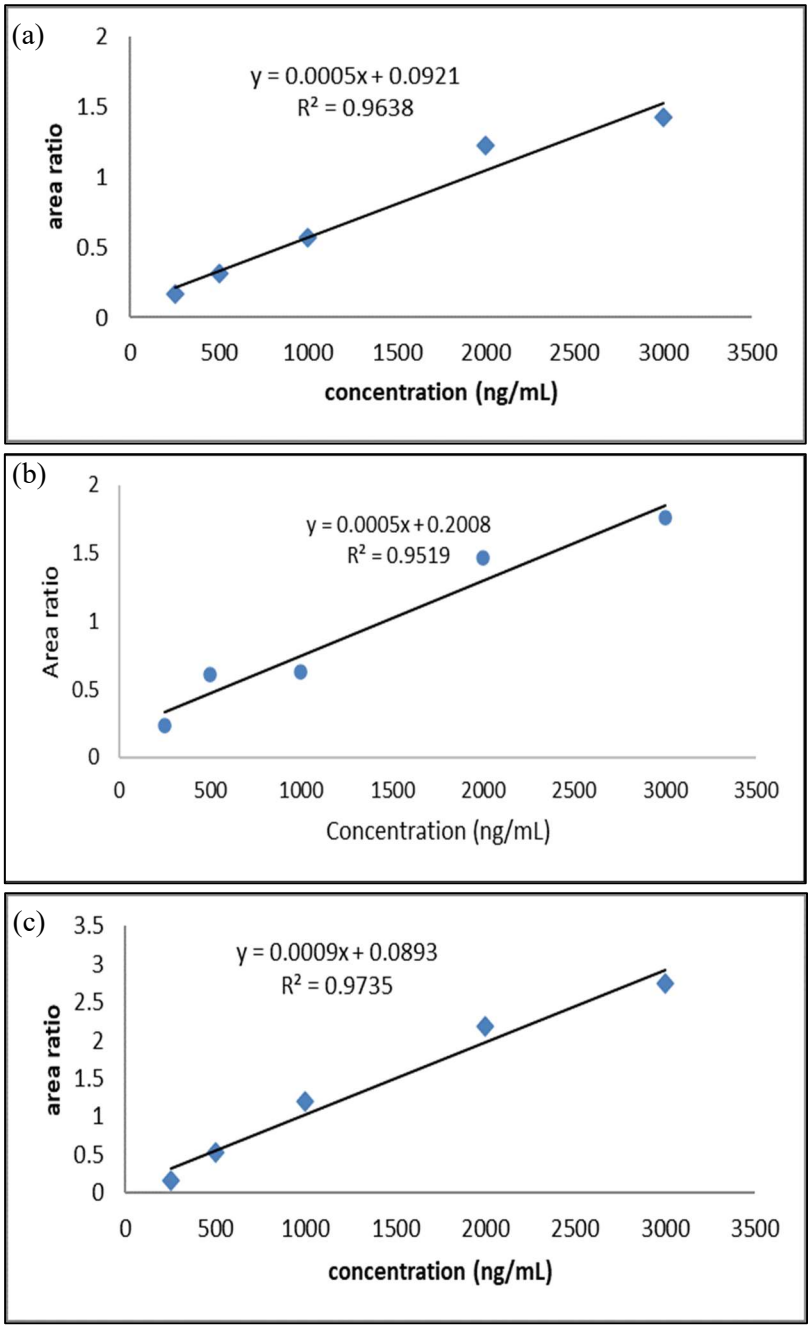

Figure 3. Inter-day validation: calibration curves of the area ratio of delphinidin-3-O-glucoside chloride to cyanidin-3-5-0-glucoside chloride versus delphinidin-3-O-glucoside chloride's concentrations a) validation day, 1 b) validation day 2, and c) validation day 3

The precision and accuracy of the assay were determined from the low (350 ng/mL), medium (1500 ng/mL), and high (2500 ng/mL) QC plasma samples. Intra- and inter-day were determined for each QC rat plasma sample, with each sample in triplicates for each day, and expressed as a percentage of the coefficient of variation (CV). The assay's mean analyte recovery rate served as the accuracy definition. The precision determined at each concentration should not exceed 15% CV, except for LOQ, which should not exceed 20%

CV, according to the CDER (2018). It also strongly advises against using accuracy and precision data independently, especially when it comes to drugs. The precision and accuracy results determined for the HPLC method's intra- and inter-day values are shown in Table 3.

Table 3. Precision and accuracy of delphinidin-3-O-glucoside chloride in intraday

Concentration (ng/mL)	Mean (ng/mL)	SD	Precision (CV)	Accuracy (%)	Percentage Difference
Delphinidin-3-O-glucoside chloride intraday (within batch) (*n*=3)					
2500	2495	0.03	2.72	99.8	- 0.2
1500	1305	0.05	8.12	87.0	- 13.0
350	389	0.005	3.36	87.1	12.86
Delphinidin-3-O-glucoside chloride intraday (between batch) (*n*=9)					
2500	2315	0.12	9.84	92.6	- 7.4
1500	1616	0.07	7.63	92.3	7.73
350	341	0.01	4.89	97.4	- 2.57

The lowest analyte concentration in a sample that may be quantitated is known as LOD, although it is not always possible to determine it under certain experimental conditions. In contrast, the LOQ in the calibration curve can be consistently measured with relative standard deviation (RSD; 20%) and precision (80-120%). In this study, LOD and LOQ were 47 ng/mL and 213 ng/mL, respectively. However, some research findings on delphinidin's LOD and LOQ are far different from these values. For instance, a recent study on the determination of delphinidin-3-O-glucoside in plasma using ultra-high performance liquid chromatography–tandem mass spectrometry (UHPLC-MS) found LOD to be 2.3 ng/mL and LOQ to be 8.1 ng/mL [21]. Another study proposing the determination of anthocyanin and non-anthocyanin in Jussara extracts via UPLC-MS showed that the LOD and LOQ of delphinidin-3-O-glucoside were 5.60 µg/L and 18.50 µg/L, respectively [22]. A third study found the LOD to be 0.14 mg/kg and LOQ to be 0.42 mg/kg for delphinidin-3-O-glucoside in grape extract [23].

Conclusion

In conclusion, this developed and validated HPLC method coupled with SPE for sample preparation is rapid and convenient for the quantification of delphinidin-3-O-glucoside chloride in rat plasma samples. The calibration curve of delphinidin-3-O-glucoside chloride was linear in the concentration range. Intra- and inter-day validation showed a good coefficient of determination above 0.95. The mean recovery was 80.377%, while the slope ratio was 71.43%. This study therefore showed good precision and accuracy data for delphinidin-3-O-glucoside chloride in rat plasma. Except for LOQ, which should not exceed 20% of the CV, CDER [15] states that the precision determined at each concentration should not be greater than 15% of the CV. The LOD and LOQ were 47 ng/mL and 213 ng/mL, respectively. To conclude, the validations in this study indicate that these findings, as determined via HPLC, are achievable, reproducible, and reliable for further studies of anthocyanin pharmacokinetics and bioavailability in rat plasma.

Abstract

Coomassie Brilliant Blue G 250 (CBB G 250) is mainly generated from industrial textile effluent. Due to its non-degradable nature, it is not only environmentally hazardous, but also affect human health, causing irritations of the eye, respiratory or gastrointestinal tract. Therefore, a strategy for treating this colorant is necessary. This research highlights the synthesis of Fe_3O_4 Magnetic nanoparticles (Fe_3O_4 MNPs) as a low-cost adsorbent for removal of CBB G 250 dye from aqueous solutions. Fe_3O_4 MNPs were synthesized using chemical coprecipitation method. Characterization results revealed that the peaks at 537, 3400 and 1604 cm^{-1} in the Fourier Transform Infrared Spectroscopy spectrum represented the Fe-O band, O-H stretching and bending on the Fe_3O4 MNPs surface, respectively. Crystal phase analysis indicated that Fe_3O_4 MNPs has a cubic spinel structure. Morphological analysis showed Fe_3O_4 MNPs are in nano-sized, spherical in shape, and have uniformly distributed particle size. The result from magnetic and surface area analyses demonstrated that Fe_3O_4 MNPs have 63.30 emu g^{-1} saturation magnetization and 123.5 m^2 g^{-1} surface area. Thermal stability analysis showed that adsorbed water and hydroxyl group (6.25%) were lost at temperature below 100 °C. At temperature between 260 °C and 540 °C, approximately 2.09% weight loss were recorded due to change from magnetite (Fe_3O_4) to maghemite (Ɣ- Fe_2O_3) in crystal phase. Elemental analysis revealed that the Fe_3O_4 MNPs showed 24.50 % of Fe and 75.50 % of O. Following the confirmation of Fe_3O_4 MNPs structure, the impact of various parameters such as adsorbent dosage (0.02-0.14 g), contact time (5-20 minutes), initial concentration (25-100 ppm) and pH (3-10) on the adsorption of CBB G 250 dyes were investigated. Experimental results showed that Fe_3O_4 MNPs achieved 95% removal of CBB G 250 at optimum conditions of 0.12 g dosage, 15 minutes contact time, 50 ppm initial dye concentration and at pH value of 8. Adsorption isotherms and kinetics revealed that the adsorption process using Fe_3O_4 MNPs in this study obeys both Langmuir and Freundlich isotherm and pseudo-second-order kinetic. The results obtained from this study confirmed that Fe_3O_4 MNPs can be used as an adsorbent material for the removal of dye from effluent.

Keywords: Fe_3O_4 magnetic nanoparticles, adsorbents, Coomassie Brilliant Blue G 250, dye removal

Abstrak

Coomassie Brilliant Blue G 250 (CBB G 250) ialah efluen tekstil perindustrian yang kebanyakannya dihasilkan daripada efluen tekstil. Disebabkan sifatnya yang tidak terdegradasi, ia berbahaya kepada alam sekitar dan kesihatan manusia dan membawa

kepada kerengsaan mata, saluran pernafasan atau gastrousus. Oleh itu, strategi untuk merawat pewarna ini adalah perlu. Oleh itu, penyelidikan ini mengetengahkan sintesis Magnetik nanopartikel Fe_3O_4 (Fe_3O_4 MNPs) sebagai penjerap kos rendah untuk penyingkiran pewarna CBB G 250 daripada larutan akueus. MNP Fe_3O_4 telah disintesis dengan menggunakan kaedah kopresipitasi kimia. Keputusan pencirian mendedahkan bahawa puncak pada 537, 3400 dan 1604 cm^{-1} dalam spektrum Spektroskopi Inframerah Transformasi Fourier masing-masing mewakili jalur Fe-O, regangan O-H dan lenturan pada permukaan Fe_3O_4 MNPs. Analisis fasa kristal menunjukkan bahawa Fe_3O_4 MNPs mempunyai struktur spinel padu. Analisis morfologi menunjukkan Fe_3O_4 MNPs dalam saiz nano, dalam bentuk sfera, dan mempunyai saiz zarah teragih seragam. Hasil daripada analisis magnet dan kawasan permukaan menunjukkan bahawa Fe_3O_4 MNPs mempunyai 63.30 emu g^{-1} kemagnetan tepu dan 123.5 m^2 g^{-1}, masing-masing. Analisis kestabilan terma menunjukkan bahawa air terjerap dan kumpulan hidroksil (6.25 %) hilang pada suhu di bawah 100 °C. Pada suhu 260 hingga 540 °C, penurunan berat lebih kurang 2.09 % direkodkan hasil daripada perubahan daripada magnetit (Fe_3O_4) kepada maghemit (ɣ- Fe_2O_3) seperti dalam fasa kristal. Analisis unsur mendedahkan bahawa Fe_3O_4 MNPs masing-masing menunjukkan 24.50% dan 75.50% Fe dan O. Selepas struktur Fe_3O_4 MNPs disahkan, pelbagai parameter seperti kesan dos penjerap (0.02-0.14 g), masa sentuhan (5-20 minit), awal kepekatan (25-100 ppm) dan pH (3-10) pada penjerapan pewarna CBB G 250 telah disiasat. Keputusan eksperimen menunjukkan bahawa Fe_3O_4 MNPs mencapai 95% pada keadaan optimum pada 0.12 g dos, 15 minit masa sentuhan, 50 ppm kepekatan awal dan nilai pH 8. Isoterma dan kinetik penjerapan mendedahkan bahawa proses penjerapan menggunakan Fe_3O_4 MNPs pada kajian ini mematuhi kedua-dua Langmuir dan Freundlich isoterm dan kinetik pseudo-second order, masing-masing. Keputusan yang diperolehi daripada kajian ini mengesahkan bahawa Fe_3O_4 MNPs boleh digunakan sebagai bahan penjerap untuk penyingkiran bahan pewarna daripada efluen.

Introduction

One of the biggest and most urgent problem in the modern world is environmental pollution. Textile industries are one of the major polluters not only due to high amounts of water used in manufacturing, but the industry also generate high liquid effluent pollutants. In the textile industry, the largest amount of coloured aqueous waste is disposed through dyeing processes, and not only does it has strong persistent color, but also high biological demand for oxygen (BDO) [1].The presence of these dyes in water causes cancer, toxicity, birth defect and teratogenicity, reducing light penetration into the water and consequently preventing photosynthesis of aquatic plants [2]. Coomassie Brilliant Blue G 250 (CBB G 250) is one of the triphenylmethane dyes used widely in the textile industry. These dyes are hazardous to both the environment and human health because of its non-degradable nature, and causes eye irritations as well as respiratory and gastrointestinal tract irritations. Therefore, it is important to treat these types of dyes [3].

Various techniques are currently being used in order to remove dye effluents that are released into open waters, and this includes coagulation [4], precipitation [5], oxidation-ozonation [6], adsorption [7], ion exchange [8], and biological methods. Adsorption method is considered one of the most promising method due to its flexibility, ease of operation, simple design and high efficiency [8]. It has therefore been used extensively in recent years to treat colours. Common adsorbents such as activated carbon, biochar and graphene oxide have been used previously for the removal of dyeing from wastewater. However, these sorbents have several drawbacks, one of which occur during the separation process, a common issue as these sorbents require centrifugation, a procedure which prolongs analysis time especially when dealing with large sample volume [9]. Thus, it cannot be used extensively for the removal of organic dyes from aqueous environment. Therefore, it is necessary to develop a reliable, easy and rapid adsorbent for efficient treatment of dyeing effluents.

One of the potential adsorbent is magnetic nanoparticle (MNPs). Among the various types of MNPs, iron oxides such as magnetite (Fe_3O_4), maghemite (γ-Fe_2O_3) and hematite (α-Fe_2O_3) are common and attractive options due to their biocompatibility, great saturation magnetization and magnetic susceptibility. The advantages of Magnetite (Fe_3O_4) include the best magnetization among the iron oxides, low price, low toxicity and a high specific surface area. Fe_3O_4 magnetic

nanoparticle (Fe_3O_4 MNPs) can also be an adsorbent for remediation of organic dye such as CBB G 250 due to its unique features [10]. Since the use of Fe_3O_4 MNPs is seldom documented for decontamination of CBB G 250 from water environment, it is a good idea to study efficiency of Fe_3O_4 MNPs as an adsorbent for treatment of organic dyes from aqueous environment.

The purpose of this study is to develop Fe_3O_4 magnetic nanoparticles (Fe_3O_4 MNPs) for adsorption of CBB G 250 from aqueous solution. The structure of Fe_3O_4 MNPs was characterized using Fourier Transform Infrared Spectroscopy (FTIR), X-ray Diffraction (XRD), Field Emission Scanning Electron Microscopy (FESEM), Energy Dispersive X-ray Spectroscopy (EDX), Thermogravimetric analysis (TGA), Vibrating Sample Magnetometer (VSM) and Brunauer-Emmett-Teller (BET). After the structures of Fe_3O_4 MNPs were confirmed, it was then used as an adsorbent for treatment of CBB G 250 from aqueous environment. During the application part, the screening of several parameters such as dosage of adsorbent, contact time, initial dye concentration, pH of the solution were performed in order to determine characteristcis that influence the efficiency of Fe_3O_4 MNPs to adsorb CBB G 250. Widely-used models were described and analyzed to evaluate the best theoretical adsorption capacity such as adsorption kinetic (pseudo-first, second order and intraparticle diffusion) as well as some isotherm models (Langmuir and Freundlich). The regeneration performance of the Fe_3O_4 MNPs was also examined in six consecutive cycles.

Materials and methods

Chemicals

Iron (III) chloride hexahydrate, iron (II) chloride tetrahydrate and aqueous ammonia were purchased from Fluka Analytical (Germany). The standard for Coomassie Brilliant Blue G 250 (CBB G 250) was obtained from Supelco (Belleffonte, USA). The stock solutions of CBB G 250 dye were prepared in distilled water at 100 ppm. All stock solutions were kept at 4 ºC.

Instrumentation

The functional groups of the synthesized nanoparticles were first characterized using a FTIR spectrometer (Spectrum 400 PerkinElmer) with a diamond ATR accessory, absorption mode with 4 scans at a resolution of ±4 cm^{-1}, and a wavenumber range of 4000 to 450 cm^{-1}. FESEM images and EDX analysis of the prepared Fe_3O_4 MNPs were performed using scanning electronic microscopy (SEM HITACHI SU8220, OXFORD Instruments) that was equipped with an energy dispersive X-ray spectrometry. The crystal phase of the prepared nanoparticles was determined using a PANanalytical EMPYREAN X-ray powder diffraction (XRD) diffractometer (CuK, radiation, $\lambda = 1.541874$ nm), at a scanning speed of 0.07 / min from 15 to 75 (2θ). The surface area and pore size were measured using Brunauer-Emment-Teller (BET) by nitrogen adsorption isotherm at 77.350 K in Micromeritics (ASAP2020, Georgia, and USA). The magnetic properties were analysed using vibrating sample magnetometer (VSM LakeShore 7400 series, Tokyo, Japan). A thermogravimetric analyzer (Perkin Elmer, TGA 4000, Waltham, MA, USA) was used to study the thermal behavior of the prepared adsorbents at temperatures ranging from 30 ºC to 900 ºC with a heating rate of 20 ºC min^{-1} under nitrogen flow. Adsorption studies of CBB G 250 dye were performed using UV spectrophotometer (Shimmadzu, Kyoto, Japan) at a wavelength of 590 nm.

Synthesis of Fe_3O_4 MNPs

The preparation of Fe_3O_4 MNPs were adapted from work published by Zarei et al. [11]. Briefly, 3.1736 g of $FeCl_2.4H_2O$ and 7.5709 g of $FeCl_3.6H_2O$ were dissolved in 320 mL deionized water. The solution was agitated for 1 hour at 80 ºC. 40 mL of aqueous ammonia was then added slowly into the reaction mixture and was further agitated for another 1 hour before allowed to cool to room temperature. The obtained Fe_3O_4 MNPs were magnetically collected and rinsed five times with hot water until the filtrate turned neutral. Figure 1 depicts the schematic synthesis of Fe_3O_4 MNPs.

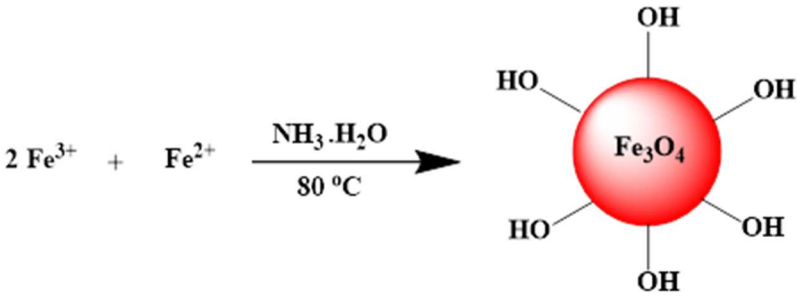

Figure 1. Schematic illustration of synthesis Fe_3O_4 MNPs

Batch adsorption studies

The batch adsorption of CBB G 250 dye from water using Fe_3O_4 MNPs is illustrated in Figure 2. İn this experiment, a quantity of Fe_3O_4 MNPs was added to 10 mL of 50 ppm CBB G 250 dye solution in 50 mL centrifuge tube at room temperature. 0.1 M NaOH and 0.1 M HCl were used to alter the pH of the solution. The solutions were shaken and stirred in an incubator shaker. An external magnet was used to isolate the Fe_3O_4 MNPs from the sample solution. In this experiment, several parameters were studied, such as: 1] adsorbent dosage (0.02–0.14 g), 2] contact time (5-20 min), 3] initial concentrations of CBB G 250 dye (25-100 ppm), and 4] pH of the solutions (3-9) [3]. The concentration of the treated dye in the clear filtrate was determined using an UV spectrophotometer at a wavelength of 590 nm. The removal percentage, (%R) and adsorption capacity (qe) were defined using Equation 1 and Equation 2, respectively [12].

$$R(\%) = \frac{Ci-Ce}{Ci} \times 100\% \quad (1)$$

The equation shown above indicates initial concentration (C_i) and final concentrations (C_e) in ppm of dye ion. Meanwhile,

$$q_e(mg/g) = \frac{C_o-C_e}{m} \times v \quad (2)$$

İn this second equation, q_e denotes adsorption capacity; C_o denotes the initial concentration (ppm); C_e is the final concentration (ppm); m is the adsorbent dosage (g) and v is the volume of working solution.

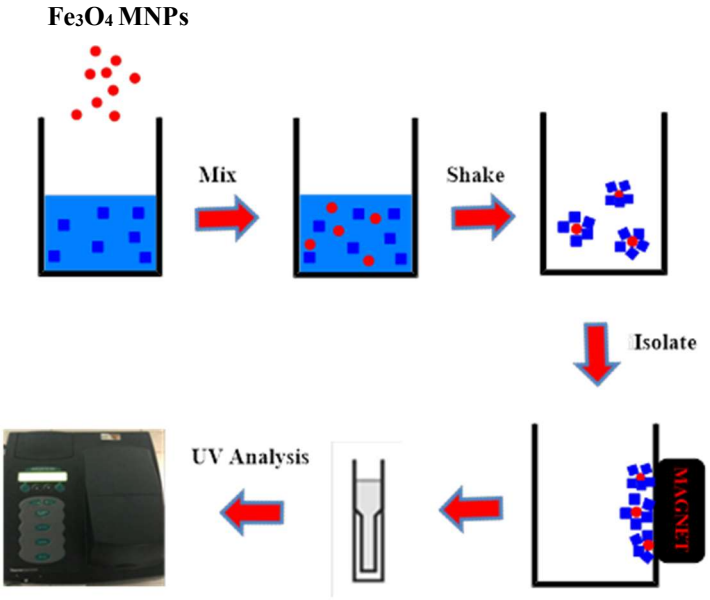

Figure 2. The removal process of CBB G 250 dye using Fe_3O_4 MNPs

Results and Discussion

Characterization

The investigation of FTIRs in the produced Fe3O4 MNPs was performed to examine the functional groups. and the result is illustrated in Figure 3(a). The peak at 537 cm^{-1} in the FTIR spectrum represents the Fe-O band vibration. The two peaks at 3400 and 1604 cm^{-1} adsorption are equivalent to O-H stretching and bending respectively, on the Fe_3O_4 MNPs surface [13]. XRD were used to determine the crystal phases of the prepared Fe_3O_4 MNPs (Figure 3(b)). The spectrum of Fe3O4 MNPs showed the presence of diffraction peaks at 2θ=30.42°, 35.59°, 43.42°, 53.63°, 57.35°, and 63.02° and are respectively assigned to the (220), (311), (400), (422), (511), and (440) planes of Fe_3O_4 (JCPDS 88-O4 0866). These peaks indicate that Fe_3O_4 MNPs has a cubic spinel structure [14].

The magnetic behavior of the Fe_3O_4MNPs was investigated using vibration sample magnetometry (VSM) at room temperature. As observed in Figure 3(c), the superparamagnetic behavior of Fe_3O_4 MNPs indicates a remanence characteristic and a coercivity near to zero. The result of the VSM demonstrates that Fe_3O_4 MNPs have a 63.30 emu g-1 saturation magnetization. The result suggests that manufactured Fe_3O_4 MNPs can be easily collected with an external magnet in water solution (see photo inset of Figure 3(c)). Following this, an analysis was done to study the surface area of Fe_3O_4 MNPs in nitrogen adsorption/desorption (Figure 3(d)). The result shows the specific surface area of Fe_3O_4 MNPs is 123.5 m^2 g^{-1}. It depicts that Fe_3O_4 MNPs have high surface area, suggesting this adsorbent as a good adsorbing agent of organic dyes, particularly CBB G 250 [15].

In order to identify thermal stability of Fe_3O_4 MNPs, thermogravimetric analysis (TGA) was carried out. Thermogram of Fe_3O_4MNPs is presented in Figure 3(e). The finding shows that adsorbed water and hydroxyl group (6.25 %) were lost at temperature below 100 ℃. At temperature between 260 and 540 ℃, the weight loss of approximately 2.09 % was recorded as a result of change from magnetite (Fe_3O_4) to maghemite (ϒ-Fe_2O_3) in crystal phase [16].

FESEM analysis was used to investigate the morphology of prepared Fe_3O_4 MNPs. The FESEM images of synthesized Fe_3O_4 MNPs is shown in Figure 4 ((A)-(B)). Fe_3O_4 MNPs were observed in nano-sized, spherical in shape, and have a uniformly distributed particle size [17]. The elemental analysis was performed to confirm the composition of the Fe_3O_4 MNPs and the EDX spectrum of Fe_3O_4 MNPs is shown in Figure 4(C). The EDX results revealed 24.50% Fe and 75.50% of O [18], thus confirming the successful synthesis of the Fe_3O_4 MNPs.

The optimization of the parameter for CBB G dye removal: Effect of adsorbent dosage

The amount of adsorbent is crucial to achieve the maximum removal of CBB G 250 dye. Seven different amounts of Fe_3O_4 MNPs (0.02-0.14g) were used for the adsorption of CBB G 250 dye. Figure 5(a) displays the influence of the adsorbent mass on the removal of target CBB G 250 dye. As seen from the result, as the mass of Fe_3O_4 MNPs increases, so did its adsorption efficiency due to initial availability of the large number of active sites on Fe_3O_4 MNPs [19]. The maximum percentage removal of targeted dye was found at 0.12g of Fe_3O_4 MNPs. Beyond the 0.12g dosage, the adsorption efficiency of Fe_3O_4 MNPs reached equilibrium. This indicates that the active site of the Fe_3O_4 MNPs had become saturated [20]. Consequently, 0.12g was selected for the subsequent experiments.

Effect of contact time

The maximal adsorption of CBB G 250 requires sufficient contact time. The time profile for adsorption was explored by varying the time between 5 and 20 minutes of adsorption. The adsorption recoveries of CBB G 250 increased for up to 15 minutes, after which it plateaued (Figure 5(b)), thus no longer actively absorbing. This is because initially, there are many accessible sites for interaction of CBB G 250 dye which readily allows adsorption. However, as time progresses, more active sites are occupied, which leads to the saturation of the active site on the Fe_3O_4 MNPs becoming saturated after 15 minutes. Hence, 15 minutes of contact time was chosen for future experiments.

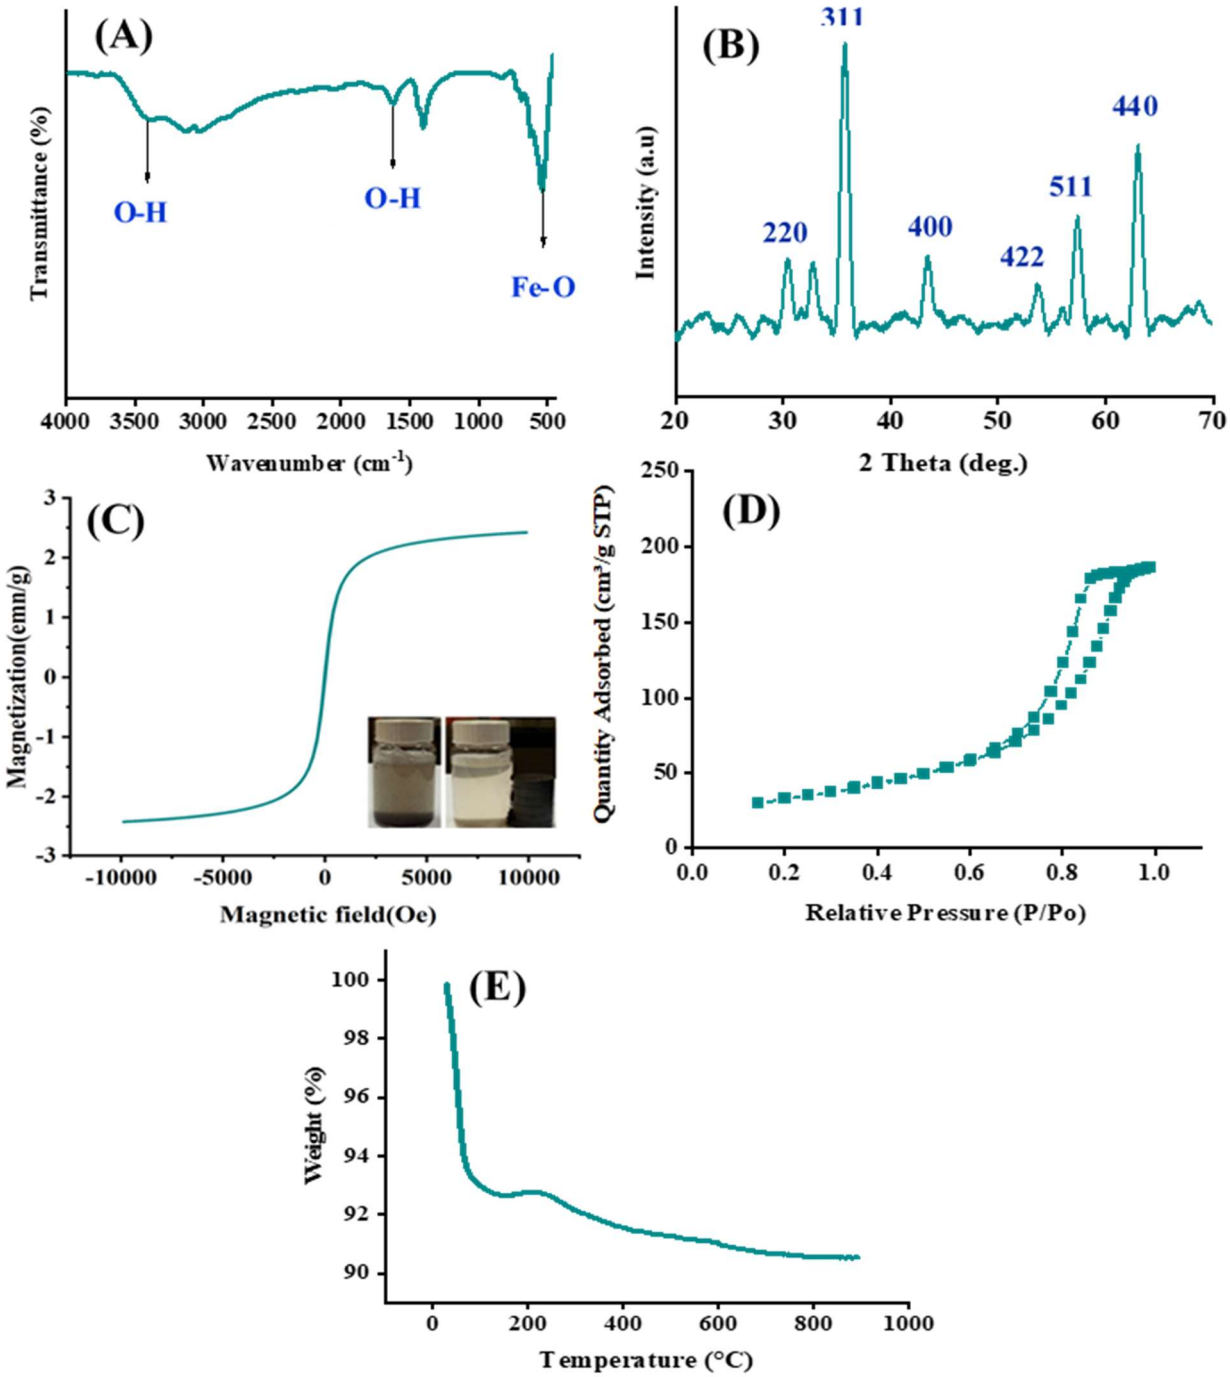

Figure 3. (a) FTIR, (b) XRD, (c) VSM, (d) BET and (e) TGA analyses of Fe_3O_4 MNPs

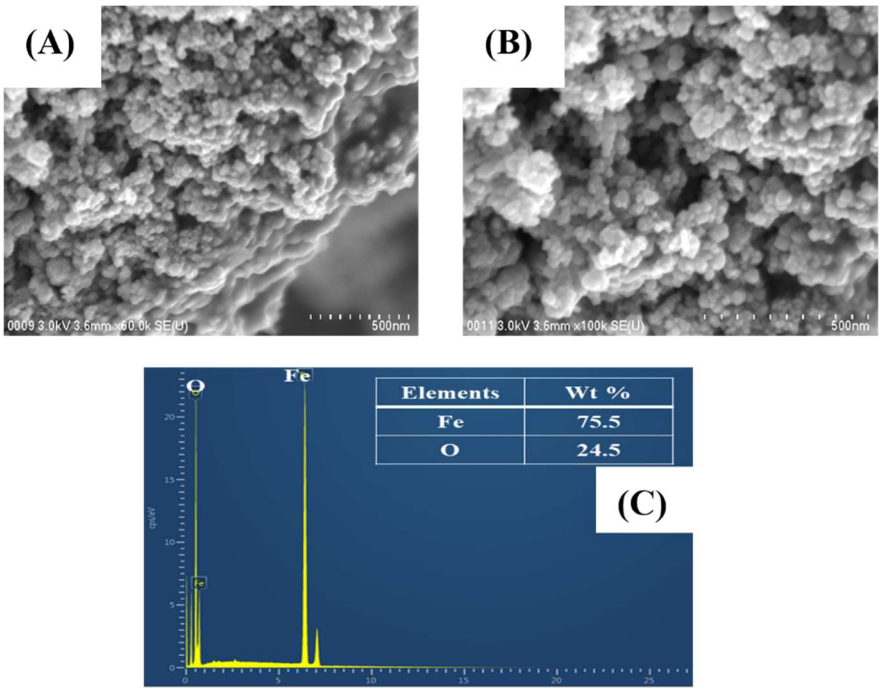

Figure 4. (a-b) Morphological image and (c) EDX spectrum of Fe_3O_4 MNPs

Effect of initial concentration

A suitable concentration of CBB G250 dye is important to achieve a better adsorption efficacy of targeted dye on Fe_3O_4 MNPs. The initial concentrations of CBB G 250 dye ranged from 25 to 100 ppm. Figure 5(c) shows an increasing trend up until 50 ppm of initial dye concentration, suggesting that there are unoccupied active sites on the Fe_3O_4 MNPs adsorbent surface at this stage. The maximum adsorption removal (92%) of targeted dye using Fe_3O_4 MNPs was found at 50 ppm of initial concentration. Beyond this point, the adsorption efficiency of CBB G 250 using Fe_3O_4 MNPs decreases due to the saturation of adsorption sites on the adsorbent surface. This finding agrees with the research conducted by Pandey et al. [21], who reported that the percentage adsorption of Brilliant Green (BG) dye removal decreases with the rise in BG dye concentration. Pandey and coworkers also reported that with the rise in BG dye concentration, the surface area and active sites of the adsorbent became saturated, which then reduces the percentage adsorption of BG. Hence, 50 ppm of initial CBB G 250 concentration was selected for subsequent studies.

Effect of pH

The adsorbent's efficacy is significantly influenced the surface load of the adsorbent material, its ionizing nature of target analytes and the ionization/dissociation of the adsorbed molecules functional groups. Based on Figure 5(d), the high removal of CBB G 250 more than 80% was obtained from pH 3 until pH 10. This phenomenon can be explained based on the structure of CBB G 250 dye and Fe_3O_4 MNPs. Betancur Jiang et al. [22] revealed that Fe_3O_4 MNPs is electropositive for pH < 6 and electronegative for pH > 6.5 which meant that the isoelectric point of Fe_3O_4 MNPs falls between pH 6 and 6.5. Therefore, under acidic conditions, the electropositive Fe_3O_4 MNPs interacted well with the negative charges of the SO_3^- CBB G 250 dye via electrostatic attraction (Figure 6(a)). Meanwhile, under neutral conditions, Fe_3O_4 MNPs adsorbed CBB G 250 dye through hydrogen bonding (Figure 6(b)). Under alkaline conditions, the electronegative Fe_3O_4 MNPs interacted with the positive charges of the N^+ CBB G 250 dye via electrostatic attraction (Figure 6(c)), indicating the good removal of CBB G 250 dye using Fe_3O_4 MNPs at this condition . In this case, pH 8, the natural pH of the sample, is selected as the best pH to use.

Adsorption kinetic models

The kinetic model delivers a relationship between the rate of adsorption as well as the type of reaction mechanism engaged. To better understand the adsorption mechanism of CBB G 250 dye molecules onto Fe_3O_4 MNPs, the pseudo first-order (Figure 7(a)), pseudo second-order (Figure 7(b)) and intraparticle diffusion (Figure 7 (c)) were used in this study. The kinetic parameters of different models are shown in Table 1. According to this table, the pseudo second-order models fit the experimental data better than that of the pseudo-first-order and the intraparticle diffusion kinetic models, obtaining a correlation coefficient of 0.9507. This indicated that most of the CBB G 250 molecules were adsorbed onto the surface of Fe_3O_4 MNPs by chemisorption mechanism, which involves valence forces via the sharing or exchanging of electrons. Additionally, the adsorption mechanism might depend on both the adsorbate and the adsorbent. The result obtained in this work is similar with the results reported in other published works by Dhananasekaran et al. [23] and Kadeche et al. [24].

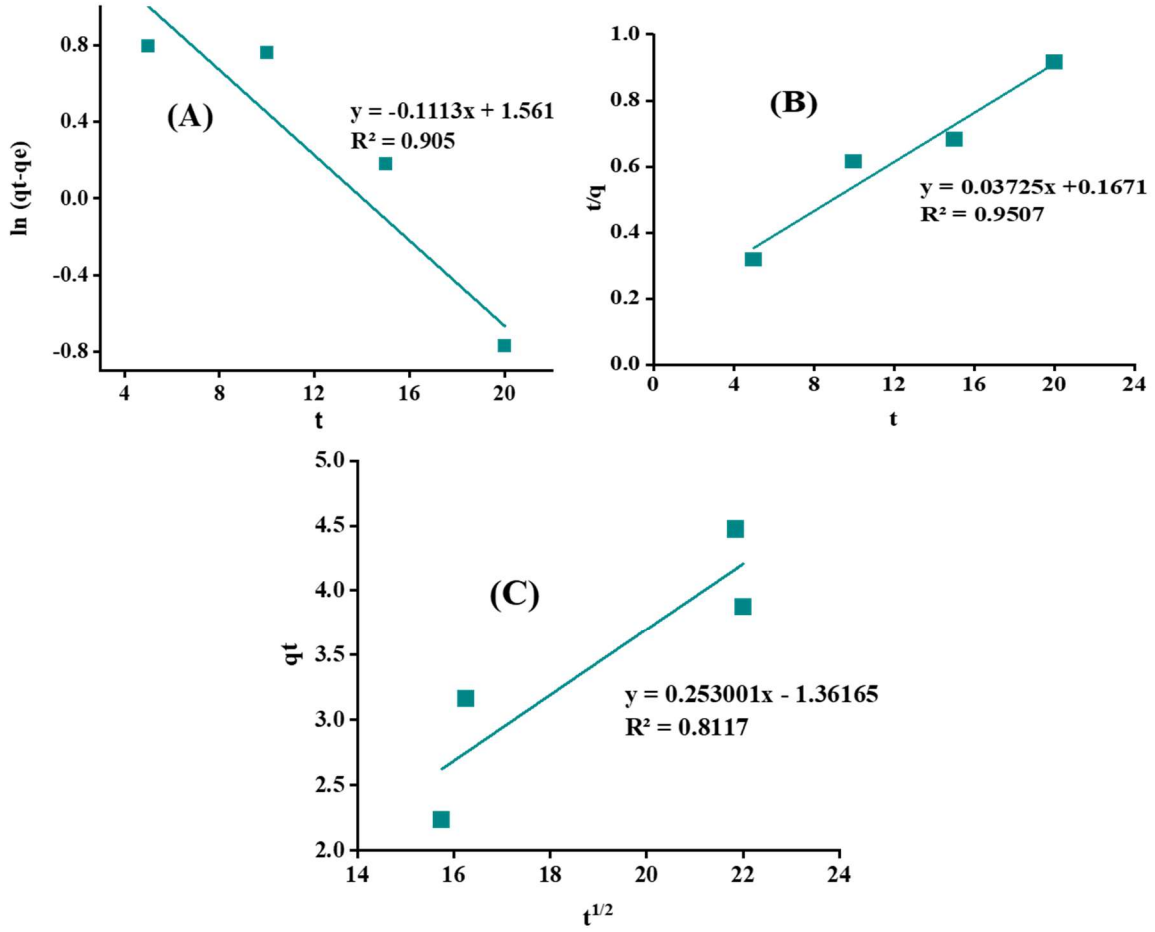

Figure 7. (a) Pseudo-first-order, (b) Pseudo-second-order and (c) Intraparticle Diffusion of removal CBB G 250 by Fe_3O_4 MNPs

Table 1. Kinetic modeling constants and coefficient of determination for adsorption of CBB G 250

Model	Equation /Value
Pseudo-first-order kinetics	$\ln(q_e - q_t) = \ln q_e - k_1 t$
q_e(mg g^{-1})	6.262
R_1^2	0.905
k_1 (min^{-1})	-0.111
Pseudo-second-order kinetics	$\frac{t}{q_1} = \frac{1}{k_2 q_e^2} + \frac{t}{q_e}$
q_e (mg g^{-1})	5.43
R_2^2	0.951
k_2 (g $mg^{-1}min^{-1}$)	0.037
Intraparticle Diffusion	$q_t = k_{id} t^{1/2} + C_i$
R^2	0.957
k_{id} (mg g^{-1} min^{-1})	0.253
Ci (mg g^{-1})	7.939

Adsorption isotherm models

In order to describe further the interaction between the adsorbent and adsorbates, adsorption isotherm models such as Langmuir (Figure 8(a)) and Freundlich (Figure 8(b)) models were studied to fit the equilibrium data. Table 2 shows the adsorption of isotherm constant for CBB G 250 on Fe_3O_4 MNPs. From the table, the high correlation coefficient values for Langmuir (R^2 = 0.998) and Freundlich (R^2 = 0.999) models strongly imply that the Fe_3O_4 MNPs adsorption of CBB G 250 dye closely follows both Langmuir and Freundlich models of adsorption under the present experimental conditions. This finding is similar to previous study by Kulal & Badalamoole [25] who also found that adsorption of Rhodamine 6G (R6G) dye by Magnetite nanoparticle embedded Pectin-graft-poly (N-hydroxyethylacryl amide) hydrogel followed both Langmuir and Freundlich equations. Othman et al. [26] also stated that the analysis of adsorption of methylene blue using graphene oxide-magnetic iron oxide nanoparticles revealed that the data is well fitted with Langmuir and Freundlich adsorption isotherm model ($R^2 > 0.97$), indicating the multilayer adsorption of dye on the surface of adsorbent.

Table 2. Isotherm modeling constants and coefficient of determination for adsorption of commassie brilliant blue G 250

Model / Isotherm constant	Equation /Value
Freundlich adsorption isotherm	$\ln q_e = \ln K_F + \frac{1}{n} \ln C_e$
q_e(mg g^{-1})	124.33
R_1^2	0.998
k_F	7.3207
$\frac{1}{n}$	-0.349
Langmuir adsorption isotherm	$\frac{q_e}{C_e} = \frac{C_e}{q_m} + \frac{1}{q_m b}$
q_m (mg g^{-1})	91.743
R_2^2	0.9999

Analysis of CBB G 250 Dye Loaded Fe_3O_4 MNPs

The FTIR spectra of the synthesized Fe_3O_4 MNPs, raw CBB G 250 and CBB G 250 loaded Fe_3O_4 MNPs are shown in Figure 9. From the spectrum of CBB G 250 loaded Fe_3O_4 MNPs, the broad peak at 3439 cm^{-1} is attributed to the overlapping of OH band from Fe_3O_4 MNPs and NH stretching from CBB G 250. Additionally, the peaks at 3179 cm^{-1}, 2052 cm^{-1} and 1063 cm^{-1} suggest the presence of CH stretching and CN stretching, respectively, of CBB G 250. Furthermore, the peak found at 1588 cm^{-1} indicated C=C stretching of CBB G 250. This result proved that CBB G 250 was adsorbed on the surface of Fe_3O_4 MNPs.

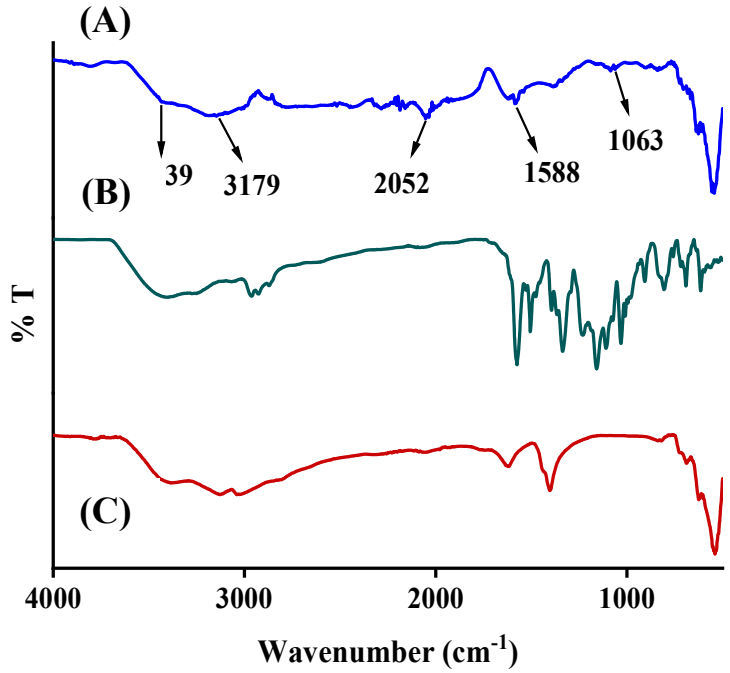

Figure 9. FTIR spectrum of (a) CBB G 250 loaded Fe_3O_4 MNPs (b) CBB G 250 dye (c) Fe_3O_4 MNPs

Recyclability of Fe_3O_4 MNPs

When estimating the efficacy of Fe_3O_4 MNPs in absorbing CBB G 250 in the environment, reusability is a crucial element to take into consideration. Fe_3O_4 MNPs were washed and dried multiple times with ethanol, before being utilized in a second adsorption, to estimate the reusability or adsorption of Fe_3O_4 MNPs. As shown in Figure 10, Fe_3O_4 MNPs can be reused at least six times without any apparent decrease of its efficiency in CBB G 250 removal, suggesting the regeneration efficacy and stability of the prepared adsorbent.

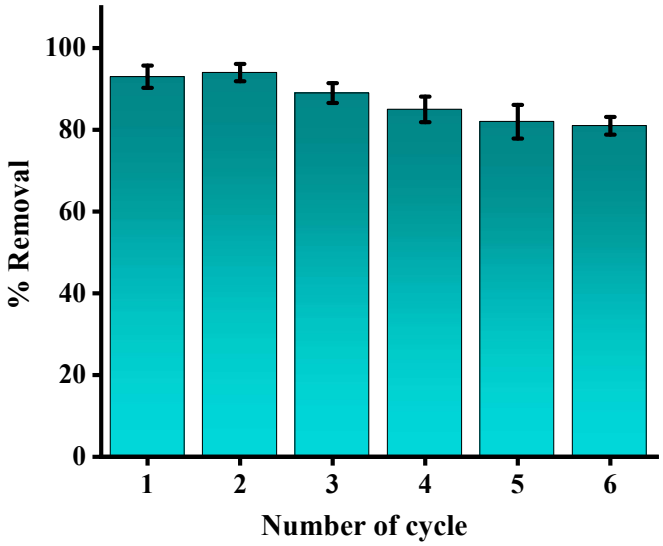

Figure 10. Reusability of Fe_3O_4 MNPs for adsorption efficiency of CBB G 250

Comparison of Fe_3O_4 MNPs with other reported adsorbents for removal of CBB G 250 dye

In Table 3, the present adsorbent, Fe_3O_4 MNPs, was evaluated with previously reported adsorbents for the adsorption of CBB G 250 dye from aqueous environment in terms of amount of adsorbent, contact time, percentage removal, adsorption capacity, kinetic study and isotherm study. The results revealed that proposed Fe_3O_4 MNPs is rapid, reliable, and a highly efficient adsorbent for the treatment of CBB G 250 from water sample. Fe_3O_4 MNPs has the highest adsorption capacity and good percentage removal of CBB G 250 with comparable amount of dosage and contact time as compared to other reported adsorbents.

Conclusion

This present study shows that the synthesized Fe_3O_4 MNPs can be potentially used for the removal of organic dyes from aqueous environment. FESEM, FTIR, and EDX, as well as XRD, TGA, and BET analyses confirmed the successful synthesis of Fe_3O_4 MNPs. Experimental results show that Fe_3O_4 MNPs achieved 95% adsorption at optimum conditions of; 1) 0.12 g dosage, 2) 15 minutes contact time, 3) 50 ppm initial dye concentration, and 4) pH value of 8. The Fe_3O_4 MNPs can also be reused up to six times without losing efficiency. FTIR analysis proved that CBB G 250 dye was adsorbed by Fe_3O_4 MNPs, as evidenced by the intense peaks attributed to the CBB G 250 in the FTIR spectrum. This study demonstrated that Fe_3O_4 MNPs are appropriate for decontamination and treatment of organic contaminants from aqueous environments because they provide excellent magnetic separation, aqueous sample stabilization, high recoveries, and rapid separation.

Abstract

Lignosus rhinocerotis, a polypore found in the tropical forests of Malaysia is traditionally used by the locals to treat various diseases. The objectives of the study were to quantify linoleic acid and β-glucan, characterize polysaccharide structure as well as to evaluate the cytotoxicity effects of *L. rhinocerotis* extracts. The linoleic acid and β-glucan concentrations in six different extracts of *L. rhinocerotis* were quantified using HPLC and β-glucan assay kit, respectively and the polysaccharide structure were analyzed using FTIR and XRD. The proliferation rate of human bronchial epithelial BEAS-2B cells treated with the *L. rhinocerotis* extracts were also analyzed. The highest linolic acid content and β-glucan composition were found in petroleum ether extract and hexane residue, respectively. Cold water and petroleum ether extracts showed cytotoxic effect with 30% reduction of cell viability at 72 hours at the concentration of 62.5-250 µg/mL while the other extracts are not cytotoxic. Quantification of linoleic acid and β-glucan as well as characterization of polysaccharide structure in *L. rhinocerotis* extracts have been successfully determined. The observed effects on BEAS-2B cells are likely attributable to the immunomodulatory properties exhibited by the active compounds of linoleic acid and β-glucan.

Keywords: *Lignosus rhinocerotis*, linoleic acid, beta-glucan, high performance liquid chromatography, cytotoxicity

Abstrak

Lignosus rhinocerotis merupakan polipor yang terdapat di hutan tropika Malaysia telah digunakan secara tradisi oleh penduduk tempatan untuk merawat pelbagai penyakit. Kajian ini bertujuan untuk mengukur tahap asid linoleik dan β-glukan, mencirikan struktur polisakarida serta menilai kesan sitotoksisiti ekstrak *L. rhinocerotis*. Tahap asid linoleik dan β-glukan di dalam enam ekstrak *L. rhinocerotis* yang berlainan masing-masing diukur dengan kaedah HPLC dan kit ujian mezayme yis dan cendawan β-glukan. Struktur polisakarida juga dianalisa menggunakankan kaedah FTIR dan XRD. Titisan sel epitelium bronkus manusia

BEAS-2B dikultur dan dirawat dengan ekstrak *L. rhinocerotis* dan ujian kesitotoksikan telah dijalankan. Petroleum eter menghasilkan jumlah asid linoleik yang paling tinggi, manakala ekstrak residu heksana menghasilkan komposisi β-glukan tertinggi. Ekstrak air sejuk dan petroleum eter menunjukkan kesan sitotoksik ringan pada kepekatan 62.5-250.0 µg/mL dengan penurunan kadar kebolehhidupan sel adalah tidak melebihi 30% manakala kebanyakan ekstrak lain tidak sitotoksik. Tahap asid linoleik dan β-glukan serta pencirian struktur polisakarida di dalam ekstrak *L. rhinocerotis* telah berjaya ditentukan. Kesan ekstrak ini terhadap titisan sel epitelium bronkus manusia BEAS-2B juga telah berjaya dikaji dan berkemungkinan disebabkan oleh sifat imunomodulator yang ditunjukkan oleh sebatian aktif, iaitu asid linoleik dan β-glukan.

Kata kunci: *Lignosus rhinocerotis*, asid linoleic, β-glukan, kromatografi cecair berprestasi tinggi, kesitotoksikan

Introduction

Lignosus rhinocerotis (*L. rhinocerotis*) or domestically known as tiger milk mushroom by the local community in Malaysia, is a polypore found in the tropical rainforests in Malaysia. *L. rhinocerotis* is traditionally used to reduce body temperature, as a postpartum medicine for women after childbirth, as a contraceptive and in the treatment of breast and cervical cancers [1], asthma, cough, joint pain, food poisoning, liver-related illnesses as well as a general tonic [2].

Besides, *L. rhinocerotis* is believed to possess anti-inflammatory activities against inflammatory mediators during inflammation. This action may be contributed by the high amounts of active compounds found in this fungus, primarily the polysaccharide of β-glucans and the polyunsaturated fatty acid of linoleic acid. β-glucans are mostly derived from the fruiting bodies of mushrooms, and it is believed to be an immune system booster where it has demonstrated to effectively stimulate the host immune response against microbial infections [3]. Additionally, β-glucan is also used as an adjuvant to enhance the effectiveness of modern medicine [4]. Meanwhile, linoleic acid which is an omega-6 polyunsaturated fatty acid; a precursor for arachidonic acid which is often associated with inflammation [5]. The low levels of pro-inflammatory cytokines such as TNF-α and IL-6 and the high levels of anti-inflammatory cytokines including IL-10 was reported in corresponding to the presence of polyunsaturated fatty acid in the plasma, suggesting its effect in inflammation [6]. In our previous study, the volatile compositions of *L. rhinocerotis* in hot water extract showed that linoleic was the one with the most abundant polyunsaturated fatty acids when analyzed through gas chromatography-mass spectrometry (21.35%) [7].

Numerous studies have reported on the cytotoxicity of L. *rhinocerotis* extracts. According to Fauzi et al. [8], *L. rhinocerotis* is reported to induce apoptosis in HCT 116 colon cancer cells. *L. rhinocerotis* was also found to induce apoptosis that led to cell death in the human breast carcinoma cell line, MCF-7 and the human lung carcinoma cell line, A549 [9]. In this study, human lungs epithelial BEAS-2B cells was chosen because of its role in conserving the normal airway function by acting as defensive barrier and secreting the inflammatory mediator in response to the inflammation. BEAS-2B is widely used as a pulmonary epithelium model in many types of in vitro studies including toxicology testing [10], respiratory injury and remodeling [11].

Thus, the objectives of the study were to quantify linoleic acid and β-glucan as well as to characterize polysaccharide and crystalline structure in *L. rhinocerotis* extracts. The cytotoxicity of the extracts in human lungs epithelial BEAS-2B cells was also evaluated.

Materials and Methods

Sample preparations

The samples were prepared by dissolving *L. rhinocerotis* powder in methanol. Water-based extract such as hot water, cold water, hexane residue and petroleum ether residue extracts were prepared at 8 mg/mL while the concentration for solvent-based extracts such as hexane and petroleum ether extracts were at 100 µg/mL. Table 1 shows three different extraction methods used for the extraction of *L. rhinocerotis*.

HPLC analysis for linoleic acid

A reversed phase high performance liquid chromatography (HPLC) was performed on an Agilent

1260 Infinity System (Agilent Technologies, Santa Clara, USA). Instrument control and data collection were carried out using an Agilent OpenLab ChemStation Edition C.01.05 software. The column used was COSMOSIL 5C18-MS-II (250 X 4.6 mm I.D: 5 µm) (Nacalai Tesque, Inc, Japan) coupled with a guard column (10 X 4.6 mm I.D: 5 µm) (Nacalai Tesque, Inc, Japan) with similar packing material. The detection was done by an ultraviolet detector at 208 nm. The mobile phase used was a combination of acetonitrile, methanol, and hexane in the ratio of 90:8:2 with the addition of 0.2% acetic acid at a flow rate of 1.0 mL/min. Indomethacin was used as internal standard. The total analytical time was approximately 10 minutes. HPLC method validation were performed according to FDA guideline [11] to evaluate calibration curves, linearity, precision, accuracy, and recovery.

Quantification of β-glucan

Quantification of β-glucan in *L. rhinocerotis* extracts was conducted using mushroom and yeast Beta-Glucan Assay Kits (Megazyme, Bray, Ireland) where both total and alpha glucans were measured. Concentrations of β-glucan were determined by subtracting the concentrations of alpha glucan from the total values.

Table 1. Different extraction methods for the extraction of *L. rhinocerotis*

Extraction Method	Soxhlet	Maceration	Ultrasound-Assisted Extraction
Step by step procedures	1. TMM powder (50 mg) was transferred into an extraction thimble. 2. Distilled water (500 ml) was put into a round bottom flask. Soxhlet extraction set was set up. 3. The extract was then concentrated using a rotating evaporator. 4. The concentrated extract was dried, weighed, and stored in a tightly capped container for further use.	1. TMM powder (50 g) was macerated in 500 ml of water for 24 hours in cold room (4 °C) with agitation. 2. After 24 hours, the extract was centrifuged at 2500 g for 10 min. 3. The supernatant was collected and dried using freeze dryer.	1. TMM powder (50 mg) was dissolved in 500 ml of solvents and transferred into a water bath sonicator for 30 min at 40 °C. 2. The solution was centrifuged at 2500 g for 10 min. Then, the supernatant was concentrated, dried and stored. 3. The pellet was resuspended in 500 ml of water before being subjected to ultrasound in a water bath sonicator for another 30 min prior to centrifugation at 2500 g for 10 min. 4. The supernatant was collected, concentrated, dried, weighed and stored.
Product	Hot water extract	Cold water extract	Step 1-2: hexane and petroleum ether extract. Step 3-4: hexane residue and petroleum ether residue extract.

Determination of polysaccharide structural analysis

Fourier-transform infrared spectroscopy (FTIR) was used to determine polysaccharide structural analysis in *L. rhinocerotis* extracts. Infrared radiation (IR) spectra of *L. rhinocerotis* crude extract was performed using KBr-disk method where the sample was ground with KBr powder and pressed into 1 mm pallet. The pallet was analyzed using FTIR spectrometer (Tensor 27, Bruker, Germany) spectrometer in the range 4000-400 cm^{-1}.

Determination of crystalline structure

The X-ray diffraction (XRD) of *L. rhinocerotis* crude extract was analyzed using diffractometer (D2 Phaser, Bruker, Germany). Copper lamp radiation (Cu Kα) was applied to the sample at 10mA and 30 kV with rotation speed of 15.0 s. The diffraction angle was shifted from 10º to 90º to identify the crystalline structure.

BEAS-2B cell culture

BEAS-2B was purchased from American Type Culture Collection (Manassas, USA) (resource number: ATCC® CRL 9609™). The cells were cultured in a complete Dulbecco Modified Eagle's Medium (DMEM) at 37oC and 5% carbon dioxide humidified atmosphere. Complete DMEM was prepared by adding 1% penicillin-streptomycin and 10% fetal bovine serum. Cells from passage 6 to 8 were used in all experiment.

Proliferation assay

BEAS-2B cells were seeded at 2 x 103 cells per well. After 24 hours, the cells were treated with six different extracts: hot water, cold water, hexane, petroleum ether, hexane residue and petroleum ether residue extract at various concentrations (250, 125, 62.5, 31.25 and 15.625 µg/mL, respectively) for 24, 48 and 72 hours. An untreated negative control was included in the study. Proliferation assay was carried out using MTS assay kit (Promega, USA) following the manufacturer's instruction.

Statistical analysis

Statistical analyses were performed using the Statistical Package of Social Science software, version 21.0. A one-way ANOVA was used to analyze the findings. All statistical analyses were performed at significance level of $p < 0.05$.

Results and Discussion

Chromatography

A typical chromatogram of the analysis of linoleic acid in *L. rhinocerotis* extracts obtained on COSMOSIL 5C18-MS-II column, is shown in Figure 1. The calibration curve for linoleic acid was linear in the concentration range of 5 to 200 µg/mL. The inter- and intra-day calibration curves showed consistent linearity, as seen in consistency of intercept, slope and coefficient of correlation. A typical concentration curve for linoleic acid had a slope of 0.0053, an intercept of 0.0005 and r^2 = 0.9978 (Figure 2).

The precision of the test was evaluated by determining the relative standard deviation (RSD) of the measured peak area ratios for different drug concentrations. RSD was calculated as follows: $\bar{x}$ = mean of peak area ratio and s = standard deviation of peak area ratio. Based on the FDA guideline [12], the acceptable precision for each concentration is RSD < 15% except for the limit of detection concentration which is at 20%. Accuracy was expressed as the mean percentage of analyte recovered in the assay with a targeted acceptable range within 80-120%. Our data indicated that the method is both precise (relative standard deviation less than 15%) and accurate (mean percentage recovery of between 80-120%).

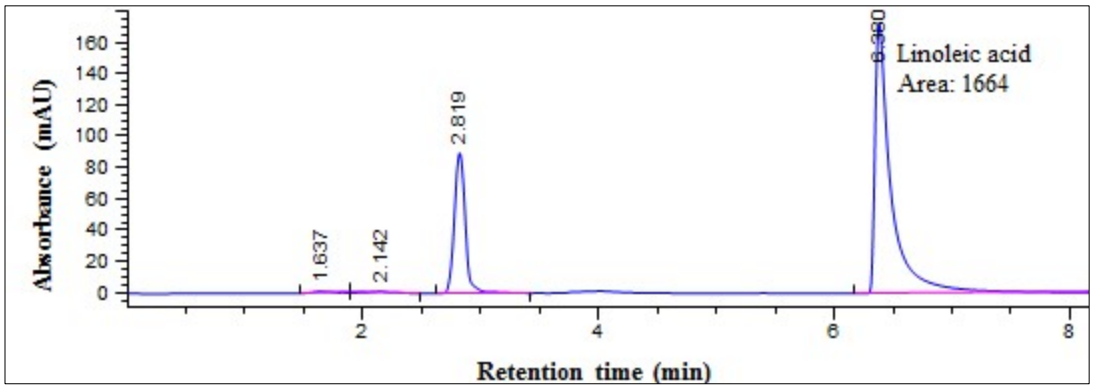

Figure 1. Chromatogram of linoleic acid (6.680 min) and internal standard, indomethacin (2.819 min) when using combinations of acetonitrile, methanol and hexane for mobile phase in the ratio of 90:8:2 with the addition of 0.2% acetic acid at a flow rate of 1.0 mL/min. The detection was done by an ultraviolet detector at 208 nm.

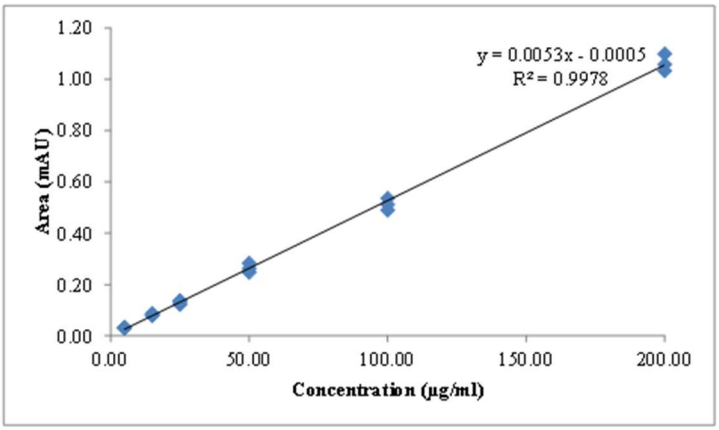

Figure 2. A typical concentration curve for linoleic acid

Measurement of linoleic acid in *L. rhinocerotis* extracts

Table 2 shows the amount of linoleic acid in 100g of the extracts. Based on the results, water-based extracts such as hot water, cold water, hexane residue and petroleum ether residue extracts recorded a low amount of linoleic acid which is approximately 0.05g in 100g of extract. The non-polar extracts such as hexane and petroleum ether yielded significantly higher amounts of linoleic acid which are 16.79 and 17.55g in 100g of extract, respectively.

Table 2. Measurement of linoleic acid in *L. rhinocerotis* extracts

Extract	Mean Linoleic Acid Content in Extract (g) ± Standard Deviation
Hot water	0.049 ± 0.277
Cold water	0.049 ± 0.115
Hexane	16.790 ± 0.629*
Petroleum ether	17.550 ± 0.221*
Hexane residue	0.046 ± 0.113
Petroleum ether residue	0.048 ± 0.133

*p <0.05

Analysis of β-glucan in *L. rhinocerotis* extracts

Analysis of β-glucan composition in water-based *L. rhinocerotis* extracts indicated that it is present at 29.0, 33.6, 39.8 and 32.1g in 100g extracts of hot water, cold water, hexane residue and petroleum ether residue extracts, respectively. On the other hand, the amount of β-glucan in non-polar extracts such as hexane and petroleum ether extracts were 31.5 and 24.1g, respectively. Hexane residue is the best extract for β-glucan (Table 3).

Table 2. Measurement of β-glucan in *L. rhinocerotis* extracts

Extract	Mean β-Glucan Content in Extract (g) ± Standard Deviation
Hot water	29.0 ± 0.001*
Cold water	33.6 ± 0.006*
Hexane	31.5 ± 0.001*
Petroleum ether	24.1 ± 0.001*
Hexane residue	39.8 ± 0.002*
Petroleum ether residue	32.1 ± 0.004*

*p <0.05

Analysis of the FTIR spectrum

The FTIR spectrum of *L. rhinocerotis* crude extract was shown in Figure 3a. A broad band observed at 3423 cm^{-1} is attributed to –OH group stretching vibration in the polysaccharide or moisture of sample [13]. The band 2931 cm^{-1} is attributed to the C-H stretching vibration which include CH, CH_2 and CH_3 stretching, which are the characteristic absorptions of polysaccharides. The band between 1000 and 1200 cm^{-1} region indicated the presence of C-O stretching vibration of C-O-H and C-O-C glycosidic bonds are also characteristic of polysaccharides. An intense band in the region 1639 cm^{-1} is associated to the C=O stretching vibration of amide I group [14].

X-ray diffraction (XRD)

The crystallinity of the *L. rhinocerotis* crude extract was evaluated and the diffractogram pattern is shown in the Figure 3B. The sample shows diffraction peak at 13.8, 20.5º, 21.2, 25.7 and 33.9º 2θ (Degrees) of the crystallinity. The computed crystallinity is at 19.5% and amorphous is at 80.5% within 10 to 90º 2θ.

The effect of extract on cell viability

Analysis of cell proliferative activity was conducted by MTS in BEAS-2B treated with various concentrations (250, 125, 62.5, 31.25 and 15.625 µg/mL) of *L. rhinocerotis* extracts after 24, 48 and 72 hours of incubation is shown in Figure 4. The viability of cell treated with hot water extract, hexane residue extract and petroleum ether residue extract did not show any significant different after 3-day treatment. However, petroleum ether extract at the concentration of ⩾ 31.25 µg/mL showed significant reduction throughout the 3-day treatment. Cell treated with cold water extract at the concentration of 125 and 250 µg/mL also significantly reduced, starting from the second day of the treatment. Reduction in cell viability could also be seen in cell treated with hexane extract (125 and 250 µg/mL) on day 3.

Mushrooms are rich in polyunsaturated fatty acids especially linoleic acids. Our results indicated that linoleic acid concentration was significantly lower in water-based extracts than in solvent-based extracts which extracted a higher number of compounds. Hexane and petroleum ether which are non-polar, can pull out non-polar compounds [15] in extraction of fatty acids from flaxseed oil. The reason is that the organic solvents used for the extraction process were specific for the extraction of fatty acids. It is plausible that the non-polar solvents such as hexane and petroleum ether attract the long hydrocarbon alkane chain present in fatty acids. The effect was similarly shown in another study on the extraction of fatty acids from flaxseed oil where non-polar solvents such as hexane and petroleum ether fatty acids were found to be better at extracting fatty acids as compared to polar solvents [15].

Linoleic acid is the most abundant polyunsaturated fatty

acid in *L. rhinocerotis* and represents about 21.35% of total volatile compounds [7]. A study on fatty acid analysis from nine wild edible mushrooms (*Aleurodiscus vitellinus, Cortinarius magellanicus, Hydropus dusenii, Cyttaria hariotii, Fistulina antarctica, F. endoxantha, Grifola gargal, Lepista nuda and Ramaria patagonica*) from Argentina indicated that linoleic acid was the predominant fatty acid found in the investigated mushroom species [16]. Another study on the phytochemical analysis of the *Rhizopogon luteolus* showed that eight fatty acids were detected in *R. luteolus* with linoleic acid, making up 45.8% of the total fatty acids present [17]. Twenty-eight fatty acids were detected in 16 strains of *Pleurotus ostreatus* mushroom lipids where the linoleic acid was predominant in all samples (56.8–80.5%) [18], indicating that it is an important constituent to be analyzed in mushroom samples.

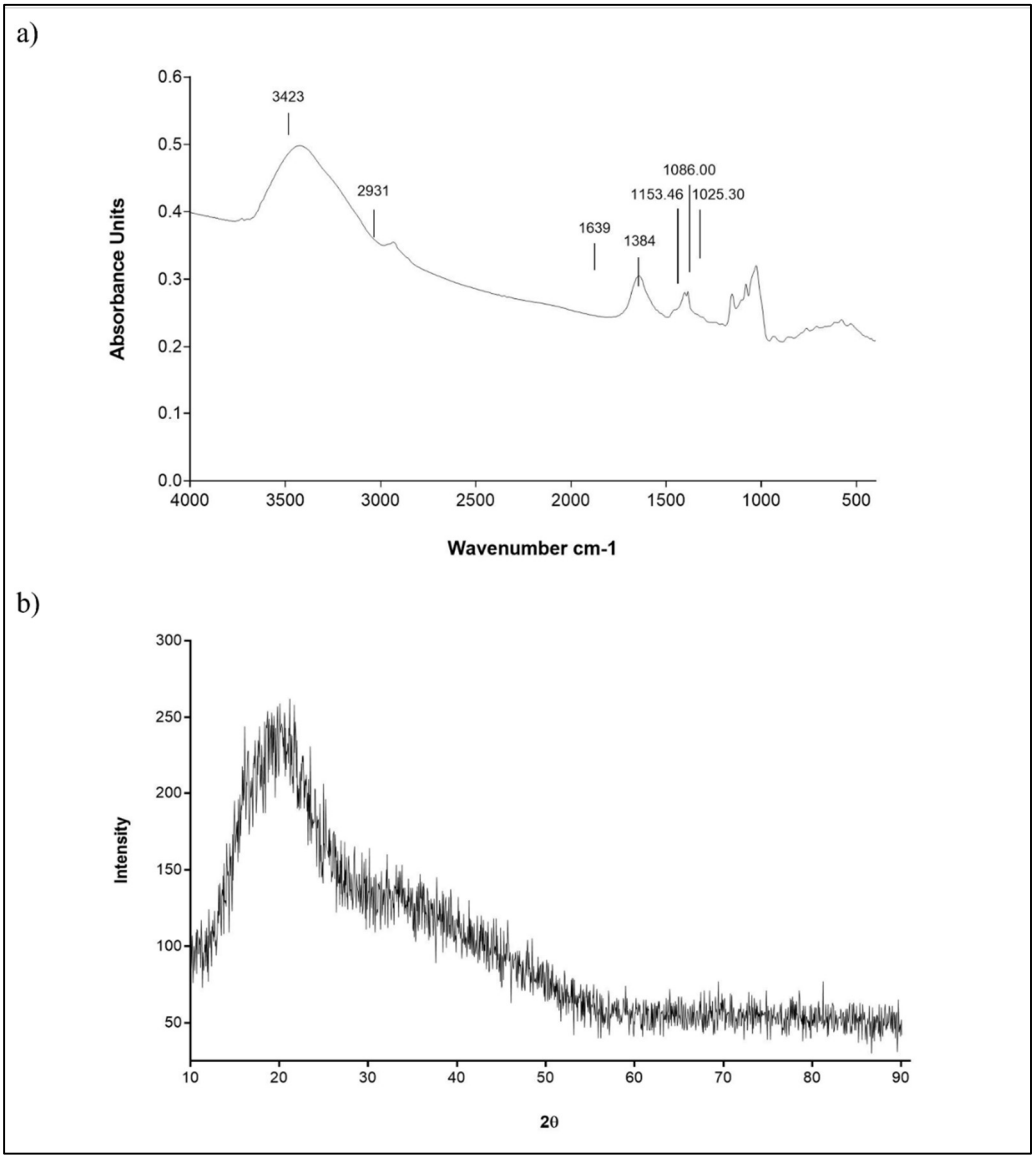

Figure 3. Analyses of (a) FTIR spectra and (b) XRD of *L. rhinocerotis* crude extract

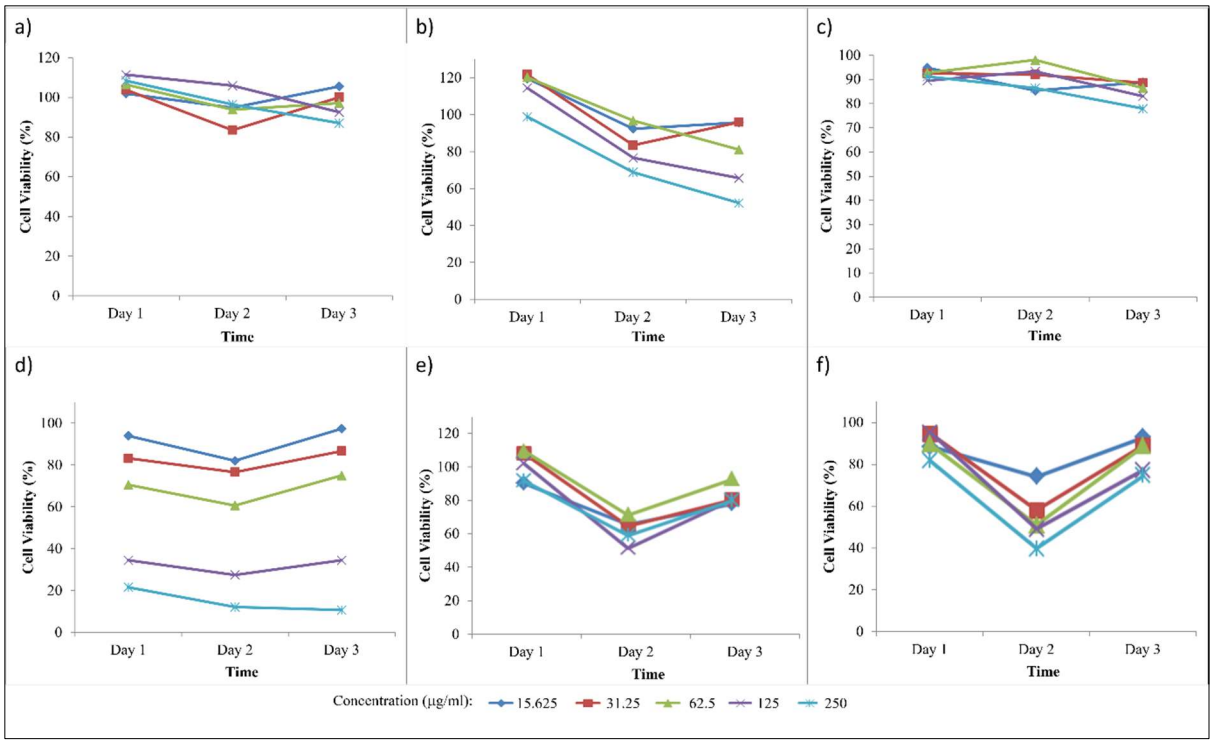

Figure 4. The effects of various concentrations of a) hot water, b) cold water, c) hexane, d) petroleum ether, e) hexane residue and f) petroleum ether residue extracts on viability of BEAS-2B cell line. Untreated cells were used as a control. The differences between concentrations of each extract were tested statistically using Kruskal-Wallis. Data are presented as mean ± standard deviation for three independent experiments. *$p < 0.05$ vs control.

There are several studies reported on the β-glucan composition in *L. rhinocerotis* with conflicting data. Jamil et al. [19] reported that β-glucan constituted more than 50% of glucan content in *L. rhinocerotis* while another study Lau et. al. [1] reported that β-glucan constituted the majority of glucan, ranging from 82 to 93% (w/w). However, another study on the β-glucans content stated that β-glucan constituted only 9% of total glucan compositions [20]. Meanwhile, the data obtained from this study shows that β-glucans make up more than 20% of total glucan in all extracts. Nevertheless, the difference in β-glucan content may be attributed to the different extraction method used in each study.

The peak characteristic of FTIR spectrum suggested the presence of both polysaccharide and protein. The absorption bands of O-H, C-H and C-O groups represent the typical polysaccharide characteristic in FTIR [21]. The amide group is characterized by the peptide bond of secondary structure of protein [22]. The absorption bands of O-H, C-H and C-O groups represent the typical polysaccharide characteristic in FTIR [21]. Previous studies reported the presence of polysaccharides as the major constituents in *L. rhinocerotis* extracts [23]. The XRD result confirms the existence of both broad peak amorphous behavior and a small crystalline structure region in *L. rhinocerotis* crude extract which is very common in nature. The profile suggested the sample is composed of monodisperse particle. Several studies also reported the similar profile pattern [9,24,25].

In this study, cold water and petroleum ether extracts between 62.5 and 250.0 µg/ml show cytotoxic effect since the reduction of cell viability at 72 hours is more than 30%. Other extracts did not show cytotoxic effect against BEAS-2B cell line. The data is consistent with a previous study on the anti-proliferative effect of the cold sclerotia of *L. rhinocerotis* [9]. Lee et al. [9]

hypothesized that the cytotoxic effect of the cold-water extract was due to the presence of thermolabile compounds in cold water extract which were absent in hot water extract. The study reported that cytotoxic cold-water extracts contained more proteins than non-cytotoxic hot water extract, suggesting that the cytotoxic activity might be attributed to the additional proteins in the cold-water extract. In the case of cytotoxic effect shown by petroleum ether extract, it might be attributed to the presence of alkaloids and terpenoids that might be present in the extract since petroleum ether has the ability to extract these compounds [26]. In fact, many plants that are reported to have toxic properties usually contain certain terpenoid and alkaloids [27]. Interestingly, *L. rhinocerotis* extracts did not confer any apoptotic effect on normal lungs epithelial cell line, BEAS-2B. It is plausible that the *L. rhinocerotis* extracts used in the study do not cause harmful effect to the normal cell line.

Conclusion

In conclusion, quantification of linoleic acid in hot water, cold water, hexane, petroleum ether, hexane residue and petroleum ether residue extract of *L. rhinocerotis* has been successfully determined using HPLC. In addition, the amount of β-glucan in *L. rhinocerotis* extract has also been successfully quantified using the optimized method. The characterization of polysaccharide and crystalline structure in *L. rhinocerotis* extracts have been also successfully determined. All extracts (especially at high concentration, 125 and 250 µg/mL) showed reduced proliferative activities as compared to control at 72 hours; although the majority of the extracts were not cytotoxic to BEAS-2B cell line. The observed effects are likely due to the high content of immunomodulatory active compounds, such as linoleic acid and β-glucan, present in the extract.

Abstract

Adsorption processes using low-cost sorbents such as bio-polymer adsorbents are an attractive option for removing methylene blue from wastewater. This study involved magnetic sporopollenin (MSp) synthesis and its application for removing methylene blue (MB) from an aqueous solution via adsorption process. The synthesized MSp was characterized by FT-IR and FESEM analyses. The effects of pH 2 - pH 8, sorbent dosage (10 mg - 50 mg), and contact time (0 - 60 min) were studied in batch mode and optimized. Adsorption isotherms models, Langmuir and Freundlich were used to simulate the equilibrium data. The Freundlich isotherm model is best fitted with the experimental data compared to the Langmuir model. A maximum absorption capacity (q_m) of 6.357 mg/g was obtained for MB. In addition, pseudo-first-order and pseudo-second-order were used to study the kinetics of MB adsorption onto MSp. The dye adsorption process obeyed the pseudo-second-order kinetic expression as proven by the high correlation coefficient (R^2 = 0.999). Overall, these findings confirmed the potential of MSp as an alternative and efficient sorbent for the removal of MB dye, offering promising prospects for wastewater treatment applications.

Abstrak

Proses penjerapan menggunakan penjerap kos rendah seperti penjerap bio-polimer merupakan pilihan yang menarik untuk penyingkiran metilena biru daripada air sisa. Kajian ini melibatkan sintesis sporopollenin magnetik (MSp) dan aplikasinya untuk penyingkiran metilena biru (MB) daripada larutan akueus melalui proses penjerapan. MSp yang disintesis dicirikan oleh analisis FT-IR dan FESEM. Kesan pH 2 - pH 8, dos sorben (10 mg - 50 mg), dan masa dikaji (0 - 60 min) dalam mod kelompok dan dioptimumkan. Model isoterma penjerapan, Langmuir dan Freundlich digunakan untuk mensimulasikan data keseimbangan. Model isoterma Freundlich paling sesuai dengan data eksperimen berbanding dengan model Langmuir. Kapasiti penyerapan maksimum (q_m) sebanyak 6.357 mg/g diperolehi untuk MB. Di samping itu, pseudo-tertib pertama dan pseudo-tertib-kedua digunakan untuk mengkaji kinetik penjerapan MB ke MSp. Proses penjerapan pewarna mematuhi ekspresi kinetik pseudo-tertib-

kedua seperti yang dibuktikan oleh pekali korelasi tinggi (R^2 = 0.999). Secara keseluruhan, penemuan ini mengesahkan potensi MSp sebagai sorben alternatif dan cekap untuk penyingkiran pewarna MB, menawarkan prospek yang menjanjikan untuk aplikasi rawatan air sisa.

Introduction

Recently, the abundance of pollutants in water has become a severe environmental issue. Amongst the industrial activities, dyeing industries are aggressively moving forward because of the extensive use of dyes in manufacturing industries, such as food, textile, paper, and plastic. Until now, more than 100,000 synthetic dyes have been produced, creating significant problems for the environment and human beings due to their toxicity and mutagenic effects [1]. The removal of synthetic dyes is an important concern as the incomplete degradation of dyes causes the production of carcinogenic and harmful amines [2]. Furthermore, the presence of color substances in the water may decrease light transmission and photosynthesis activity, leading to bacteria growth and hence inhibiting the growth of the plant and aquatic ecosystem in the water [3].

Methylene blue (MB) dye is a cationic dye commonly used in the industry's coloring processes. It also has broader applications, including usage as a temporary hair colorant, a colorant for cotton and wools, and a coating for paper stock. MB has been classified as a non-biodegradable dye and needs to be treated before being discharged into the environment [1]. MB can cause harmful side effects to humans, such as vomiting, shock, increased heart rate, and jaundice in newborn babies.

Many treatment techniques have been applied to different types of water and wastewater contaminated with dyes. These treatment techniques, include physical or chemical treatment processes. Treatment processes, include chemical coagulation [4], ozonation [5], oxidation [6], photodegradation [7], ion exchange [8], irradiation [9], nanofiltration [10], and adsorption [11]. Unfortunately, several of these techniques are costly, require various tools, and have limitations. Based on the literature [12], low-cost sorbent has been developed as an alternative for dye removal. Several low-cost adsorbents have been investigated for dye removal such as wood waste activated carbon [13], olive oil activated carbon [14], apricot stone activated carbon [15], weeds activated biochar [16], and ZnO-nano rods-activated carbon [17].

With the prevalence of adsorption as an essential technique for purifying dye-contaminated wastewater, the development of magnetic nanoparticles (MNPs) sorbent materials such as magnetite (Fe_3O_4) has gained notable recognition in water purification [18]. It is based on the advantages of having a simple manipulation process, high separation efficiency under an external magnetic field, and easy functional modifications for specificity and operation conditions [19]. Moreover, the high surface area-to-volume ratio properties possessed by MNPs ensure a better adsorption capacity and high recovery compared to other sorbents [20]. Nevertheless, adsorption also has a certain limitation that needs to be countered. For example, separation and recovery processes. After adsorption, separating the adsorbent from the solution can be challenging, especially when dealing with fine particles or colloidal materials. Thus, this process often requires additional filtration or centrifugation steps. Next, limitation is the environmental impact which some traditional adsorbents may have environmental implications due to their non-biodegradability or potential release of toxic substances during the adsorption process. Hence, these issues need to be countered properly.

Sporopollenin is a natural bio-polymer obtained from *Lycopodium clavatum*, which is highly resistant to chemical reactions, has a stable chemical structure and occurs naturally as a component of spore walls [21]. Furthermore, sporopollenin exhibits significant stability even after prolonged exposure to mineral acids and alkaline. Due to its efficiency and biocompatibility, sporopollenin is a well-known potential biomaterial used to remove various types of dye from the aqueous solutions. Sunset yellow [22], methyl orange [23], crystal violet [24] and Rhodamine B [25] have been successfully absorbed from an aqueous solution by

sporopollenin and its derivatives. Moreover, biopolymer sporopollenin is typically biodegradable, minimizing the environmental impact associated with the disposal of used adsorbents.

Sporopollenin loaded with magnetic functionality increases the total efficiency of the adsorption process and helps facilitate fast recovery. By incorporating magnetic nanoparticles or attaching magnetic moieties to the bio-polymer sporopollenin, it becomes responsive to external magnetic fields. This enables easy separation and recovery of the adsorbent from the solution by using a magnetic field, simplifying the overall process. Hence, a composite made from magnetic material is a suitable sorbent and thus a potential candidate for the removal of MB. A simple method for loading sporopollenin microcapsules with nanoparticles and insoluble salts is through a chemical reaction or a precipitation process that generates the encapsulated compounds inside the sporopollenin shell. This method produced magnetic sporopollenin loaded with magnetite nanoparticles and low solubility of organic salts [26].

Magnetic sporopollenin (MSp) was prepared as adsorbents in this study to remove MB dyes (Figure 1) from an aqueous solution. Two models, Langmuir and Freundlich, were used to describe the sorption process of MB adsorption onto the magnetic sporopollenin. Furthermore, the kinetics of MB adsorption onto the magnetic sporopollenin was investigated by using a pseudo-first-order and a pseudo-second-order models.

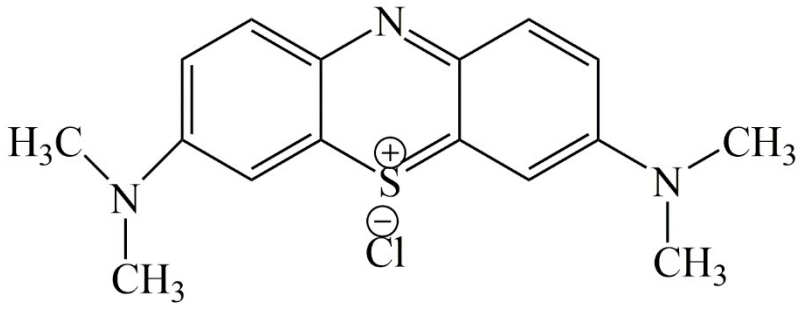

Figure 1. Structure of methylene blue (MB)

Materials and Methods

Materials

Analytical grade ammonia, ethanol, hydrochloric acid and sodium hydroxide pellet were purchased from Merck (Darmstadt, Germany) and used without further purification. Ferrous chloride tetrahydrate (CAS no. 13478-10-9) and ferric chloride hexahydrate (CAS no. 10025-77-1) were obtained from Sigma-Aldrich (Steinheim, Germany). All commercial grade solvents were stored over molecular sieves (4 Å, 8–12 mesh) from Aldrich (Steinheim, Germany). *Lycopodium clavatum* with a particle size of 25 µm was purchased from Aldrich (Steinheim, Germany). Methylene blue was obtained from Merck (Steinheim, Germany). The pH of the solution was adjusted by mixing an appropriate amount of HCl and/or NaOH (0.1 M). Deionized water that passed through a Milli-Q system (Lake End, UK) was used to prepare the solutions.

Instrumentation

Fourier transform infrared (FTIR) spectrometry (Spectrum 400 Perkin Elmer, Waltham, MA, USA) utilizing the ATR technique. Field emission scanning electron microscopy (FESEM) analysis was performed by using scanning electronic microscopy (HITACHI SU8220), OXFORD Instrument (Oxfordshire, UK). Ultraviolet-Visible (UV-Vis) spectrophotometer (Shimadzu, Tokyo, Japan) equipped with 1 cm quartz cells.

Preparation of magnetic sporopollenin (MSp)

MSp was prepared as follows: 13.32 g $FeCl_3.6H_2O$, 19.88 g $FeCl_2.4H_2O$, 5 mL of 5M HCl, 40 mL deionized water and 5 mL of ethanol were mixed in a 100 mL flask. The solution was stirred at room temperature until a complete dissolution of the salts. Then, 1.0 g of the

freshly prepared sporopollenin was redispersed in 30 mL of this solution and stirred for 2 h at room temperature. The sporopollenin suspension was filtered, and the filtrate was quickly washed with deionized water and immediately transferred to a 1.0 M ammonia solution. After 2 h stirring at room temperature, the MSp (with a core of magnetic nanoparticles) were collected by neodymium magnet, washed thoroughly with deionized water, and dried under vacuum. Figure 2 shows the preparation of MSp sorbent.

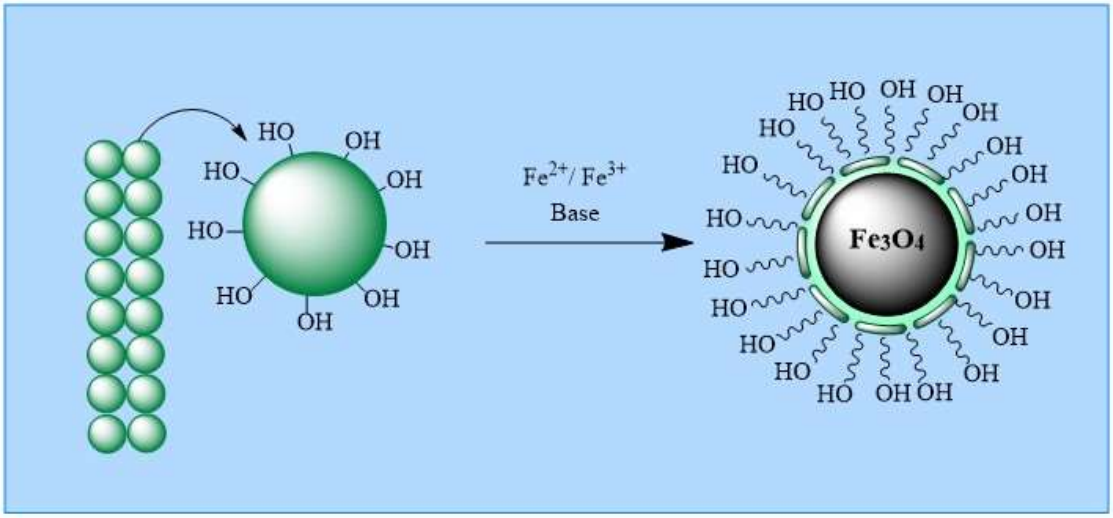

Figure 2. Synthesis of magnetic sporopollenin (MSp)

Sorption study

The batch sorption study was carried out to evaluate the MB removal efficiency of MSp sorbent. Different parameters, such as sorbent dosage (10 mg - 50 mg), pH (pH 2 - pH 8), and contact time (0 - 60 min) were optimized to achieve the optimum sorption results. The experiments were conducted in 25 mL Erlenmeyer flasks with glass caps containing the amount of the sorbent and concentration of sorbate solution, i.e., 5 ppm aqueous solution of MB. The Erlenmeyer flasks were stirred on a horizontal shaker operating at a constant speed (100 rpm) at room temperature for 10 min to obtain sorption equilibrium. Then, the sorbent was removed before measurement by using an external magnet. The MB concentration before the treatment and the residual concentration of MB in the aqueous phase after the treatment was analysed through UV-Vis spectrophotometer at 664 nm. The percentage removal and adsorption capacity of MB utilizing the synthesized MSp were calculated using Eq.1 and Eq.2, respectively. The percentage removal and q_e of MB were calculated through Eq. (1) as follows:

$$\frac{C_i - C_f}{C_i} \times 100\ \% \quad (1)$$

Where, C_i (mol L^{-1}) is initial concentration of MB before sorption, and C_f (mol L^{-1}) is final concentration of MB after adsorption.

$$q_e = \frac{V\,(C_0 - C_e)}{W} \quad (2)$$

Where, q_e is adsorption capacity (mg g^{-1}), V is aqueous volume (L), W is adsorption dosage (mg), and C_e (mol L^{-1}) and C_o (mol L^{-1}) are residual and initial concentrations of MB.

Results and Discussion

Characterization of adsorbent

The FTIR spectra provided information about the presence of functional groups. The FT-IR spectra for the synthesized MSp and sporopollenin were similar except for the characteristic peaks near 570 cm^{-1}, corresponding to (–Fe-O) bond stretching in Fe_3O_4. This characteristic peak showed that the sporopollenin was successfully magnetized with Fe_3O_4 [27]. The remaining peaks with their corresponding assignment were as follow: 3289 cm^{-1} (–OH), 1646 cm^{-1} (–C=O), 1546 cm^{-1} (–C=C), 1442 cm^{-1} (–C-C), 1260 cm^{-1} and 1113 cm^{-1} (–C-O) as shown in Figure 3.

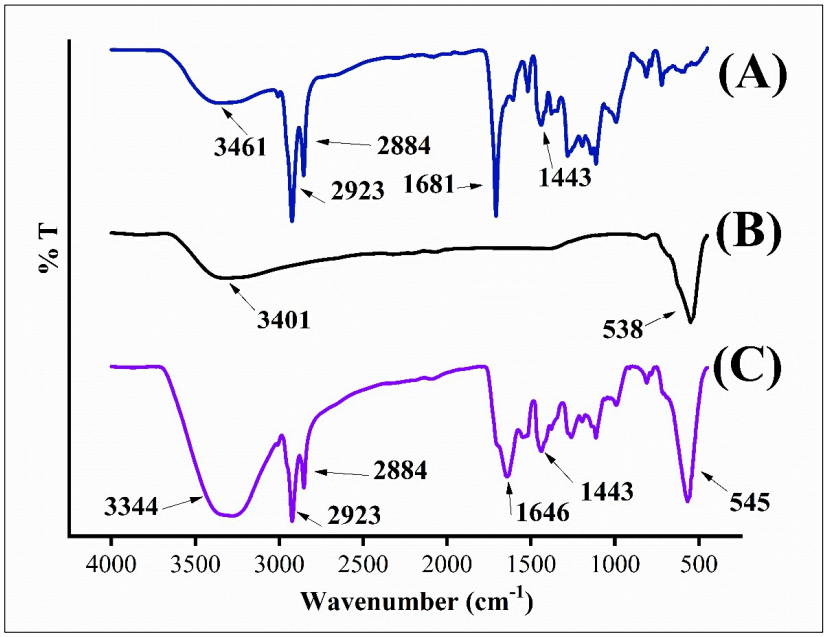

Figure 3. FTIR spectra of (a) raw Sp, (b) MNP, and (c) MSp

Field emission scanning electron microscopy (FESEM) is widely used to observe synthesized materials morphology and size distribution. FESEM images in Figure 4(a) show an open uniform pores structure and smooth surface morphology of sporopollenin. Meanwhile, Figure 4(b) shows a surface loaded with magnetic nanoparticles, which caused the change of porous structure to become limpid. This scenario confirmed that sporopollenin's surface has been successfully magnetized and was predominantly localized with magnetic nanoparticles [28].

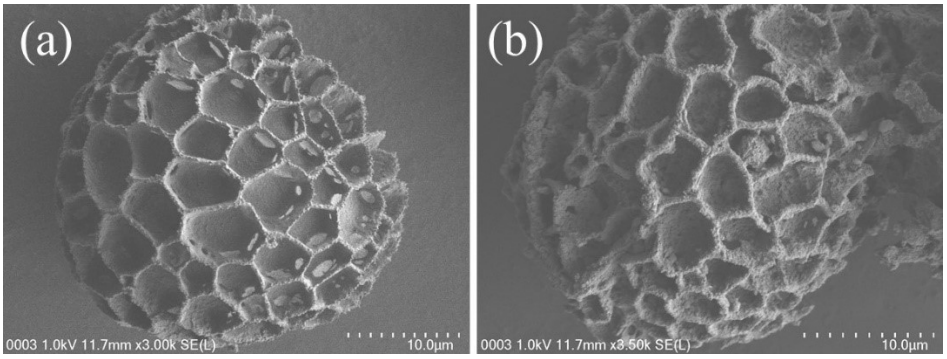

Figure 4. FESEM images of (a) sporopollenin and (b) MSp

Optimization of effective parameters on the removal of MB: Effect of sorbent dosage

Figure 4(a) shows the sorbent dosage's effect on MB adsorption. From the results, the percentage of MB removal increased rapidly from 61% to 90%, with increasing sorbent mass from 10 mg to 50 mg. The removal of MB was greater with the increase of sorbent dosage due to more available sites for adsorption. The amount of sorbent for further adsorption experiments was selected as 30 mg because beyond this point; there was no signification increase in adsorption of the MB. Therefore, all experiments were carried out with a fixed amount of 30 mg sorbent.

Effect of solution pH

This study investigated the effect of solution pH on the removal of MB (Figure 5b) at different pH ranges. The removal of MB increased with the pH of the solution from pH 2 to pH 8. Above pH 8, the removal of MB reached an equilibrium. This was due to the cation exchange between the sorbent and dye solution. The reported pH_{zpc} for MNP was pH 6.5 [29]. Beyond the pH_{zpc} point, the sorbent surface was in its protonated form, resulting in electrostatic repulsion between the positively charged MB and the sorbent surface. The higher amount of hydrogen ions in the solution prevented the negative charge formation on the MSp surface; thus, reducing the dye uptake. Above the pH_{zpc} point, the sorbent surface deprotonated the hydroxyl groups on the surface of MSp and provided more negative sites for electrostatic attraction between the cationic form of the dye molecules and the sorbent surface. Percentage removal was higher at this point; thus, the optimum pH for the maximum adsorption capacity of MB was determined to be pH 8.

Effect of contact time

Figure 5(c) shows that the amount of MB adsorbed (mg/g) increased with the contact time as predicted. During the first 5 min of the adsorption process, the percentage removal rapidly increased. As the contact time increased to 10 min, the adsorption of MB dye reached a maximum level and achieved an equilibrium. By further increment from 10 min to 60 min, the percentage of removal showed no significant changes that could be due to saturated binding sites on surface of MSp. Thus, 10 min was sufficient for removing MB and selected as the optimum contact time for further analysis.

Sorption isotherm

Adsorption isotherms described how analytes interact with sorbent materials in optimizing adsorbents. Therefore, the relationship between the removal ability of the material and the concentration of the contaminant solution can be illustrated by adsorption isotherms. It is crucial to establish the most appropriate correlation for the equilibrium curve to optimize the design of an adsorption system to remove dye from the solutions [30]. The investigation of the adsorption process was employed by Langmuir and Freundlich isotherm models. Furthermore, linearized forms of their equations have been used to describe the isotherm curves. The relative parameters of each equation were obtained by using the linear regressive analysis. In this study, the adsorption isotherm of MB by MSp was measured by shaking it for 10 min at different initial concentrations at pH 8 at room temperature.

The Langmuir isotherm suggested that sorption occurred on a homogeneous surface to obtain maximum adsorption capacity. No further adsorption process will occur if a solute occupies the site [31-32]. Langmuir isotherm models assumed the sorbate's monolayer coverage on a sorbent surface at a constant temperature. The linear fit of Langmuir for the adsorption of MB onto MSp is shown in Figure 6(a). The following equation represents the Langmuir isotherm:

$$\frac{C_e}{q_e} = \frac{C_e}{q_m} + \frac{1}{q_m b} \quad (3)$$

Where q_e is amount of solute sorbed on the surface of the sorbent, C_e is equilibrium ion concentration in the solution, q_m is maximum surface density at monolayer coverage, and b is Langmuir adsorption constant. The plot of $\frac{C_e}{q_e}$ vs. C_e for the sorption gives a straight line of slope $\frac{1}{q_o}$ (Figure 6a).

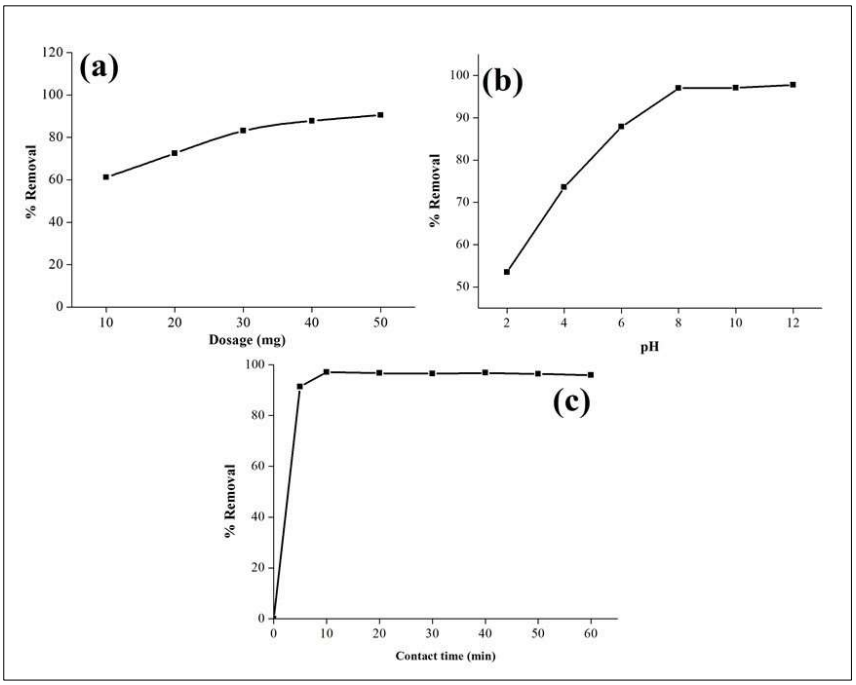

Figure 5. The effect of (a) dosage, (b) pH, and (c) contact time on the sorption of MB

The value of q_m, b and R^2 are presented in Table 1. The results indicated that the linear form of the Langmuir model showed a minimal deviation from the fitted equation as indicated by the R^2 value of 0.9637. This result suggested that the Langmuir model could not describe the relationship between the adsorbed amount of MB and its equilibrium concentration in the solution. Hence, the adsorption data would not follow the Langmuir model as compared to the Freundlich model.

Freundlich isotherm model suggested the sorbent surface heterogeneity with different energy of active sites and reversible adsorption which is restricted to multilayer formation. The Freundlich isotherm equation is shown as below:

$$\log q_e = \log K_F + \frac{1}{n}\log C_e \quad (4)$$

Where K_F and n are Freundlich constants related to the adsorption capacity and adsorption intensity, respectively. q_e is equilibrium solute concentration on sorbent, and C_e is equilibrium concentration of the solute.

The linear plot of $logq_e$ versus $logC_e$ for the Freundlich isotherm is shown in Figure 6(b). The constants of K_F and $1/n$ can be evaluated from the intercept and slope of the linear plot of experimental data are shown in Table 1. A larger value of K_F indicates the greater adsorption capacity while n values indicate the favourability of the adsorption process. If n is above unity, then the adsorption process is favourable.

The Freundlich isotherm plot was found to be linear over the studied concentration range, and the correlation coefficient (R^2 = 0.9988) obtained was higher than the Langmuir isotherm model. In addition, the Freundlich constant, K_F was 82.38 L/mg. In the present study, the value of n (indicative of favorability) is 1.476, which is above unity, indicating the favourability of the adsorption process. This showed that the interaction force between the MB dye and MSp sorbent was strong. Therefore, the Freundlich model is a good model to describe the adsorption data. The applicability of the

Freundlich adsorption model proposed the multilayer coverage of MB dye on the surface of MSp. Hence, the Freundlich model's experimental data indicated that the MSp surface's nature is heterogeneous with different adsorption sites.

Similarly, Boukhemkhem and Rida [33] reported a good adsorption potential (n = 4.17) for MB uptake modified Tamazert kaolin. The Freundlich model best fits to describe the adsorption of MB onto Tamazert kaolin relative to the Langmuir isotherm models implying multilayer adsorption onto a heterogeneous surface. In contrast, Mosleh and co-workers [34] reported magnetic sporopollenin supported polyaniline (MSP-PANI) for removal of lead ion (Pb^{2+}) was suitable for Langmuir isotherm with the maximum adsorption capacity of 163 mg/g and followed the monolayer pattern. Similarly, for magnetic sporopollenin supported magnesium nanocomposite (MSP@MgO) for removal of tetracycline (TCP) reported by Algethami and co-workers [35]. The adsorption models were investigated, and the process was fitted with the Langmuir model with adsorption capacities of 110 mg/g. Overall, the isotherm mechanism depended on the nature of the interactions between the adsorbent and the adsorbate.

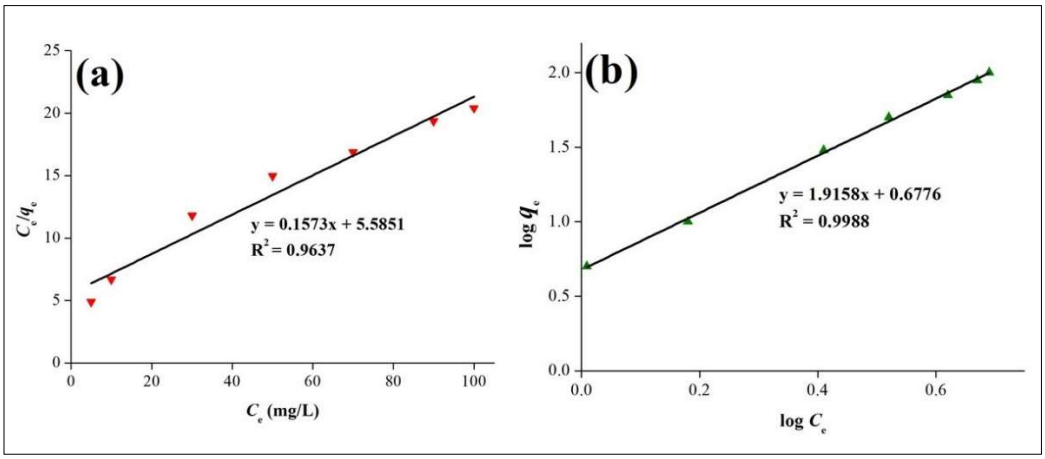

Figure 6. (a) Langmuir isotherms; (b) Freundlich isotherms for removal of MB by MSp

Table 1. Isotherm constants and regression data for adsorption of MB onto MSp at room temperature

Langmuir Constant			Freundlich Constant		
q_m (mg/g)	b (L/mg)	R^2	K_F (L/mg)	n	R^2
6.357	0.027	0.9637	82.38	1.476	0.9988

Sorption kinetics

Adsorption kinetics can describe a relationship between the amount of MB dye adsorbed to MSp in the aqueous solution. The analysis of the kinetic data is essential to generate an equation that accurately represents the results and could be used for design purposes [36]. The adsorption of MB dye onto MSp was further studied in terms of the kinetic model via pseudo-first-order and pseudo-second-order equations. The boundary layer resistance will be affected by the rate of adsorption with an increase in the contact time, which will increase the mobility of the adsorbate during adsorption. Since the uptake of adsorbates at the active sites of MSp is a rapid process, the adsorption rate is governed mainly by either the liquid phase mass transfer or the rate of intraparticle mass transfer.

Pseudo-first-order model

The pseudo-first-order model rate is based on the sorption capacity of the sorbent. The first-order model is

extensively applied for the adsorption of any solute from solution by the standard exchange procedure, which is fast and is mainly controlled by diffusion [37]. The plots of log ($q_e - q_t$) versus *t* are shown in Figure 7. The pseudo-first-order equation is expressed as:

$$log\ (q_e - q_t) = log\ q_e - K_1 t \quad (5)$$

Where, q_e and q_t are amounts of MB (mg g^{-1}) absorbed at equilibrium and at the time, *t,* respectively and K_1 is first order rate constant (min^{-1}). The values of q_e and K_1 are obtained from the linearity of pseudo-first-order rate by plotting $log\ (q_e - q_t)$ versus time, *t*.

The rate constant, K_1 and q_e are tabulated in Table 2. From Table 2, the value of R^2 = 0.7465 was low. Also, the calculated equilibrium adsorption capacities ($q_{e\ cal}$) by MSp was 0.276 mg/g, which is not consistent with the experimental data (q_e = 4.855 mg/g); hence this value is not in good agreement. This showed that the adsorption of MB onto MSp is not based on first-order kinetics.

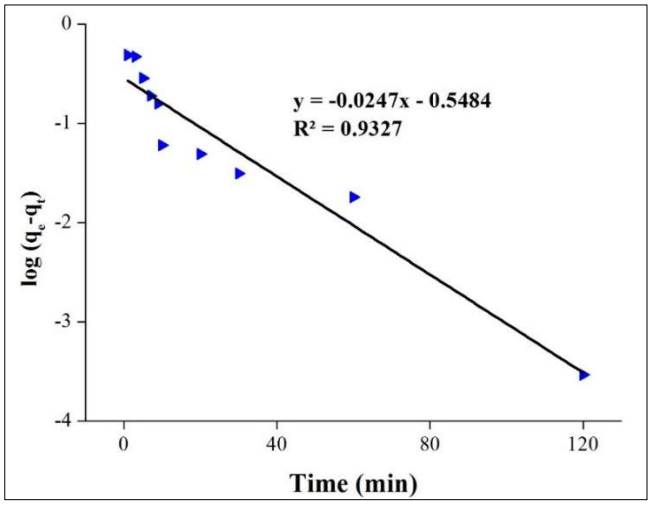

Figure 7. Pseudo-first order kinetic of MB.

Pseudo-second-order model

On the other hand, the pseudo-second-order model proposes that chemisorption is the rate-limiting step and that adsorption occurs on localized sites where no interactions between adsorbates arise [36]. Figure 8 shows the linear plots for the initial concentration studied.

The pseudo-second-order kinetic model applied for analyzing chemisorption kinetics from liquid solutions can be represented by Eq. (6) as follows.

$$\frac{t}{q_t} = \frac{1}{K_2 q_e^2} + \frac{t}{q_e} \quad (6)$$

Where K_2 is rate constant of pseudo-second-order adsorption (g/mg min). The value of K_2 and q_e can be described from the slope and the intercept of the graph $\frac{t}{q_t}$ versus t, respectively.

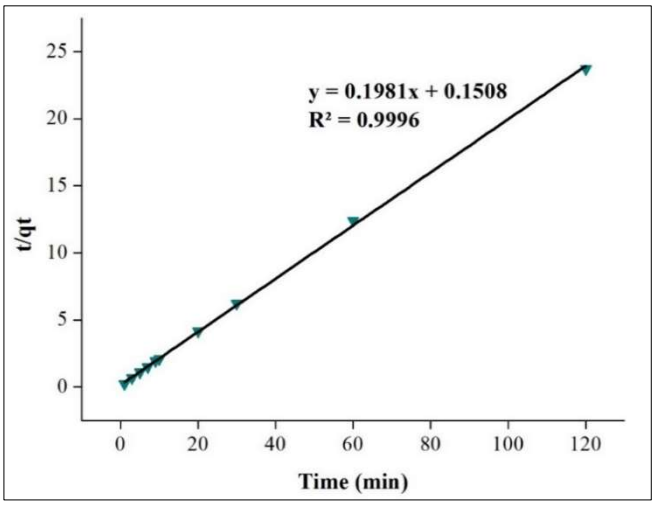

Figure 8. Pseudo-second order kinetic of MB

From Table. 2, the correlation coefficient (R^2) for the pseudo-second-order model is better (0.9996) than the pseudo-first-order model. The calculated equilibrium adsorption capacities ($q_{e\,cal}$) by MSp was found to be 4.684 mg/g, which is consistent with the experimental data ($q_{e\,exp}$ = 4.855 mg/g). A comparison between the calculated ($q_{e\,cal}$) and experimental ($q_{e\,exp}$) adsorption capacities revealed the pseudo-second-order model high applicability to describe the sorption process. Hence, the adsorption of MB onto MSp indicated that the adsorption kinetic is better represented by the pseudo-second-order model. Because of these results, it can be said that the pseudo-second-order kinetic model provided a good correlation for the adsorption of MB onto MSp in contrast to the pseudo-first-order model. This trend showed that the electron sharing between adsorbate and adsorbent is suited to uptake MB from aqueous media with high efficiency [38]. Numerous authors have reported similar pseudo-second-order kinetics, for adsorption of MB on different adsorbents, such as polyvinyl alcohol/carboxymethyl cellulose isolated from pineapple peel (PVA/CMC/GO/bentonite) [39], carboxymethyl cellulose-acrylamide-graphene oxide (CMC/AAm-GO) [40], and chitosan-g-poly(acrylic acid) modified cellulose nanowhiskers (Chitosan-g-PAA/CNW) [41].

Table 2. Kinetic parameters for adsorption of MB onto MSp

C_0	$q_{e\,exp}$ (mg/g)	Pseudo-First-Order Model			Pseudo-Second-Order Model		
		q_e (mg/g)	K_1 (1/min)	R^2	q_e (mg/g)	K_2	R^2
30	4.855	0.276	0.055	0.7465	4.684	0.855	0.9996

Comparison of sorption capacities of MSp with other adsorbents for MB removal

A comparison between MSp and other reported adsorbents in the literature is listed in Table 3. The performances were evaluated regarding the adsorption capacities. The data showed that the sorption capacity of MSp is relatively high as compared to other common sorbents except for several adsorbents such as spent rice biomass.

Table 3. The sorption capacities of the proposed MSp compared to other common adsorbents for the removal of MB

Adsorbent	Type of Analyte	Sorption Capacities (mg/g)	Ref
Glass wool	MB	2.20	[42]
Cashew nutshell	MB	5.31	[43]
Pyrolyzed petrified sediment	MB	2.39	[44]
Spent rice biomass	MB	8.30	[45]
Coir pith carbon	MB	5.87	[46]
Mansonia wood sawdust	MB	15.32	[47]
Padina sanctae-crucis	Methyl violet	10.02	[48]
Calcined lotus leaf	Methyl violet	26.32	[49]
Walnut shells	MB & methyl violet	6.5	[50]
Magnetic sporopollenin (MSp)	MB	6.4	This study

Conclusion

This study offered a unique method for removing methylene blue (MB) from aqueous solutions by implementing the economical adsorbent magnetic bio-polymer sporopollenin (MSp). The successful synthesis of MSp is confirmed by characterization by using FESEM analysis and FTIR spectroscopy. The optimum adsorption capacity of MB was achieved, and investigation of adsorption mechanisms sorption isotherms and isotherm kinetics revealed the Freundlich model and pseudo-second-order providing the best fit with the multilayer sorption on a heterogeneous surface. Some future prospects can be considered, including incorporating sporopollenin into polymer-based matrices, such as hydrogels or composite materials, to create hybrid adsorbents. The porous nature and flexibility of polymer matrices can enhance the adsorption capacity and stability of sporopollenin, making it suitable for various applications. Additional isotherm models, such as the Temkin model, Hasley model and Dubinin-Radushkevich isotherms model can be done to provide further insights into the adsorption behavior of methylene blue. These models can help characterize the energetic heterogeneity of the adsorbent surface, assess the feasibility of adsorption processes, and improve the understanding of the adsorption mechanisms. Lastly, in terms of regeneration and reusability to investigate the regeneration potential of MSp after MB adsorption. This is to ensure the restoration of the adsorption capacity of MSp, allowing for its repeated use and reducing overall operational costs.

Abstract

Dyes are widely used as coloring agents globally in the industrial field, especially in the textile industry. As proof, 10,000 types of dyes have been introduced and are continuously used, reaching a usage viability of 700,000 tons. The widespread use of synthetic dyes is caused by their economic factors, ready availability, superior strength, and ability to cover a wide range of shades. However, the discharge of commercial dyes is increasing at a swift rate as industrialization continues to grow, leading to severe hazards to living organisms due to their toxic and harmful impacts. The discharge of dyes into water reservoirs is a concern because of their high toxicity and bioaccumulation in living organisms. One of the most used commercial dyes, azo dyes, possesses a benzidine function that needs to be treated soon due to its side effects. Dyes contain toxicity and have a strong tendency toward eutrophication. The major globally concerned issues are water and soil pollution. The massive use of these dyes in industrial sectors is the main reason behind these environmental issues. Even at concentrations lower than one ppm, around 10% of the untreated discharged dyes impart an intense color, making the water highly detrimental. As an unwanted consequence, this exhibits an immense environmental hazard to the surroundings. Thorough studies on dye metabolites and their constituents have been developed to reduce the acute diverse effects of dyes. However, a few outdated techniques such as ozonation and chlorination are still being utilized to break down untreated dye discharge for various reasons, including economic factors. In this review, the ability of the green oxidation catalysis method of degradation to degrade dye is reviewed owing to its eco-friendliness and safety.

Keywords: azo dyes, green oxidation, catalysis, degradation of dyes, toxicity

Abstrak

Pewarna telah digunakan secara meluas sebagai agen pewarna di dalam bidang industri global, terutamanya di dalam bidang tekstil. Buktinya, terdapat 10,000 jenis pewarna telah diperkenalkan dan digunakan secara berterusan sehingga mencapai tahap penggunaan 700,000 tan. Penggunaan pewarna sintetik yang secara meluas adalah disebabkan faktor ekonominya yang sedia ada, kekuatan yang unggul, dan kebolehan untuk meliputi julat warna. Pembuangan pewarna komersil telah meningkat secara pantas selari dengan kadar pertumbuhan perindustrian, menyebabkan risiko yang serius kepada hidupan bernyawa telah dikenal pasti kerana impak pewarna yang toksik dan berbahaya. Pembuangan pewarna di dalam takungan air diberi perhatian kerana kesan toksik yang tinggi dan bioakumulasi dalam hidupan bernyawa. Pewarna komersil yang sangat biasa digunakan, pewarna azo memiliki fungsi benzidine yang perlu dirawat dengan segera kerana kesan sampingannya. Pewarna mempunyai toksik yang tinggi dan mempunyai kecenderungan yang kuat terhadap eutrofikasi. Isu utama yang menjadi perhatian secara global adalah pencemaran air dan tanah. Penggunaan perwarna secara berleluasa dalam sektor industri adalah punca utama isu pencemaran ini berlaku. Walaupun pada kepekatan bawah daripada 1 ppm, sekitar 10% pewarna yang dibuang dan tidak dirawat menghasilkan warna yang terang yang menyebabkan kandungan air menjadi sangat berbahaya. Sebagai kesan yang tidak diingini, bahan ini menunjukkan bahaya kepada alam sekitar dan sekelilingnya. Satu kajian yang mendalam mengenai metabolit pewarna dan unsur-unsur ini telah dibangunkan untuk mengurangkan pelbagai kesan pewarna yang berbahaya. Walau bagaimanapun, beberapa teknik yang lama seperti pengozonan dan pengklorinan masih digunakan untuk merawat pewarna yang dibuang dan tidak dirawat atas beberapa faktor termasuk faktor ekonomi. Dalam ulasan ini, kebolehan cara pemangkinan pengoksidaan hijau untuk degradasi pewarna diulaskan kerana ianya mesra alam dan selamat.

Kata kunci: pewarna azo, pengoksidaan hijau, pemangkinan, degradasi pewarna, ketoksikan

Introduction

The critical part of natural dye removal is using the appropriate method without creating environmental problems. As it is known, textile dyes discharge uncountable effluents that extant significant ecological issues. These effluents are mostly from dye manufacturing and textile wet processing industries. About 7 x 107 tons of synthetic dyes are produced annually worldwide, with over 10 000 tons of dyes being used by textile industries [1]. The discharge of dye is likely to rise phenomenally due to the growth in fiber consumption worldwide, such as wool, silk, and leather, which are included in the usage of clothes and bags, among others. Almost all modern dyes are degradation resistant and chemically stable by bleach, sunlight, water, and perspiration in a brief time or even a lifetime [2]. Since its structure contains an aromatic and -N=N- group, it harms the environment by being highly toxic, carcinogenic, and teratogenic [3]. The degradation of the dye-effluent-containing wastewater is quite tricky due to its resistance. Azo dyes are synthetic and organic chemical compounds applied in many industries, such as fabrics, medicine, food, and cosmetics. In addition, azo dyes contain combinations of the azo group chemically represented as (R-N = N-R'), with (-N=N-). Examples of azo dyes are orange (II), tartrazine, Congo red, eriochrome black T, methylene blue, and brilliant green [4]. Dyes in wastewater, especially azo dyes like Orange (II), create aesthetic problem [2] that limits the usage of the water and lessens the effectiveness of wastewater treatment using microbiological method due to its toxicity to the environment and harm to organisms [5].

There are physical, chemical, and biological methods to degrade dyes. One of the commonly used physical methods is adsorption, which is performed by removing organic compounds in water involving separating substances from one phase to the surface of another. Adsorption using activated carbon is an efficient process for organic micro-pollutant removals such as pesticides, fertilizers, cosmetics, pharmaceuticals, and personal care products, which are deployed by porous materials [6]. However, the cost of production, as well as the regeneration of activated carbon, is expensive. Various chemical methods have been employed by breaking the chemical bond, such as the azo bond, for degradation and decolorization of the dyes. Examples of chemical methods include ozonation, the Fenton reagent method, and photocatalytic reactions. The drawbacks of chemical methods are their less efficiency, limited versatility, high cost, and utilize a significant amount of energy. Abundant studies and research have taken severe actions, especially in attempting new methods for

wastewater purifying treatment with less chemical impact on nature in terms of economically controlled [7]. An escalating number of contaminants continuously flow into the water supply annually, ranging from common contaminants like heavy metals to emerging micro-pollutants such as nitrosamines and endocrine disruptor compounds [7].

The possible method that can be conducted to overcome this kind of drawback is the application of green chemistry with the use of green oxidation catalyst technique through the Fe (III)–TAML-H_2O_2 system. Green oxidation technique is a technique that uses an oxidizing agent, which is safer towards the environment since it consumes less energy, low cost, and is environmentally friendly. The oxidizing agent usually oxidizes dye and eventually degrades its color. With current concerns regarding the treatment of dye effluents, there is an urgent need for a much greener degradation of pollutants. Besides being the greener method, it is also efficient, as proven by research that dye and other contaminants including 17α-ethynyl estradiol can be 100% degraded using this method [8]. In conclusion, it can be proved that Fe (III)-TAML-H_2O_2 systems have substantial potential in providing a greener technology.

Common azo dyes

Orange (II)

Orange (II) dye with IUPAC name [*p*-(2-hydroxy-1-naphthylazo) benzenesulfonic acid sodium salt]$^+$ as shown in Figure 1 with a molecular formula of $C_{16}H_{11}N_2NaO_4S$ is a most common anionic dye that is water soluble. (Usage) It is commonly used in industry for a range of raw materials such as nylon, aluminum, cosmetics, wool, silk, and detergents [9]. (Harmful effect) The orange (II) dye causes severe health issues in humans. The toxicity of orange (II) dye can cause upper respiratory tract, mucous membrane, eye, and skin irritation after ingestion. It can also lead to anemia, which can cause severe nausea, headaches, and water-borne diseases such as bone marrow loss [9]. Chronic toxicity is developed from the electron-withdrawing character of the azo group, which causes electron deficiency and reduces to carcinogenic amino compounds [10]. However, it is proven that azo dyes are able to permeate.

Organisms affect their metabolic processes by reacting with reducible chemicals produced. Production of 1-amino-2-naphthol from reduced Orange (II) dye can stimulate tumors in the bladder. In addition, Orange (II) dye can undergo enzymatic breakdown effortlessly and produce aromatic amines that can cause methemoglobinemia [11] and tend to oxidize the hem iron of hemoglobin from Fe(II) to Fe(III) and block oxygen-binding activity [12]. Besides, ingestion of Orange (II) dye is considered genotoxic [9]. Therefore, the dye needs to be removed, especially from the environment, to prevent the toxicity of the dye. The toxicity and carcinogenic nature are shown by removing Orange (II) dye by biodegradation and photosensitization on TiO_2 particles. The biodegradation of Orange (II) dye is carcinogenic towards the metabolic intermediates [2]. The generation of toxic intermediates during the process is possible and most likely to occur from the high solubility of the dye in water. There are some works of orange (II) dye removal reported. However, most of them revealed some side effects and need to be more environmentally friendly. Several degradation methods used in the degradation of Orange (II) dye include Fenton's reagent, photocatalyst, and heterogeneous [13].

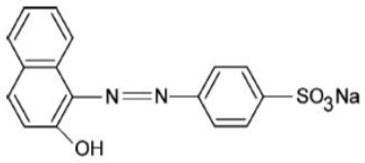

Figure 1. Structure of Orange (II) [p-(2-hydroxy-1-naphtlyazo) benzene sulfonic acid sodium salt]

Tartrazine

Tartrazine (Yellow Dye No.5), as shown in Figure 2, is an anionic azo dye widely used in the food industry as a coloring agent. Tartrazine originates from coal tar, which has been identified to have high toxicity and the ability to cause mutations in living things due to its high solubility in water. The high solubility in water makes the tartrazine interact with the body and form allergic reactions when in contact with the cellular processes in the body. Tartrazine is potentially phototoxic [14] and

proved as a possible cause of angioedema, urticaria, and asthma [15]. Since food azo dyes are not eco-friendly [16] as it is non-biodegradable, the conventional biological treatment processes are inefficient for degrading these dyes in wastewater. Hence, physio-chemical processes are typically used for azo dyes wastewater treatment. However, the removal processes produce a lump of sludge that requires good treatment. This dye has been degraded by the benzoic acid/TiO_2 system with 99.08% removal within 90 minutes [17]. The optimum H_2O_2 concentration for T degradation is 2 mM. Under experimental conditions, 95% of the T can be degraded by a novel Fe-composite (NZ-A-Fe) containing iron in a natural zeolite [18].

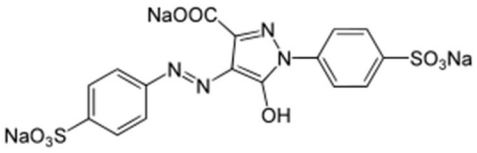

Figure 2. Chemical structure of tartrazine

Congo red

Figure 3 shows the structure of Congo red dye or knowns as sodium salt of 3,3′-([1,1′-biphenyl]-4,4′-diyl) bis (4-aminonaphthalene-1-sulfonic acid). Congo red is water soluble and yields a red colloidal solution. It is a well-known dye belonging to an anionic group commonly used in most industries, including the textile and paper industry. As an additional usage, it plays a vital role in diagnosing amyloidosis for amyloid as a pH indicator [19]. In addition, it also helps to detect free hydrochloric acid in gastric contents. Congo red adversely affects the human body, leading to diseases such as platelet aggregation, thrombocytopenia, and disseminated micro-embolism by lowering blood protein content [20]. Regarding this severe problem, several methods have been studied for successfully degrading Congo red using different nanomaterials [21] such as TiO_2 nanoparticles and bimetallic Fe–Zn nanoparticles [22].

The commonly used metallic nanoparticles such as Ru act as electron donors in azo bond conversion using a reducing agent through electron transfer. As desired results, the degradation rate of Congo red has increased by 200% [23]. Extract from Chinese spinach leaf, *Amaranthus gangeticus Linn,* has been used to synthesize silver nanoparticles with good catalytic efficiency by 50% within 15 minutes [24] for degrading Congo red dye. In addition, the biogenic silver nanoparticles with Senna leaf demonstrated 89.6% degradation of Congo red, onion silver nanoparticles, and acacia catechu with 96% and 97% degradation, respectively [25].

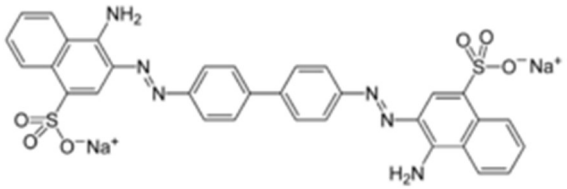

Figure 3. Chemical structure of Congo Red dye

Eriochrome Black T

Eriochrome Black T or Sodium 1-[1-Hydroxynaphthylazo]-6-nitro-2-naphthol-4-sulfonate structure is shown in Figure 4. It is commonly utilized in silk, wool, and nylon dyeing. It is also widely used in today's laboratories to determine the pre-accurate estimation of Zn^{2+}, Ca^{2+}, and Mg^{2+} ions [26]. Carcinogenic azo dye is one of the trademarks of Eriochrome Black T with its intermediate product called Naphthoquinone, which is toxic and not a desired product [27]. A severe problem has arisen worldwide for successfully treating Eriochrome Black T-containing effluent since it can potentially be harmful if not well treated [28]. Nevertheless, the breakdown of Eriochrome Black T has been carried out by numerous researches as a future need basis using different nanomaterials.

It was successfully found that the photocatalytic degradation of Eriochrome Black T has been enhanced to 88% with crystalline anatase TiO_2 under basic conditions around pH 11.0, which occurred from the higher concentration of hydroxyl radicals [29]. Generally, TiO_2 nanostructures of different shapes with Fe^{3+} and Pt^{4+} impregnation [30] successfully photodegraded Eriochrome Black T by about 82% within 90 mins under UV irradiation.

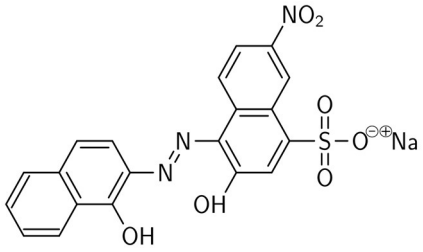

Figure 4. Chemical structure of Eriochrome Black T

Methylene blue

Methylthioninium chloride, commonly called Methylene blue, is a common thiazine dye used as a chemotherapeutic agent and anti-malarial in aquaculture [31]. The structure of methylene blue is shown in Figure 5 below. This dye gives side effects such as headache, shortness of breath, vomiting, high blood pressure, and allergic reaction [32]. Thiazine dye can effectively undergo degradation by a variety of nanomaterials, including copper-supported clay nanocomposite [33], ZnSe/Graphene nanocomposites, and titanium dioxide [34]. The implementation of Cu-supported organo-treated clay can result in the complete removal of the dye. However, 99.6% degradation efficiency has been obtained [35] using ZnSe/Graphene nanocomposites.

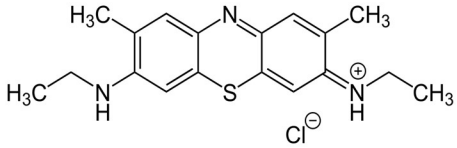

Figure 5. Chemical structure of methylene blue dye

Brilliant green

Brilliant green (zelyonka or zelenka), as shown in Figure 6, is a universally known cationic dye used as a biological stain and an antiseptic [36]. This dye displays an explicitly tremendous effect on gram-positive bacteria. This Brilliant green is highly carcinogenic to target organs and lungs after ingestion [37]. About 92% of the dye has been adsorbed by nano ferrites effectively under optimized conditions [38]. TiO_2 nanoparticles and Graphene oxide are usually doped with alkaline earth metal ions such as Sr^{2+}. Graphene oxide nanoparticles showed a degradation value of 93% in 10 min [39], while 96% of degradation efficiency was obtained when doped with TiO_2 nanoparticles within 1 hour [40].

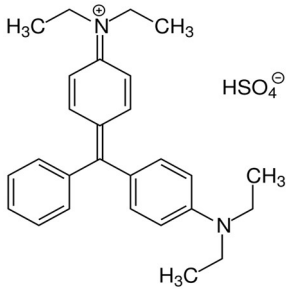

Figure 6. Chemical structure of the brilliant green dye

Current approach used in dye wastewater treatment place for dye degradation

Since dyes started being used in the textile industry, comprehensive treatment methods have yet to be introduced for dye wastewater treatment. As there are few techniques introduced since then, oxidation, anaerobic treatment, adsorption, and coagulation are majorly used methods in physical and chemical treatments for effluents containing various dyes. Therefore, there are some current approaches used in dye wastewater treatment places for dye degradation, which are direct chemical oxidation, oxidative processes with H_2O_2, ozonation, oxidation processes with sodium hypochlorite, photochemical oxidation process, electrochemical oxidation process, and combination of advanced chemical and biological processes.

Direct chemical oxidation

Direct chemical oxidation is an old conventional method for degrading water-soluble dyes in textile wastewater. Nonetheless, water-insoluble disperse dyes have chlorine decolorization resistance, making decolorization of reactive dyes require extended time for treatment. Moreover, dye chromophores with an amino or substituted amino group are susceptible to rapid chlorine decolorization. The chlorine treatment produces toxic chlorinated organics including halogenated hydrocarbons that harm humans and the environment [41]. The general advantages of chemical oxidation are rapid reaction rates, mineralization of organics, and removal of soluble and insoluble dyes, with the overall disadvantage of not being suitable for dispersed dyes. They release toxic compounds such as

aromatic amines and involve complex chemistry [42].

Oxidative processes with hydrogen peroxide

The oxidative process with hydrogen peroxide (H_2O_2) is an alternative wastewater treatment that has been done using two systems: a homogenous system and a heterogenous system [43]. A homogenous system uses UV light, chemical activators, and soluble catalysts (Fenton reagents). The Fenton reagent utilizes hydrogen peroxide, which is then activated by iron salts and Fe^{2+} salts. This is done without UV producing hydroxyl radicals (OH). These radicals are strong oxidants than H_2O_2 and ozone but are harmful to environments when released into thin air. At the same time, the heterogenous system uses semiconductors like TiO_2 and modified zeolites with Fe and Al, such as FeY11.5 and FeY5.

The homogenous catalytic oxidation demonstrated color removal of 56.20% at a pH of 4 for Remazol Rose RB and Remazol Arancio 3R dye-containing effluents [44] with a minimal 0.18 M of H_2O_2 and 1.45 mM of Fe^{2+}. Meanwhile, heterogenous catalytic oxidation led to color removal of 53% - 83% at pH 3-5 for Procion Marine H-pEXL dye-containing effluents [45] with H_2O_2 and FeY11.5 within 10 mins. As for H_2O_2 and FeY5 at pH= 5 using the same textile effluent in the treatment, 95% color removal was achieved within 10 min of oxidation and 97% for 60 min of oxidation [46].

Ozonation process

Ozonation is the most straightforward process, which depends on oxidizing agents and ozone. The ozone efficiently decomposes organic pollutants from industrial effluents and cleaves aromatic rings in textile dyes. Ozone with conjugated double bonds decomposes organic dyes and produces carcinogenic compounds. This process has most probably been used with a physical method to reduce its toxicity with extra costs required. Based on several studies, it was proven that ozone can react with dye molecules either directly or indirectly [47]. Since the ozone molecule is an electron acceptor, the hydroxide ions catalyze the ozone decomposition into hydroxyl radicals (·OH) in effluents through the direct pathway. However, due to its complicated process, the indirect path is not recommended for industrial dye degradation.

The main advantages of ozonation are that ozone does not affect wastewater in terms of volume and minimizes the production of extra sludge apart from its application in a gaseous state. The disadvantages of ozonation include its destabilization by the temperature, the short half-life of around 20 min, and the installation of an ozonation plant that requires additional cost. The combination with irradiation [48] improves the performance of ozonation. In a study, the treatment of wastewater containing dye effluent indicated color removal of 62% with ozone [49], followed by chemical coagulation using $Ca(OH)_2$.

Oxidation process with sodium hypochlorite

The oxidation process with sodium hypochlorite starts when the Cl^- ion attacks the amino group in the dye molecule, followed by initiation and azo-bond cleavage acceleration. This dye removal and decolorization process can be favored by increasing the chlorine concentration and decreasing pH [50]. The dye-containing amino or substituted amino groups on the naphthalene ring, such as naphtylamino-sulphonic acid and amino-naphthol, are most vulnerable to the decolorization of chlorine. Thus, this process is unsuitable for dispersing dye. The negative effect of this treatment is that it is prone to release aromatic amines and toxic molecules into water, making it a less desired treatment. Furthermore, pigments used worldwide contain chlorine of approximately 40% [51], while this method uses less than 0.02% of the total chlorine production.

Photochemical oxidation process

The presence of H_2O_2 is most necessary for the photochemical process. This process decomposes dye molecules into low-weight organic molecules such as water, carbon dioxide, hydrides, and inorganic oxides. The additional by-products produced are organic and inorganic acids, organic aldehydes, and halides, which vary depending on the initial materials used in decolorization treatment. The generation of hydroperoxide radicals is shown in Equation 1, while hydroxyl radicals as shown in Equation 2 will initiate the dye decomposition.

$$H_2O_2 + HO\cdot \rightarrow HO_2\cdot + H_2O \quad (1)$$

$$H_2O_2 + h\upsilon \rightarrow 2HO\cdot \quad (2)$$

The treatment is set up in a batch or continuous column unit and mainly depends on the dye structure, pH, and intensity of the UV radiation. This photo-oxidation treatment displayed color removal around 81% - 94% after 1 hour with 88 mM H_2O_2 with minimal pH at 4 [52] for Acid Red G dye-containing effluent.

Electrochemical oxidation process

The electrochemical treatment is a unique treatment that presents high removal efficiencies and pollution control for dispersed and metal complex dyes known as acid dyes. The oxidizing agent in the electrochemical process is hypochlorous acid or hypochlorite ion produced from naturally occurring chloride ions [53]. The by-products are commonly less hazardous than any other oxidation process discharged into the water without health precautions or environmental risks.

Some advantages of this treatment include the requirement of no additional chemicals, simplified operation, prevention of the production of unwanted by-products, and minimization of all emissions such as the emission of solid waste, liquid effluent, and gases [54]. Electrochemical oxidation is believed to be an economical and efficient treatment for recycling textile wastewater. However, since the metallic electrode in the cell generates metallic hydroxide, this process has usage limits.

The color removal for the effluent containing blue-26 anthraquinone dye demonstrated the highest percentage within 220 min of electrolysis, a higher rate at neutral pH of 7 using NaCl, and a current density of 4.5 A/dm^2 [55]. The color removal obtained was 95.2% for the same dye-containing effluent in a flow reactor working at a rate of 5 mL/min and a current density of 29.9 mA/cm^2.

Combination of advanced chemical and biological processes

Photodegradation and biodegradation are the most appropriate methods for degrading the harmful compounds in wastewater. Aromatic hydrocarbons and phenols use photodegradation to degrade effluents containing dye. Generally, the pollutants are eliminated using biodegradation by microbes. Implementation of chemical oxidation together with biological processes proves the enhancement of efficiency and lowers operating costs [56].

The process begins when H_2O_2 and Fe (II) are operated in optimum requirements in the combined process. At 25 °C, the biological reactor was operated for 10 cycles for 12 hours per cycle. After adjusting to neutral pH in the first cycle, the biological reactor was supplemented with 2.5 L of wastewater. Adding 2.5 L of activated sludge made the final volume 5 L. The reactor was supplemented with 2.5 L of effluent to compensate for the quantity of treated effluent released. Chemical Oxygen Demand (COD) and Dissolved Organic Carbon (DOC) were examined at the end of each cycle. Automatic unit control and data acquisition were attained using Lab View 5.0 software [57]. The advantages of this method are enhanced efficiency and lower operating costs. This system significantly achieved 99% of color removal, COD removal of 88%–98%, and 91%–98% of DOC removal. Furthermore, this combined system reduced operating costs by 24–39%. The by-products include DCIP reductase, veratryl alcohol oxidase, riboflavin reductase, azo reductase, and laccase. However, this method involves complicated processes with high maintenance costs.

Proposed approach in degradation of Orange (II) dye in wastewater

This part explains the oxidation of the Fe-TAMLs/ H_2O_2 System (Oxidative Catalysis), the general procedure for degradation of Orange II by Fe(III)TAML-H_2O_2, and toxicity measurements of Orange (II) dye. This method can potentially reduce cost as the reagent requirement can be decreased as oxidation efficiency.

Oxidation of Fe-TAMLs/ H_2O_2 system (oxidative catalysis)

Collins and Lenoir developed a landmark example based on a Fe (III) metal center coordinated to a tetra-amido macrocycle that coordinates the metal with four anionic amide groups (Fe-TAML). The activation of H_2O_2 acts as a terminal oxidant owing to its highly active characteristics toward the complete degradation of

different species in aqueous solutions such as resistant chlorinated phenol derivatives, water effluents, and dyes from paper industries [58]. This green oxidation method is a notable application involving the total degradation of organophosphorus pesticides such as Parathion and Fenitrothion with a prevalent agricultural use [59].

Iron (III)-Tetra Amidato Macrocyclic Ligand (TAML) is a unique catalyst suitable for commercialized industrial uses in wastewater treatment. The development of this catalyst started over 20 years, which revealed its unique properties. Common biochemical elements form this catalyst with little or no toxicity properties impacting its biodegradable functionalities. It has high stability in various ranges of pH and is also water-soluble. Besides, it is effective at minute concentrations from 0.1 to 4 ppm.

Fe-TAML catalysts that exhibit oxidation catalysis act as among the finest green catalysts [60]. The use of hydrogen peroxide as an essential source of oxidizing equivalent can be done flawlessly by TAML oxidant activators [61]. The oxidation mechanism of catalysis by Fe (III)-TAML is crucial for industrial and academic purposes. The synthetic oxidation catalyst process displays unprecedented selectivity and high reactivity water while utilizing environmentally friendly oxidants. This research could be a milestone in the further development of green chemistry in the future [61]. Green oxidation catalysis is a frontier at risk elimination for further development. Green procedures that decrease risk detoxify effluent streams and serve as substitutes for polluting processes have been used in several circumstances. Further improvement of TAML systems is potentially suitable for various new green applications from the intermediate, which allows the process.

The dye is reduced by TAML activators when compared with incumbent technologies. The TAML risk reduction theory is supported by mechanistic understanding developed by previous studies proposed in Fenton chemistry, which served as a foundation for developing efficient catalysts [62]. The Fe (II) salts activate the oxidation process in the presence of H_2O_2 known as Fenton chemistry. This chemistry induces the generation of radical species in solution and a wide range of organic substrates with poor selectivity [63].

The tendency to decompose the oxidant, which implies the need for over-stoichiometric amounts of H_2O_2, is one of the main drawbacks of this system [64]. It also requires help controlling the coordination of the oxidation state of the metal and geometry, which undoubtedly leads to the coexistence of some analogous oxidation processes. Nevertheless, it appears to be fine and produces toxic by-products like other wastewater treatment methods, whereas only produces organic compounds in excess amounts. Catalytic oxidation processes can be found in applications including environmental clean-up using soluble iron complexes. Compared to the electrochemical method, this system is cost-effective and relies on readily available and inexpensive reagents such as hydrogen peroxide and ferrous ions. Besides, it is simple to set up and operate and can be applied to a wide range of wastewater samples or dye formulations. It is easy to control the reaction conditions such as pH, temperature, and dosage of H_2O_2, in addition to its high degradation efficiency.

General procedure for degradation of Orange II by Fe(III)TAML-H_2O_2

Under isothermal conditions, Orange (II) was added along with buffered solution stirring at a precision temperature of ± 0.5 °C. Then, the final concentration of H_2O_2 of 0.01 M was achieved after a diverse amount of 30% H_2O_2 was added. The absorption band for Orange (II) at the maximum was then examined. More precisely, it was only done once using a UV-Vis spectrophotometer. Lastly, quenching of the mixture was carried out by an appropriate method for the analysis, which involved adding a quenching agent to neutralize the oxidizing species and stop the reaction. A sodium bisulfite solution was prepared by dissolving a proper amount of sodium bisulfite powder in deionized water. The concentration of sodium bisulfite should be sufficient to react with the excess hydrogen peroxide and oxidizing species present in the mixture. Once the desired reaction time has elapsed, the sodium bisulfite solution was carefully added to the reaction mixture. The amount of sodium bisulfite required depends on the specific reaction conditions and the concentration of the oxidizing agents. It was typically added in excess to

ensure complete quenching. After that, the reaction mixture was thoroughly mixed to ensure proper contact between the quenching agent and the reactive species. The mixture was allowed to stand briefly to provide a complete reaction and neutralization of the oxidizing agents.

Toxicity measurements of Orange (II) Dye

The toxicity of the dye and degradation products was analyzed using *Daphnia magna* of one day born at different concentrations of *Daphnia magna* (0.8, 1.3, 2.2, 3.6, 6.0, and 10.0 mg/L). Laboratory-grown daphniids were fed with *Scenedesmus subspicatus chodat,* cultured microbes. Doubly distilled water was used to prepare all the solutions at 20 °C under room temperature. Then, each test beaker was filled with 10 daphniids and 50 mL of final volume to identify the toxicity levels by immobilization test method for 24 hours of exposure. Results were evaluated based on the immobilization percentage obtained by dividing the number of immobilized organisms by the total organisms. The toxicity of wastewater samples is considered toxic when the immobilization percentage is higher than 50% [65].

Main findings for degradation of Orange II by Fe(III)TAML-H_2O_2

In optimizing the degradation of Orange (II) dye, the parameters involved were the concentration of Fe-TAML, H_2O_2, and pH. Initially, the Fe-TAML catalyst (0.5 µM) and H_2O_2 (16 mM) showed the color removal of 41% from wastewater in the Fe-TAML-H_2O_2 system after 30 minutes at 50 °C in the first trial [66] as shown in Figure 7(a). Moreover, the reduction of color differed from 9% to 42%, which led to the final color of 495 ± 68 CPU over seven repetitions without any mixings. The final color of 348 ± 8 CPU while mixing was used. The production of hydroxyl radicals occurred with the reaction between aqueous Fe^{2+} salts and H_2O_2 solutions. The color evaluation was performed by ultraviolet-visible spectroscopy (UV-Vis).

The maximum color removal of 44% was obtained under the most favorable conditions of the catalyst at 1 µM and H_2O_2 at 16 µM, which suggests its ability to reduce cost and time significantly, as claimed by Pinzon-Espinosa [67]. Maximum color removal of about 55% as shown in Figure 7(b) was reached within approximately four hours. Based on Fe-TAML catalyst degradation characteristics that can speed up the rate of reaction and lower the activation energy, color removal will reach its maximum within one hour with conditions of catalyst at 3 µM and H_2O_2 at 20µM.

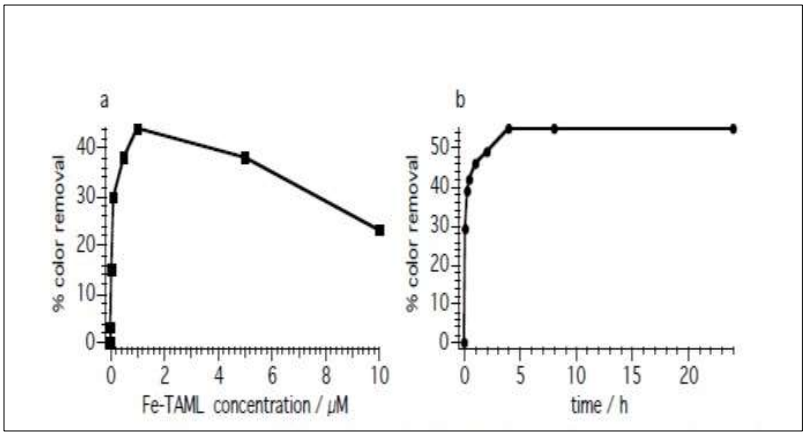

Figure 7. Effects of color removal dependence on Fe-TAML concentration (30 min)

Color removal probability was tested using Fe-TAML-H_2O_2, which might be caused by the reaction with catalyst breakdown derivatives, which are free Fe^{2+}/Fe^{3+}. The reactions were examined when the Fe-TAML catalyst was replaced by $FeCl_3$ [51]. The concentration of Fe^{3+} was similar to the catalyst concentration of Fe-TAML, which was about 1µM. There was no effect observed following the addition of

Fe^{3+}. Hence, the Fe-TAML-H_2O_2 combination is responsible for the degradation of the color. The H_2O_2 concentrations and reaction time, along with the optimization of the catalyst (by investigating the concentration, reaction time, and pH of the solution), were examined. The system's efficiency was demonstrated by a significant surge in color removal within a slight array of catalyst concentrations of 0.05 to 0.1 μM. Since Fe-TAML catalyzed H_2O_2 disproportionation at catalyst concentration larger than 5 μM, less color was removed [68].

The oxidation of Orange (II) was monitored by electronic spectroscopy. The dye has an intense absorption band with a maximum of 485 nm in water. Hydrogen peroxide oxidized Orange (II) very slowly, while Fe (III)-TAML activators immensely increased the rate. The spectral changes observed during catalyzed oxidation of Orange (II) dye are presented in Figure 8 below:

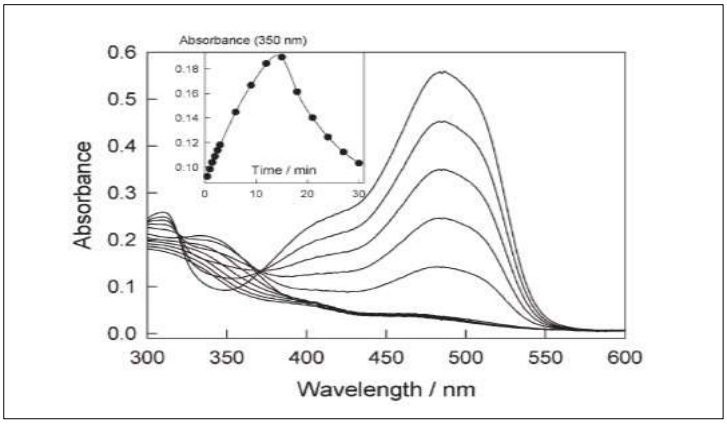

Figure 2. Spectral changes of Orange (II) catalytic oxidation

During treatment with the Fe-TAML-H_2O_2 system, the complex nature of the effluent brings difficulty in determining a high degree of certainty. The complexity of the effluent can arise from various factors, such as the presence of multiple contaminants, varying concentrations of pollutants, and diverse chemical compositions. These complexities make it difficult to precisely predict the treatment process's outcome and determine the certainty level in achieving desired results, thus may require a combination of scientific understanding, practical experience, and ongoing refinement of the treatment approaches. Still, several chemical analyses and spectroscopic methods can provide certain conceptions, including UV-Vis spectroscopy [66]. Firstly, the difference in ionization spectra revealing phenolic α-carbonyl and phenolic group structures in the sample of effluent fragment ions can provide evidence of the presence of phenolic alpha carbonyl groups in the sample. Phenolic alpha carbonyl groups typically refer to a carbonyl (C=O) group adjacent to a phenolic (OH) group. These groups can exhibit specific characteristic peaks in ionization spectra. The fragment ions can provide evidence regarding the presence of phenolic alpha carbonyl groups in the sample. Phenolic groups, referring to compounds containing a hydroxyl (OH) group attached to an aromatic ring, also exhibit characteristic features in ionization spectra. In mass spectrometry, phenolic compounds can produce a molecular ion peak (M+) corresponding to the intact molecule with the hydroxyl group.

The second treatment step involved exposing the Fe-TAML-H_2O_2 effluent to sodium periodate as oxidants using an oxidative procedure to maintain the facile, one-pot conversion approach [69]. Thirdly, the removal of aliphatic double bonds like stilbenes or alkenes from the treated material was demonstrated by controlled hydrogenation and effluents treated with Fe-TAML-H_2O_2. Lastly, groups of carbonyls like quinones and α-carbonyls were reduced using sodium borohydride indicating two types of structures that were eliminated

from the treated samples. However, Fe-TAML-H_2O_2 treatment removed the mentioned structure efficiently. Some methods could ensure the structure is eliminated from the effluent, which include UV-Vis spectroscopy, high-performance liquid chromatography (HPLC), mass spectroscopy, and total organic carbon (TOC) instrument. Apart from that, some studies revealed that lowering the concentration of starting color is possible with Fe-TAML catalyst, even in the absence of H_2O_2. Non-aqueous chemistry describes that Fe-TAML catalyst can rapidly activate O_2. Direct reaction of the Fe-TAML catalyst with O_2 reduces the Fe-TAML catalyst. The catalyst then reacts with oxygen to oxidize other chromophores. [70]. As seen in Figure 9, the Fe-TAML catalyst is pH dependent. Meanwhile, pH 11 shows a higher initial rate compared to pH 9.

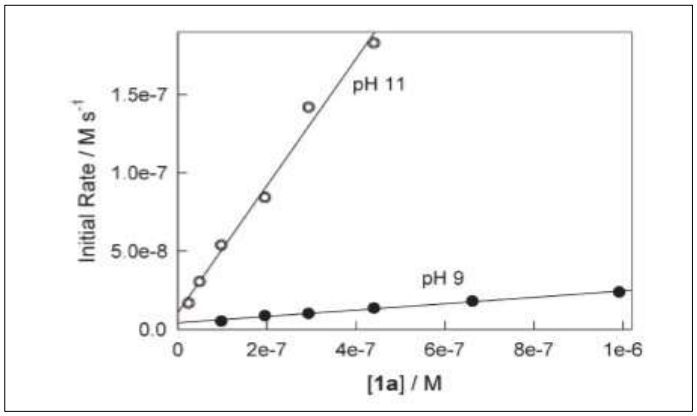

Figure 3. Initial rates of catalyzed bleaching of Orange (II) dye by H_2O_2 as a function at pH 9 and 11. Conditions:[Orange (II)] 4.5 x 10^{-5} M, [H_2O_2] 3.3 x 10^{-4} M, 25 ℃

The evaluation of toxicity was done before and after the degradation. The non-toxic compounds, such as more minor aromatic compounds, carboxylic acid, and inorganic ions, were produced as degradation products. The initial toxicity of Orange (II) decreased after the treatment. The test sample's value measured toxicity using one-day-old *Daphnia magna* exposed to different dye concentrations. The percentage of immobilized or decreased *Daphnia magna* was calculated by plotting a dose-response curve representing the dye concentration versus the response (mortality or immobilization) of Daphnia magna. Later, the median lethal concentration (LC50) was determined, which is the concentration at which 50% of the Daphnia Magna are immobilized or deceased. This value indicates the toxicity of the Orange (II) dye to the test organism. The larger the number of values, the smaller the toxicity level. Figure 10 illustrates the effects of orange (II) and the degradation on the immobilization of D. Magna, showing maximum toxicity of 20% observed in both experiments. Daphnia *magna* in the control tubes showed zero mortality. This result demonstrates that the Fe (III)–TAML catalyzed degradation of Orange (II) by H_2O_2 is safe and free from the formation of toxic oxidation products [71].

Conclusion

Green oxidation catalysis treatment involving Fe (III)–TAML-H_2O_2 system has been proven to significantly impact the degradation of azo dye compared to other existing industrial methods. Based on this study, the system significantly degraded Orange (II) dye into non-toxic organic and biodegradable products. Meanwhile, the other method harms the environment and consumes more energy and cost. Extensive mineralization can be observed in its green chemistry principles, such as synthesized biofuels and green ZnO [72]. Oxidation has the potential to occur quickly compared to other chemical systems formerly conducted. The ecotoxicological examination suggests that the described method is much more environmentally harmless than metal catalysts including ruthenium (Ru) or osmium (Os). Thus, the application of green chemistry in the oxidation catalysis treatment

involving the Fe (III)TAML-H_2O_2 system is greatly needed to treat dye effluents. In summary, Fe (III)TAML-H_2O_2 system has been significantly proven to carry substantial potential in providing a greener technology.

Abstract

Clinacanthus nutans (CN) is widely grown in Southeast Asia, especially in Malaysia. People belief that consuming the leaves can treat various diseases it has many medicinal properties. The aim of this study is to investigate the potential of different solvent systems of CN leaves as a source of natural antioxidant by screening its phytochemical constituents and presence of major active compounds with potential biological activities. CN leaves were extracted using different solvent followed by its polarity (methanol, hexane, dichloromethane and aqueous residue). Phytochemical's determination involved total flavonoid content (TFC) and phenolics (TPC) assay. Antioxidant activity was measured using 2, 2-diphenyl-1-picrylhydrazyl (DPPH) scavenging assay and ferric reducing antioxidant powder (FRAP). The chemical constituents of all extracts were identified using gas chromatography-mass spectrometry (GCMS). The percentage of extract yield has more on aqueous fraction (82.84%) and the lower very lower amount of methanol extracts (3.63%). The TFC and TPC were a result of higher and lower phytochemicals content, which were aqueous residue and dichloromethane fractions, respectively. The percentage of scavenging ability of DPPH was higher in aqueous residue (80.994%) and followed by crude methanol extracts (51.829%), dichloromethane fraction (32.426%) and hexane fraction (11.038%). Ferric reducing antioxidant (FRAP), to confirm the existence of antioxidant constituents was found to be higher and a lower activity is shown by aqueous residue and dichloromethane fractions. GCMS was identified as bioactive compounds in all different solvent extracts that indicated various medicinal properties. Thus, aqueous residue and crude methanol extracts CN leaves extracts may be explored as new sources of antioxidants in medicinal plant research. However, dichloromethane indicated a variety of bioactive compounds and medicinal properties.

Abstrak

Clincanthus nutans (CN) banyak ditanam di Asia Tenggara khususnya di Malaysia. Orang ramai percaya bahawa dengan memakan daunnya boleh merawat pelbagai jenis penyakit kerana mempunyai banyak khasiat perubatan. Objektif kajian ini adalah untuk mengkaji potensi pelbagai ekstrak pelarut bagi daun CN yang menjadi sumber antioksidan semulajadi dengan membuat penyaringan konstitiuen fitokimia dan mengesan kehadiran sebatian aktif utama yang berpotensi dalam aktiviti biologi. Pelbagai jenis pelarut digunakan untuk mengekstrak daun CN mengikut tahap polarity yang berbeza (metanol, heksana, diklorometana dan sisa akueus). Penentuan fitokimia melibatkan pengiraan jumlah kandungan flavonoid (TFC) dan ujian fenolik (TPC). Aktiviti antioksidan diukur menggunakan bahan ujian memerangkap 2, 2-difenil-1-pikrilhidrazil (DPPH) dan serbuk antioksidan penurun ferik (FRAP). Juzuk kimia semua ekstrak yang dikenalpasti telah menggunakan kromatografi gas-spektrometri jisim (GCMS). Keputusan menunjukkan peratusan hasil ekstrak mempunyai lebih banyak pada pecahan akueus (82.84%) dan jumlah peratusan ekstrak yang sangat rendah dalam ekstrak metanol (3.63%). Keputusan TFC dan TPC adalah hasil daripada kandungan fitokimia yang lebih tinggi dan lebih rendah, yang masing-masing merupakan sisa akueus dan pecahan diklorometana. Peratusan keupayaan penghapusan DPPH adalah lebih tinggi dalam sisa akueus (80.994%) dan diikuti oleh ekstrak metanol mentah (51.829%), pecahan diklorometana (32.426%) dan pecahan heksana (11.038%). Ujian FRAP untuk mengesahkan kewujudan juzuk antioksidan didapati lebih tinggi dan aktiviti yang lebih rendah ditunjukkan oleh sisa akueus dan pecahan diklorometana. GC-MS digunakan bagi mengenalpasti kehadiran sebatian bioaktif dalam semua ekstrak ini yang mempunyai nilai perubatan. Oleh itu, sisa akueus dan ekstrak methanol mentah daun CN boleh diterokai sebagai sumber antioksidan baru dalam penyelidikan tumbuhan ubatan. Walaubagaimanapun, diklorometana menunjukkan pelbagai sebatian bioaktif dan mempunyai nilai perubatan.

Introduction

Medicinal plant is one of the biodiversity that can be abundantly found in Malaysia. The excellent source of medicinal plants contains medicinal derivatives and phytochemicals that are beneficial for human health [1]. Medicinal plant plays a vital role in the identification of new beneficial medicinal components and their phytochemical constituents such as antioxidant, anticancer, antihypertension, antidiabetics, antihyperglycemics, antiaging and others. The applications of phytochemicals are widely used in agriculture and cosmetic that has minimal side effects as compared to the use of used synthetic products or drugs [2].

In ancient time, traditional people have been using medicinal herb for the prevention and treatment of disease. Currently medicinal plants are developed as plant derived drug. Various communities use the leaves of CN in Malaysia, Thailand and Indonesia for medicinal purposes such as antiviral, anticancer and anti-inflammatory activities and also to treat fever and diabetes. History of traditional medicine and ethnopharmacological reports of CN are partly established and therefore scientific investigations are required to justify its therapeutic potential [3]. CN is from Acanthaceae family and is known as 'Belalai gajah' in Malaysia. This small plant with full green leaves has a lot of potential phytochemicals such as vitexin, clinamide group, clinacoside group and others [4]. CN also reported to have a lot of antioxidant and benefits of phytochemical compounds. Previous study exhibited CN to have potential flavonoid group such as anticancer agents like quercitine, catechin and luteolin [5, 6]. The pharmacological effects of CN serve as antibacterial, antioxidant, antiproliferative, anti-inflammatory and antiherpes [7]. Traditionally CN in Thailand is used for inflammation, rashes, diabetes, hypertension and diuretic [5, 8].

Plant extraction investigation is important in medicinal plant research for therapeutic purpose to avoid damage to the biomolecules in the plants. The extraction method provides active plant metabolites such as alkaloids, glycoside, phenolics, terpenoids and flavonoids that have natural potential of biological activity. Medicinal plants contain antioxidants that prevent oxidative damage caused by free radicals in the human body [9]. Thus, this study aims to investigate the effects of different solvent extraction of CN leaves on phytochemical, antioxidant and potential of chemical compounds by gas chromatography-mass spectrometry.

Materials and Methods

Plant collections and botanical species identification

The plants of CN were collected and harvested from a farm located at Pongsu Seribu (HERBagus), 13200 Kepala Batas, Seberang Perai Utara, Pulau Pinang. The complete specimen, including roots, flowers, leaves and all parts of plant, was collected (Figure 1). These complete samplings were then sent to Unit Herbarium, School of Biology, and Universiti Sains Malaysia (USM) for voucher specimen preparation of the herbarium. The last step involved herbarium and plant identification by an expert taxonomist from USM. The complete herbarium was deposited with reference number of voucher specimen 111536.

Preparations of plant solvent extractions using partition coefficient

Crude methanol extract and fraction (hexane, dichloromethane and aqueous residue) were prepared using fresh CN cleaned leaves. The process of extraction started with blending the leaves into small pieces and soaking them in a mixture of solvent consisting of 80% methanol and distilled water for 24 h at room temperature. Then, it is filtered and continuously soaked for 2 times to ensure exhaustive extraction. The yield in the form of methanol crude extracts was kept at -20 ^{o}C until it was used. The filtrate was concentrated in a vacuum rotary evaporator at 40°C until about 1/10 of the original volume was left. Then, the leftover filtrate was freeze-dried to obtain the 80% methanol crude extract. The crude was used for successive solvent and partitioning extractions with different solvents of increasing polarity, starting with hexane, dichloromethane and aqueous residue by liquid-liquid extractions. The extracts of partitioning were concentrated to dryness by using a rotary evaporator. The dried powdered extracts were then stored in screw-capped glass bottles and kept in a refrigerator at 4 ^{o}C until further use.

Phytochemical analysis: Total flavonoid content

Total Flavonoid Content (TFC) was determined using aluminium chloride method with some modifications following the method of Kim et al. [10]. The extracts, standard and aluminium chloride ($AlCl_3$) solution were prepared by diluting with distilled water. Then the mixture in the wells was incubated for 10 min in the dark at room temperature. The absorbance was measured at 415nm using microplate reader. All samples were assays in triplicate. The quercitine was used as positive control and standard. The content of total flavonoid compounds was calculated as mean ± SD (n=3) from standard curve quercitine and expressed as milligrams of quercitine (QUE) in 1g of the extract and dried powder.

Total phenolic content

Total phenolic content (TPC) or Folin Ciocalteu assay were determined with modifications of colorimetric method from Sahu and Saxena [11]. Sodium carbonate ($NaHCO_3$) (7.5%) and Folin Ciocalteu reagent (2.5%) were diluted in deionized water. The extracts and gallic acid then were mixed with Folin Ciocalteu and incubated for 5 min. Then sodium carbonate was added into mixture of extracts and Folin Ciocalteu in the well plates. The mixture was incubated about 1h in the dark and measured at 765 nm using microplate reader. Gallic acid was used as standard. The total phenolic content was expressed as mean ± SD (n=3) from standard curve gallic acid and as milligrams gallic acid equivalent (GAE) in 1g of the extract and dried powder.

Antioxidant assay: 2, 2-diphenyl-1-picrylhydrazyl

Free radical scavenging effect of the 2, 2-diphenyl-1-picrylhydrazyl (DPPH) was used to evaluate the antioxidants activity of different solvents extracts of CN leaves as described in the method of Sigma protocol (1898-66-4) (D9132) ($C_{18}H_{12}N_5O_6$) (Mw: 394.33). Trolox was used as a reference compound. In brief, each extract concentration (50 µL) was mixed with 200 µL of DPPH solution (0.2 mM DPPH in 100 mL of methanol). The mixture was incubated in the dark for 30 min at 30 ^{o}C. The absorbance was measured at 517 nm against a blank methanol without the DPPH solution using microplate reader (Biotek, Model ELx808, Agilent Technologies, and Wilmington, DE, USA). The percentage of inhibition free radicals by each extract was calculated using the equation given below:

$$\% \text{ scavenging of DPPH} = (\text{Abs control} - \text{Abs sample}/\text{Abs control}) \times 100 \quad (1)$$

where Abs control is the absorbance of the DPPH solution without extracts. The capacity of the extracts to reduce DPPH was obtained from the standard curve, and the results are expressed as percentage inhibition against extract concentration.

FRAP assay

Ferric reducing antioxidant powder (FRAP) was used to determine the total antioxidant activity of different solvent extracts of CN leaves following methods described by Shui and Leong [12] with some modifications. $FeSO_{4\ was}$ diluted in deionized water. Then warmed FRAP as working solution was added in all sample extracts. After that, it was incubated in the dark for 1hr and the absorbance at 593 nm. Gallic acid was used as a positive control. The total antioxidant ability was expressed as the concentration of $FeSO_4$ standard solution.

Chemical profiling (GC-MS analysis)

GC-MS analysis was performed based on the methods described by Abdul Rahim [13]. The samples were analyzed by using an Agilent 7890A Gas Chromatograph (Agilent Technologies, Wilmington, DE, USA). Briefly, a 1 mg aliquot of an extract was weighed and added into a GC vial. The powder was then mixed with 1 mL of methanol. Next, the 10 µL mixture was injected into the GC-MS system via splitless mode. The GC-MS system was connected to an MS/MS triple quad detector. The HP-5MS GC column with an inner column and film thickness diameter of 0.25 mm x 30 m x 0.25 µm was used for the GC-MS analysis. The initial oven temperature was set at 100 ºC for 2 min before it was increased gradually to the final temperature of 280 ºC within 17 min at a rate of 10 ºC/min. Helium was used as the carrier gas with a rate of 1 mL/min. All samples were analyzed in three replicates. The spectra of the chromatogram peaks were compared against the National Institute of Standards and Technology (NIST) database library to identify the retention time (R_t) index of common primary and secondary metabolites.

Statistic

All the experiments were conducted in triplicates. The values are expressed as the mean ± standard deviation (SD). The statistical analyses were done using SPSS 25.0 windows statistical package software (SPSS Inc., Chicago, IL). Significant difference between extracts were analysed using one way analysis (ANOVA) followed by Tukey's multiple comparison test.

Results and Discussion

Traditionally CN plant was used as alternative medicinal for various cancer diseases. Many previous studies on CN used parts of leaves because they are green (Figure 1) and have high medicinal properties. In this study CN leaves extracts were prepared using solvents based on their increasing order of polarity (methanol, hexane, dichloromethane and aqueous residue). Currently many research were justified by scientific evidence that CN leaf extracts in chloroform, methanol, and water have the potentials to be used for antiproliferative and anticancer activities against various cancer cell lines [14]. Medicinal plant with anticancer properties is based on phytochemical, antioxidant and analysis of active compounds derivatives present in plant extracts [15]. In this experiment, 80% methanol and fractionation based on polarity was used. This method is effectiveness for plant extract because the different solvents and polarities give significance effects on the chemical contents of the extracts that are important to identify the optimal solvents for the extraction of antioxidant compounds from medicinal plants [16]. The crude methanol was mixed with distilled water because water was employed for the extraction and its universal solubility of polar compounds, while methanol was chosen due its ability to extract lower molecular weight polyphenols and its tendency to yield relevant antioxidant and cytotoxic compounds from CN [17]. Whereas the crude methanol extract was fractionated using different solvents to concentrate and enhance the purity of active compounds and remove unwanted interferences [18].

Extraction of yield of CN leaves was carried out using four different solvents. The yields obtained were extracted from a total dry weight of 500g CN leaves. Among the extract, the highest and the lowest yields were obtained by aqueous residue and hexane extracts, respectively (Table 1). The total percentage of all extracts obtained is 89.67% from the dry weight CN. The high yield in aqueous residue was probably due to the high solubility of phytochemical compounds such as

flavonoids and phenolic contents. Phytochemical is important in developing drug and curing health problems. Various types of solvents used in extraction can recover higher extract yield and some bioactive in plant [19]. This study revealed the significant difference in the extract yield obtained by different solvents.

Figure 1. Whole plant of *Clinacanthus nutans*

Table 1. Percentage yield of methanol extracts and fractions of *Clinacanthus nutans* leaves

No.	Solvent Extracts	Dry Weight (g)	Extract Yield (g)	Percentage of Yield (%)

3.	Dichloromethane	15	0.3276	2.184
4.	Aqueous	15	12.426	82.84

Each value is expressed as mean (n=3)

Phenolics and flavonoids are secondary metabolites and are widely distributed in various plants [20, 21, 22]. Secondary metabolites from medicinal plant were extracted using different solvents. Solvents widely used for extractions are water, ethanol, methanol, acetone and solvent mixtures of different ratios with water, with or without acid. Phenolic constituents and secondary metabolites of plant extraction are based on solvents and its polarity. Phenolic plays a role as primary antioxidant and free radical inhibitors. Whereas flavonoids are polyphenolic compound from numerous phenolics and widely spread in the plant kingdom. Previous studies reported the function of flavonoids such as UV protection, disease resistance, pigmentation and nitrogen fixation simulation in the nodules [23]. This study on phytochemical analysis focuses on the content of flavonoids (TFC) and phenolics (TPC) content (Table 2). The result found that the highest contents of TFC and TPC were in aqueous residue and lower content of TFC and TPC were found in is dichloromethane fractions. Nevertheless, it is reported that the biological properties depend not only on the total extract yield but also on its phytochemical composition [19].

Table 2. Total flavonoids and phenolic content of *Clinacanthus nutans* leaves different solvent extracts and fractions. Mean±SD. (n=3)

Solvents Extracts	Total Flavonoid Content (mgQUE/g)	Total Phenolic Content (mgGAE/g)
Methanol	14.229±0.055	562.784±0.012
Hexane	33.735±0.337	327.548±0.049
Dichloromethane	9.663±0.072	97.191±0.059
Aqueous	27.503±0.089	628.959±0.026

QE-quercitine equivalents; GAE-gallic acid equivalents. Data represented as means ± standard deviation (SD) of replicates (n=3)

Antioxidant molecules were reported in several medicinal plants beneficial in the treatment of several human disease [19] and has the ability to prevent oxidative stress. In the human body, the cell damage caused increasing level of free radical which correlates with and causes various diseases. The free radical was neutralized through antioxidant function [24, 25]. The antioxidant activity of CN could explain its wide-ranging reported bioactivities such as antidiabetic, anticancer, anti-inflammatory and wound healing activities [26]. In this study the antioxidant effects were determined by DPPH and FRAP assays. Both assays involved concentration from 0.031 to 1.0 mg/mL and the significance difference ($p<0.05$) between all the concentrations was observed. The evaluation of DPPH radical scavenging activity inhibition was higher in the crude methanol extract and the lowest was hexane factions (Figure 2). While the FRAP assay resulted clearly in the same result whereby crude methanol extract was higher and the hexane fractions were lower (Figure 3) and this may be due to various kinds of antioxidants present in the samples which react differently with the radical used. Every method has its own advantages and limitations in terms of cost, availability of chemicals, tediousness, preparation time, reproducibility and others [27]. The 1 mg/mL of CN showed the highest percentage of DPPH scavenging activity of crude methanol extract, 51.83±0.010 % followed by dichloromethane fraction (32.43±0.58%), aqueous residue (21.03±0.23%) and hexane fractions (17.38±0.23%).

The result obtained in the previous study by Ismail et al. [28], showed higher hexane fractions percentage of DPPH scavenging values (1530±3.74%) followed by dichloromethane (1039±0.87%), aqueous residue (744.30±8.45%) and lower was crude methanol (560.50±2.45%). It showed different result because the antioxidant activity can be associated with a deficient amount of nitrogen level of the soil level of moisture at different location [29]. The second most commonly used method in the determination of antioxidant is ferric reducing antioxidant power (FRAP) assay [30]. FRAP is an indicator of their potential to confirm antioxidant activity based on the reaction which measures reduction of ferric to ferrous and increase in the absorbance of the reaction mixture that indicates an increase in the reduction power [31]. Standard control of DPPH and FRAP assay were used trolox and gallic, respectively. Thus, the comparison of DPPH and FRAP activity was difficult due to different control standard was used gallic acid and trolox [31, 32, 33]. The solvent effect is an important parameter for the chemical behaviour of antioxidant compounds [30].

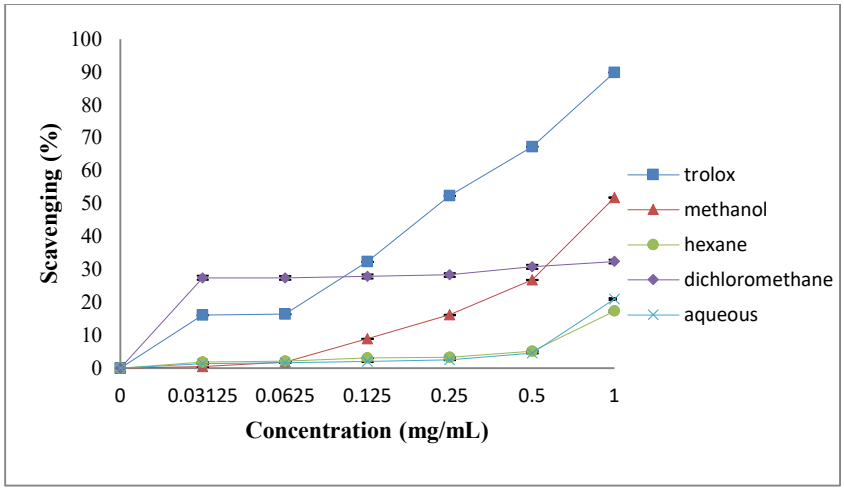

Figure 2. DPPH free radical scavenging activities of various solvent extracts of *Clinacanthus nutans* leaves and trolox

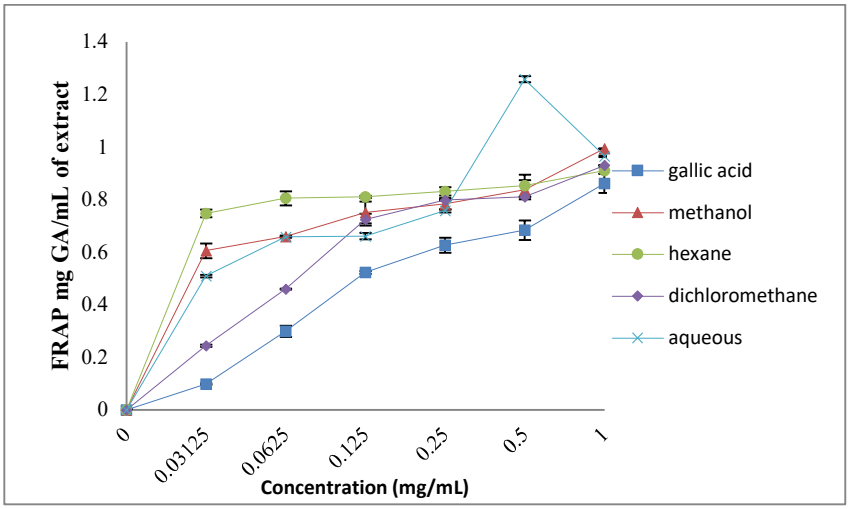

Figure 3. Ferric Reducing Antioxidant Power (FRAP) of the extracts

The phytochemical screening using GCMS found 43compounds presence with various biological activities in different solvent extracts (Table 3). The highest compounds found in hexane fractions were 23 followed by dichloromethane (16), methanol (5) and aqueous fractions (3). From this investigation most of these major compounds are known to exhibit various pharmacological activities. From the investigations methanol extracts contain sugar group such as methylgalactoside and galactoside and also contains fatty acid ester from lineloic acid group and organosulfur. The hexane fractions have the highest phytochemicals, 23 compounds from fatty acid ester (linoleic ester, palmitic acid, methyl ester), terpenoids (diterpene) and alkene. In dichloromethane fractions through the GC-MS analysis the presence of fatty acid ester (linoleic acid, methyl ester), organosulfur, phytosterols/steroid, terpenoids, triterpene and amide were found. In aqueous fractions the phytochemical compounds are present only alkene and diamine group. From these results the variety of phytochemical compounds group is highly present in dichloromethane fractions. The compounds of α and β-Amyrin from triterpene group present in dichloromethane fractions in this experiment are known to possess antidiabetic, anti-inflammatory, antiarthritic and anticancer activities [19, 34]. Amyrins can be found in various plants and plant material such as leaves, bark, wood and resins [35].

CN has been reported to have various phenolic, terpenoids and some other bioactive compounds such as benzenoids, cerbrosides, glycoglycerides, fatty acids, chlorophyll derivatives, phytosterols and sulphur containing glucosides that contribute to its diverse bioactivities [36]. Phytol that is present in hexane fractions, is an important terpenoid or diterpene that possesses antimicrobial, antioxidant and anticancer activities [19, 37, 38, 39]. Terpenoids and alkaloids compound have also been reported to have potent activity against gastric ulcers and relax cardiovascular muscle [40]. The terpenoids are widely distributed in nature and are found in higher plants. They represent the second largest class of secondary metabolites with more active constituents. It is now known that terpenes with a pleasant aroma are extracted from the vegetable or plants containing them and some are precursors of vitamins and insecticides [35, 41]. The various phenolic and fatty acid compounds were found in ethanol and ethyl acetate leaf extract of CN [26, 42]. Phenolics compounds esters, alkanes, aldehydes, alkenes and ketones are the other major volatile compounds which have antiulcer, anti-inflammatory, antiarthritic, antidiabetic, hypolipidemic and cytotoxic activities [40, 43]. Plant phenolics are one of the most abundant vital group of phytochemicals and are widely known for their antioxidant and radical scavenging activity with potential impacts on human health. The phenolics are natural antioxidants which can control oxidative stress related degenerative disease. The adverse effects of oxidative stress have been found to be controlled by the antioxidant activities of this group of bioactive compounds. [6]. The compounds have attracted great attention recently due to their potential to neutralize reactive oxygen species and other free radicals. Phenolic and flavonoid compounds display antitumor, antiadhesive, antimicrobial and anti-inflammatory properties and protection against chronic disease by the reduction of oxidative stress solely or synergistically with other phenolic containing amalgams [25]. In this study the various phenolics group was found in all the solvent and different extracts tested on CN extracts. Thus, it is shown that all the solvent extractions important roles as antioxidant are widely distributed in plants and possess ultraviolet protection, pigmentation and disease resistance [9].

Ester is a major compounds and origin from phenolics groups which shown presence in this all solvent extraction through GCMS analysis. Fatty acid is one of the groups of esters. Previous study on ethanol and ethyl acetate extract of CN indicated the presence of ester group compounds such as palmitic acid, myristic acid, linoleic acid or omega 3 fatty acid, stearic acid and oleic acid [26]. In this study the presence of ester group of linoleic acid in hexane fractions and dichloromethane fractions was shown while palmitic acid found in hexane fractions. Fatty acid methyl ester was found in hexane and dichloromethane fraction at a retention time of 26.249 minutes with percentage peak area for hexane and dichloromethane 9.01% and 1.25%, respectively. The methyl ester, stearic acid or stearate is a saturated 19-carbon-chained compound also known as octadecanoic acid methyl ester was reported to have antimicrobial, antiviral, potential anticancer properties [44], anti-inflammatory, hypocholesterolaemia, antiarthritic and antimicrobial [44, 45, 46]. In addition, phytochemical compounds found from GC-MS were not only phenolic and flavonoid contents but also consist of many other compounds such as diterpene, aromatic methyl esters, fatty acid, ester, fatty acid, vitamin and so on which were compared by NIST mass spectra l library [29]. Previous study of CN extract leaf oven and air-dried leaves demonstrated that the CN exhibited better antioxidant with the presence of phenolics, terpenoids and sulphur containing glucosidase compounds [26, 47]. Glucosidase is one of the sugar group that present in this study such as methygalactosidase and galactosidase that are present in methanol crude extract which has potential biological activity such as antioxidant and antibacterial [48, 49, 50]. Organosulfur is also present in dichloromethane fractions for antimicrobial, antibacterial and antifungal potential [51].

In this study the method of extraction involved the proses of fractionated on the crude extracts of CN leaves. The fractionated crude extracts used polar and nonpolar solvents that obtain phytoconstituent which rich of biological active standardize fractions [6]. Previous study indicated the effect of phytochemical compounds present in leaves CN is caused by first step method involved the crude extraction with macerating

the leaves with methanol to water (4:1) at room temperature. This method involved lower temperature in order to avoid degradation of compounds to produce polyphenols which produce many biological compounds functions [29, 51]. This extraction method has ability to produce biological activities profiling.

Conclusion

The greenly leaves of CN aqueous fractions and crude methanol extracts from different solvent extracts exhibited higher yield percentage of extracts and high values phytochemicals of flavonoid and phenolic contents. In addition, antioxidant study of DPPH radical scavenging and FRAP activity indicated the highest result was methanol crude extract and dichloromethane fractions may be explored as new sources of antioxidants in medicinal plant research. However, from the GCMS analysis, it is found that the dichloromethane fractions indicated a variety of bioactive compounds and medicinal properties. Furthermore, cytotoxicity study of the antioxidant and phytochemicals rich fractions is necessary to verify their suitability for future pharmaceutical applications.

Abstract

Endophytic fungi are important in drug discovery for their unique secondary metabolites, besides the extract obtained are sustainable, reproducible and culturable under laboratory conditions as compared to their host plants. However, the use of single culture leads to the production of known compounds with similar bioactivities. Therefore, single culture and co-culture between *Fusarium* sp. and *Curvularia* sp. which have been isolated from mangrove plant *Avicennia lanata* were cultured on malt agar and rice media on 7, 15 and 30 days to trigger the production of metabolites that may absent in their single cultures. In this study, dereplication study was applied to speed up the identification of secondary metabolites in the extracts. Then, the data was processed utilising MZmine 2.40.1 and SIMCA P+ 15.0 software coupled with macro analysis and Dictionary of Natural Product (DNP) database for dereplication studies. The antioxidant activity of the extracts were evaluated by using DPPH scavenging assay. Amongst the extract obtained from malt agar medium, the extract of co-culture on day 7 (MAFC7) showed the most potent activity with IC_{50} value of 0.6 mg/mL. For the rice medium, the extract from single culture *Curvularia* sp. on day 15 showed the most significant activity with IC_{50} value of 1.1 mg/mL. While, the agar disk-diffusion method was used to evaluate the antibacterial activity of the extracts and the results indicated that the extracts exhibited activity against Gram-positive bacteria, specifically *Micrococcus* sp., *Staphylococcus aureus*, and *Bacillus cereus*. The antibacterial activity of the co-culture extracts were the most active with minimum inhibition concentration (MIC) values of 0.256 mg/mL – 5.0 mg/mL. In conclusion, the extracts obtained from co-culture showed potent antioxidant and antibacterial activities that could be further scaled-up and investigated for future pharmacological properties.

Keywords: *Fusarium* sp., *Curvularia* sp., co-culture, antioxidant, antibacterial

Abstrak

Kulat endofit adalah penting dalam penemuan ubat untuk metabolit sekunder yang unik, selain itu ekstrak yang diperolehi adalah mampan, boleh dihasilkan semula dan dikultur di bawah keadaan makmal berbanding dengan tumbuhan perumah. Walau

bagaimanapun, penggunaan kultur tunggal kebiasaannya membawa kepada penghasilan sebatian yang diketahui dengan bioaktiviti yang sama. Oleh itu, kultur tunggal dan kultur bersama antara *Fusarium* sp. dan *Curvularia* sp. yang telah dipencilkan daripada tumbuhan bakau *Avicennia lanata* telah dikulturkan pada agar malt dan media beras pada hari ke-7, 15 dan 30 hari untuk mencetuskan penghasilan metabolit yang berbeza yang mungkin tidak hadir dalam kultur tunggal mereka. Dalam kajian ini, kajian dereplikasi telah digunakan untuk mempercepatkan pengenalpastian metabolit sekunder dalam ekstrak. Kemudian, data telah dianalisis menggunakan perisian MZmine 2.40.1 dan SIMCA P+ 15.0 beserta analisis makro dan pengkalan data Kamus Bahan Semulajadi (DNP) bagi kajian dereplikasi. Aktiviti antioksidan bagi ekstrak telah dinilai menggunakan asai skaveng DPPH. Antara ekstrak yang diperolehi daripada medium agar malt, ekstrak kultur bersama pada hari ke-7 (MAFC7) menunjukkan aktiviti yang berpotensi dengan nilai IC_{50} sebanyak 0.6 mg/mL. Bagi medium beras, ekstrak daripada kultur tunggal *Curvularia* sp. pada hari ke-15 menunjukkan aktiviti yang paling ketara dengan nilai IC_{50} sebanyak 1.1 mg/mL. Sementara itu, kaedah penyerapan cakera agar telah digunakan untuk menilai aktiviti antibakteria ekstrak dan keputusan menunjukkan bahawa ekstrak menunjukkan aktiviti melawan bakteria Gram-positif termasuk *Micrococcus* sp., *Staphylococcus aureus* dan *Bacillus cereus*. Aktiviti antibakteria bagi ekstrak kultur bersama adalah yang paling aktif dengan nilai kepekatan rencat minima (MIC) pada 0.256 mg/mL– 5.0 mg/mL. Kesimpulannya, ekstrak yang diperolehi daripada kultur bersama menunjukkan aktiviti antioksidan dan antibakteria yang bagus yang boleh dilanjutkan untuk skala besar dan disiasat untuk sifat farmakologi masa hadapan.

Kata kunci: *Fusarium* sp., *Curvularia* sp., kultur bersama, antioksidan, antibakteria

Introduction

Natural products are molecules derived from plants, microorganisms or animals that naturally produce primary and secondary metabolites which continuing provide varities bioactive metabolites. Overall, more than 70% of antibacterial and anticancer compounds are natural products origin [1]. Endophytic fungi are the organism live commonly within most plant species' tissues. The endophyte occupies host tissues without causing any diseases and found mostly in terrestrial plants [2]. Endophytic fungi play an important role in plant habitat adaptation, enhancing plant production and defending plant against biotic and abiotic stress [3]. In the past few years, the metabolites isolated from the endophytic fungi including steroids, alkaloids, anthraquinones, terpenes, flavonoids and cyclic peptides that are known for their biological activities, such as antibacterial, antitumour, antiviral, antifungal and anti-inflammatory [4]. In this study, endophytic fungi *Fusarium* sp. and *Curvularia* sp. have been isolated from the mangrove plant *Avicennia lanata*. *Fusarium* genus is recognised as one of the major sources of secondary metabolites with a variety of biological activities, including antioxidant activity [5]. *Fusarium* sp. has produced a variety of secondary metabolites, including peptides, alkaloids, terpenoids, amides, pyranones, and quinones with pharmacological potential [6]. Meanwhile, *Curvularia* sp. is known as pathogen associated with humans and plants. Some of *Curvularia* species are economically important pathogens worldwide, while other species are found in combination with different hosts as pathogens or epiphytes [7]. Many biologically active secondary metabolites were previously reported from *Curvularia*, for example, 11-α-methoxycurvularin, curvularin, cytochalasin B, dehydrocurvularin, radicinol and radicinin [8]. Endophytic fungi *Curvularia* sp. also produce a variety of bioactive secondary metabolites including polyketides and steroids [9]. However, the single fungi reproduce the same compounds and similar biological activities. Therefore, co-culture has been a useful research method which effectively triggers the new metabolites that are silent in single culture.

A co-cultivation is a method to challenge two or more microorganisms by imitating the actual natural microbial community competition that is carried out in a laboratory scale, becomes a successful strategy to produce novel bioactive natural products [10]. The co-culture between endophytic fungi may trigger the production of new secondary metabolites that are silent under normal condition. Production of bioactive secondary metabolites during co-culture may be related to various mechanisms, including competition for space and nutrients in which the parameter is the most important for microbial growth and survival in a competitive environment [11, 12]. Marine-derived microorganisms such as bacteria and fungi proved to be prolific sources of novel bioactive compounds which are not only considerable interest as a new drug for the

treatment of cancer, but also for other malignancies such as chronic pain [13]. Conventional method only focused on major compounds due to diversity of metabolites, thus it is challenging especially in data interpretation. Therefore, modern technologies and techniques have been developed in natural product discovery to produce a great outcome in research.

Metabolomics study is considered as a modern technique that is developed for systematic procedures to explore various mechanism as well as detecting metabolites changes in specific organism [14]. The presence of metabolites in microbes can easily be measured and compared via metabolomics. Metabolomics is used to fast track the identification of metabolites in a mixture of extract prior to isolation work to avoid repetitive works. The metabolomic study uses multivariate analysis to classify mass data collection and groups by monitoring their distribution accordingly with subjected parameter. Therefore, a clear overview of metabolites in the extract can be detected by liquid chromatography-mass spectrometry (LC-MS) coupled with multivariate analysis such as principal component analysis (PCA) and orthogonal partial least square discriminant analysis (OPLS-DA) [15]. In this study, the extracts from a co-culture between *Fusarium* sp. and *Curvularia* sp. was carried out to provide a better understanding on the metabolites as compared to the metabolites in their independent cultures.

Materials and Methods

Preparation of fungal strain

Stock cultures of endophytic fungi *Fusarium* sp. and *Curvularia* sp. isolated from the root of *Avicennia lanata* were obtained from Fungus Laboratory, Centre of Research and Field Service, Universiti Malaysia Terengganu (UMT). The single colony of both endophytic fungi were inoculated on malt agar plate independently and incubated in an incubator at 28 ± 1 ºC for 7 – 15 days for further work.

Inoculation of fungal on malt agar and rice media

Malt agar medium consists of 10.0 g of agar (Oxoid, Malaysia) and 7.5 g of malt extract (Oxoid, Malaysia) and were transferred into 500 mL of Schott Duran bottle. 500 mL of milli-Q water was added into the bottle and autoclaved. A 25 mL of warm agar medium was poured into labelled agar plates, left to cool and stored inverted at 4 °C. The fresh malt agar containing actively growing culture of *Fusarium* sp. and *Curvularia* sp. were cut into 5 x 5 mm cubes, placed on malt agar plates for single and co-culture and incubated at 28 ± 1 °C for 7, 15 and 30 days. The growth of mycelia of *Fusarium* sp. and *Curvularia* sp. in single and co-culture agar plates were monitored daily based on the shape and colour. Once the incubation period was completed, the agar plates containing the actively growing mycelia of single and co-culture *Fusarium* sp. and *Curvularia* sp. were cut and transferred into conical flasks, then 50 mL of ethyl acetate (Fisher Scientific, Malaysia) was added, sonicated for 1 h and filtered into round bottom flasks by using cotton wool (50 mL/extraction, three times). The organic phase was concentrated under vacuum by using a rotary evaporator (Buchi, Switzerland) to give an extract. The extracts were kept at 4 ºC prior to further analysis.

Meanwhile, cultivation of single and co-culture between the fungi in sterile rice medium was also carried out for up-scaling. 15 g of rice and 15 mL of milli-Q water were added into 250 mL of conical flasks. The conical flasks were covered with cotton wool and aluminium foil and kept overnight before autoclaved. The flasks were left to cool. A fresh malt agar plate containing actively growing culture of *Fusarium* sp. and *Curvularia* sp. were cut and placed on the rice medium for single and co-culture and incubated at room temperature for 7, 15 and 30 days. Once the incubation period was completed, 100 mL of ethyl acetate (Fisher Scientific, Malaysia) was added into each flask, sonicated for 1 h and filtered into round bottom flasks by using cotton wool (100 mL/extraction, three times). The organic phase was concentrated under vacuum by using a rotary evaporator (Buchi, Switzerland). The extracts were kept at 4 ºC prior to further analysis [16].

Antioxidant activity

The antioxidant activity of extracts from single and co-cultures were evaluated by using 2,2-diphenyl-1-picrylhydrazyl (DPPH) (Sigma-Aldrich, Malaysia) *in vitro* assay. The free radical scavenging activity of each sample was determined by measuring the changes of

absorbance colour from violet of DPPH into yellow by using microplate spectrophotometer (Thermo, United States) at 520 nm [18]. 50% of inhibition concentration (IC_{50}) value was defined as the concentration of the sample that scavenged 50% of DPPH radical.

5 mg/mL of extracts obtained from malt agar culture and 10 mg/mL of extract from rice culture were dissolved in dimethyl sulfoxide (DMSO) with 2-fold serial dilution method to give eight concentration values of 0 mg/mL to 5 mg/mL and 0 mg/mL to 10 mg/mL, respectively. Quercetin was used as a positive control and DMSO was used as the negative control. 4.73 mg of DPPH powder was dissolved in 200 mL of methanol (Merck, Germany), transferred into 500 mL of Schott Duran bottle and covered with aluminium foil. 20 µL of each concentration was pipetted into respective wells of the 96-well plate. 200 µL of DPPH solution was then added to each well containing extract and incubated for 30 min in dark at room temperature. The absorbance was measured by using a microplate spectrophotometer (Thermo, United States) at 520 nm. All determinations were performed in triplicate to obtain a mean value and the radical scavenging activity was calculated by using the following formula:

$$\text{DPPH scavenging effect (\%)} = ((A_0 - A_1) / A_0) \times 100 \quad (1)$$

Where as A_0 = the absorbance of the control, and A_1 = the absorbance of the extract mixed by DPPH

The half percentage of inhibition samples concentration (IC_{50}) was determined from the linear regression curve.

Antibacterial activity

The antibacterial activity of extracts from single and co-cultures used the disk-diffusion method [19]. Three Gram-positive strains – *Micrococcus* sp., *Staphylococcus aureus*, and *Bacillus cereus*, and three Gram-negative bacteria – *Salmonella* sp., *Escherichia coli* and *Vibrio parahaemolyticus* were obtained from Institute of Marine Biotechnology, UMT. 28 g of nutrient agar (Oxoid, Malaysia) /1 L, 55.1 g of marine agar (Difco, Malaysia) /1 L and 35 g of Mueller-Hinton agar (Merck, Germany) /1 L of milli-Q, stirred until homogenised and autoclaved. Each extract was prepared with 2-fold dilution to give eight concentration values of 0 mg/mL to 10 mg/mL in DMSO. Then, 20 µL of extract was loaded onto Whatman paper AA disks (Whatman, China).

Each bacterium strain was streaked on nutrient and marine agar plates, incubated at 37 °C for 24 h. After 24 h, 2 mL of sterile milli-Q water was transferred into McFarland tube and bacteria strains were added. Optical density (OD) (BioMērieux, France) was adjusted at 0.5 MFU (McFarland Unit) and 100 µL of bacterial inoculum was uniformLy spread by using sterile cotton swab onto Mueller-Hinton agar plates. The Whatman paper AA disks (Whatman, China) containing samples were placed inverted onto agar plates (3 replicates) and incubated at 37 °C for 24 h. 30 µg oxytetracycline, 10 µg ampicillin, 10 unit penicillin and 10 µg gentamycin antibiotic disks (Oxoid, United State) were used as positive control, and DMSO as negative control. For initial screening, 10 mg/mL of extract was tested on the Gram-positive and Gram-negative bacteria strains in order to observe the presence of inhibition growth zone between the extracts and bacteria.

After 24 h of incubation, inhibition zone diameter (IZD) around the Whatman paper AA disks (Whatman, China) containing extract was observed. The IZD was measured and expressed in millimetre (mm), and minimum inhibitory concentration (MIC) was taken as the lowest concentration of the extracts that inhibited the visible growth of bacteria after overnight incubation.

HRESI-LCMS analysis and data processing

1 mg of each extract was dissolved in 1 mL of methanol prior to analysis by using Accela high performance liquid chromatography (HPLC) (Thermo Scientific, UK) coupled with a 280 nm and 360 nm UV detector and an Exactive-Orbitrap high-resolution mass spectrometer (Thermo Scientific, UK) including a methanol blank. The column size used was HiCrom, ACE (Berkshire, UK) C_{18}, of 75 mm x 3.0 mm, 5 µm.

The mobile phase used was micropore water (A) and acetonitrile (B) with 0.1% formic acid at a flow rate of 300 µL/min was applied linearly. The gradient program started at 10% B and linearly increased to 100% B within 30 min and remained isocratic for 5 min before linearly decreasing back to 10% B in 1 min. The column was then reequilibrate with 10% B for 9 min before the next injection. The total analysis time was 45 min for each sample. The injection volume was 10 µL with tray temperature maintained at 12 ºC. High-resolution mass spectroscopy was carried in both positive and negative ESI ionisation switch modes with a spray voltage of 4.5 kV. The capillary temperature was set at 320 ºC with mass range from *m/z* 150 – *m/z* 1500 for ESI-MS range. HRESI-LCMS was used to conduct the dereplication study on the extracts, then data processed with MZmine 2.40.1 software, an in-house macro coupled with the Dictionary of Natural Product (DNP) 2015 and SIMCA P+ 15.0 (Umetrics AB, Umeå, Sweden). The mass spectral data was processed by using the procedure by MacIntyre et al., which was established in the Natural Products Metabolomics Group Laboratory at Strathclyde Institute of Pharmacy and Biomedical Sciences (SIPBS) as described here [16, 17]. The LC-MS chromatograms and spectra were viewed by using MZmine 2.40.1. Raw data were initially sliced into negative and positive data sets utilising the MassConvert software package from ProteoWizard (pwiz).

Results and Discussions

Extract yields of *Fusarium* sp. and *Curvularia* sp.

Daily monitoring of *Curvularia* sp. resulted in black colour of mycelia and grew all over the plate by day 9. Meanwhile, *Fusarium* sp. had yellow and slightly pink colour and occupied the whole plate by day 8. In a co-culture, *Fusarium* sp. ramified faster than *Curvularia* sp. as shown in Figure 1. Previous study reported that the fungi contained a variety of bioactive compounds with unique structures including benzopyranones, alkaloids, flavonoids, chinones, quinones, phenolic acids, terpenoids, steroids, xanthones, tetralones, and others. The bioactive metabolites are commonly used as antibiotics, agrochemicals, antiparasitics, immunosuppressants, anticancer and antioxidants agents [3]. The extract from single culture of *Fusarium* sp. 30 days (F30) from rice medium gave the highest extract yield with 204.76±12.6 mg (Table 1). Meanwhile, the extract yield from co-culture also increased from day 7 (FC7 = 151.23±17.4 mg) to 189 mg for day 15 and day 30 (FC15 & FC30 extracts). The use of sterile rice as an alternative substrate promoted a better amount of fungus mycelial that led to the production of higher yield of extract that could be used in pharmacological purposes and other applications as compared to inoculation on agar plates.

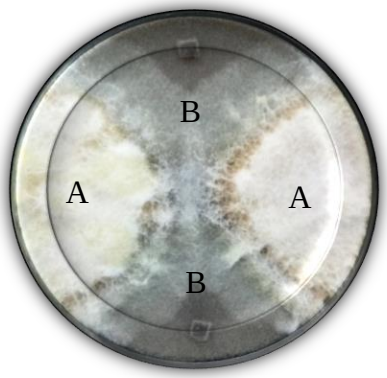

Figure 1. The co-culture between *Fusarium* sp. (A) and *Curvularia* sp. (B) on malt agar plate after 21 incubation days

Antioxidant activity

The scavenging activity of the extracts that were obtained from both media showed a significant activiy (Table 1). Extracts from malt agar plates showed a potent activity with IC_{50} values of 0.6 mg/mL – 2.4 mg/mL. While, the activity of extracts from single culture day 7 of *Fusarium* sp. and *Curvularia* sp. was also observed; MAF7 (IC_{50} = 1.7 mg/mL) and MAC7 (IC_{50} = 0.85 mg/mL), respectively. However, the extracts from agar culture that were incubated between day 15 and day 30 decreased in activity. Interestingly, the activity of extracts from co-culture grown on agar plates increased as compared to their single culture's extract. The co-culture between two or more fungi in a confined vessel promoted the competition of nutrients and space, thus triggering the production of metabolites that may responsible in increased activity. Therefore, a co-culture between *Fusarium* sp. and *Curvularia* sp. in a larger volume was introduced in this study. The use of rice as an alternative substrate gave essential nutrient for

the growth of fungi, besides it is more economic to produce better amount of extract that may have the same metabolites with similar biological activities to the extract that obtained from malt agar culture. Amongst the co-culture extracts, culture of FC15 grown on day 15 possessed in enhanced scavenging activity with IC_{50} value of 2.8 mg/mL as compared to FC7 (IC_{50} = 4.1 mg/mL) and FC30 (IC_{50} = 4.8 mg/mL). The endophytic fungi were reported possessing bioactive compounds including phenols, in which the hydroxyl groups have a potent antioxidant activity. The phenolic group is very active agent in DPPH solution because the bond dissociation energy in O-H is lower, thus it is easier to lose H atom [34]. A study on *Curvularia* sp. reported that various functional groups such as aromatic, carboxylic acid [35], phenol, ester and ketone were identified [36].

The data were expressed as mean ±SD (n=3).

Antibacterial activity

The antibacterial activity of the extracts showed more selectivity towards the Gram-positive bacteria with MIC values of 0.156 mg/mL – 10 mg/mL (Table 2), however, no activity was observed against the Gram-negative bacteria, except on *Salmonella* sp. Amongst the extracts, extracts from agar plate showed a potent activity as compared to the extracts from rice medium, except extracts from single culture of *Curvularia* sp. day 7 (C7) and day 15 (C15) also inhibited the growth of *Salmonella* sp. with MIC values of 5.0 mg/mL. The antibacterial results showed there was a significant loss of biaoactivity in the extracts grown in rice medium as compared to extracts from rice culture. Althought, the ability of the extracts to inhibit more specific activity on the bacteria used in this study, cultivation of the fungi on agar plate also can be optimised in rice medium for their mass production purposes by monitoring the diversity of chemical profiles in the extracts.

Dereplication study on extracts

Amongst the the extracts, extracts from a co-culture between *Fusarium* sp. and *Curvularia* sp. day 15 (FC15) in rice as a substrate was the optimum condition for mass production of their bioactive metabolites in these two fungi. The other parameters that have to be considered were shorter period and yield of the extract in order to have an adequate starting material for further isolation work. Dereplication studies on HRESI-LCMS data coupled with multivariate analysis on the extracts were evaluated that correlated with their bioactivities. Further investigation on FC15 extract was carried out by observing the occurrence of the metabolites in total ion chromatogram (Figure 2A). Distribution of the known and unknown compounds (highlighted rows) in the FC15 extract (Table 3) was dereplicated and putatively identified by using Dictionary of Natural Product (DNP) database. The FC15 extract possessed microlides, cyclic peptides and polyketides compounds that were putatively identified as 24-demethyl bafilomycin C1, cyclosporine C and monocerin, respectively, earlier were isolated from *Streptomyces* sp. and fungi [20].

A PCA model (Figure 2B) was also used to examine the variation and the diversity of the various extracts. However, the PCA model gave a low predictability score with Q^2 = 0.276. No significant variation can differentiate the extracts. Thus, the differences between the extracts were visualised by a supervised model. The supervised OPLS-DA (Figure 2C) scores scatter plot showed the difference between the most antioxidant active extract (colored violet) of *Fusarium* sp. (FC15), and other extracts (colored blue) that have moderate activity (FC7, FC30, C7, C15, and C30). Meanwhile, from the S-loadings (Figure 2D) scatter plot, metabolites can be predicted to be responsible for the most active group and be targeted for mass production prior to isolation work. From FC15 extract, the metabolite at *m/z* 276.159 $[M+H]^+$ was putatively identified as annotine that previously has been isolated from *Lycopodium annotinum* [24]. While, the ion peak at *m/z* 367.124 $[M+H]^+$ matched with 3-O-α-L-rhamnopyranosyl-D-galactose; 2-ac earlier reported from bacterial cell wall polysaccharides, and the ion peak at *m/z* 515.3331 $[M+H]^+$ was putatively identified as serratamolide A, that previously were isolated from bacteria *Serratia marcescens* [25]. The ion peak at *m/z* $[M+H]^+$ 309.132 was putatively identified as monocerin, that has been isolated from *Helminthosporium monoceras*, *Fusarium larvarum* and *Exserohilum rostratum* [26]. Other metabolites were also observed at *m/z* 213.112 $[M+H]^+$ and $[M-H]^-$ 257.045 that were putatively identified as canadensolide; 1',3β-Dihydro and simonyellin; 5-Deoxy, respectively, earlier were isolated from *Penicillium* sp. [27]. The ion peaks at *m/z* 243.050 $[M+H]^+$ and 301.075 $[M-H]^-$ were putatively identified as 3,4,5-trihydroxy-1,2-benzenedicarboxylic acid; 3,5-di-me ether and 1-deoxyxylitol; D-form, 2,4-methylene, 5-tosyl, respectively. While, the *m/z* $[M+H]^+$ 226.071, 241.143, 276.195 and $[M-H]^-$ 265.111, 595.359 were putatively identified as serine; (R)-form, N-(2-hydroxybenzoyl), armillariol C, 6-[2-(1-Hydroxybutyl)-4-methylphenyl]-5-hexenamide; (E)-form, vasconine and thiomarinol H, respectively. These metabolties have been isolated from *Actinomadura madurae* IFM 0745, *Armillaria* sp. strain 488, *Streptomyces* X537 [21], *Narcissus vasconicus* [28] and *Pseudoalteromonas* sp. SANK73390 [29], respectively. Other ion peaks in the FC15 extract have been dereplicated as presented in Table 3. Five discriminationg metabolites were also observed at *m/z* $[M+H]^+$ 369.131, 309.110 and *m/z* [M-

H]$^-$ 307.113, 593.343, 181.094, which did not find any match from the database.

Previous studies reported that serratamolide A possessing antimicrobial activity on the Gram-positive bacterium methicillin-resistant *Staphylococcus aureus* (MRSA) [30], while, bafilomycin C1; 24-Demethyl inhibited *Penicillium avellaneum* UC-4376 with minimal inhibitory amount at 10 µg/disc and possessed cytotoxic activity against tumour (P388) and lung cancer (A-549) cells at concentration 10^{-4} M with cell line inhibitory rate at 97.9% and 96.9%, respectively [21]. Meanwhile, compound cyclosporine C possessed a strong antifungal activity on fungi *Alternaria* sp. (MIC = 0.1 µg/mL – 0.5 µg/mL) and *Penicillium* sp. (MIC = 2.0 µg/mL - 5.0 µg/mL) [23]. Monocerin from *Fusarium* sp. possessed antioxidant activity at more than 324 µM [31] and antibacterial activity on *S. aureus* (MIC = 62.5 µg/mL) and *E. coli* (MIC = 15.62 µg/mL), while thiomarinol H also inhibited *S. aureus* [32, 33].

Conclusion

The extracts from co-culture on malt agar plate possessed a stronger antioxidant activity as compared to their independent extracts. Meanwhile, the antibacterial activity of the extracts demonstrated more selective inhibition on the Gram positive bacteria. Optimisation of the co-culture between *Fusarium* sp. and *Curvularia* sp. in sterile rice medium for up-scaling, increased the antioxidant activity in the co-culture FC15 extract as compared to other extracts. The supervised OPLS-DA scores scatter plot showed the difference in diversity of various metabolites between the most active antioxidant FC15 extract as compared to others. Therefore, the co-culture between two fungi triggers the silent gene to produce difference metabolites that absent in their independent extracts that can be further explored for pharmaceutical purposes.

Abstract

This work demonstrated the development and the application of a home-built spectrophotometer device employing Arduino microcontroller. Arduino UNO microcontroller was utilized as a data acquisition system. Arrangement of the system's hardware was based on the working principle of a commercially available benchtop instrument. For the first time in the scope of Arduino-based spectrophotometer, the developed device consisted of double light sources and innovative monochromator design to cater the requirement of ultraviolet (UV) and visible ranges. A visible white LED and UV LED emitting between 190 and 600 nm spectrum were employed. Light dependent resistor (LDR) and GUVA-S12SD UV sensor were utilized as light detectors. Innovative monochromator system was incorporated with combination of stepper motor and DVD disc as a diffraction grating for wavelength selection. The effectiveness of the UV range in the device was tested using bisphenol A (BPA) and triclosan, while Reactive Orange 16 and Reactive Red 120 dyes for visible range. The device could detect BPA from 10 to 50 ppm concentration (obtained through external linear graph producing R^2 = 0.9970), while triclosan from 1 to 5 ppm (R^2 = 0.9971). The limit of detection (LOD) and the limit of quantitation (LOQ) for BPA were 7.01 ppm and 23.38 ppm, respectively. The LOD and LOQ for triclosan were 0.60 ppm and 1.99 ppm, respectively. The results obtained from the device on all analytes were validated with a commercially available benchtop UV-vis spectrophotometer. The linearity of BPA from 10 to 50 ppm obtained a correlation of R^2 = 0.9941. Triclosan showed R^2 = 0.9965 for linearity from 1 to 5 ppm. The LOD and LOQ were 8.58 ppm and 28.61 ppm, respectively. The LOD and LOQ for triclosan were 0.66 ppm and 2.19 ppm respectively. As for visible range, the benchtop spectrophotometer could detect Reactive Orange 16 from 10 to 50 ppm concentration (R^2 = 0.9967) while Reactive Red 120 (R^2 = 0.9958). The LOD and LOQ for Reactive Orange 16 were 6.76 ppm and 22.52 ppm, respectively. The LOD and LOQ for Reactive Red 120 were 6.94 ppm and 23.13 ppm, respectively. Nearly identical R^2, LOD and LOQ were obtained for both home-built Arduino device and the benchtop UV-visible spectrophotometer. These data indicated positive outcomes with accuracy percentage 95% and 97.2% for BPA and triclosan, 98.6% and 93.5% for Reactive Orange 16 and Reactive Red 120 dye of the home-built Arduino spectrophotometer.

Abstrak

Kajian ini menunjukkan pembangunan dan aplikasi peranti spektrofotometer binaan sendiri yang menggunakan mikropengawal Arduino. Pengawal mikro Arduino UNO telah digunakan sebagai sistem pemerolehan data. Susunan perkakasan sistem adalah berdasarkan prinsip kerja instrumen komersil. Buat pertama kali dalam skop spektrofotometer berasaskan Arduino, peranti yang dibangunkan terdiri daripada sumber cahaya berganda dan reka bentuk monokromator yang inovatif untuk memenuhi keperluan julat ultraungu (UV) dan boleh dilihat. LED putih yang kelihatan dan LED UV yang memancarkan antara spektrum 190 dan 600 nm telah digunakan. Perintang bergantung cahaya (LDR) dan sensor UV GUVA-S12SD digunakan sebagai pengesan cahaya. Sistem monokromator yang inovatif telah digabungkan dengan gabungan motor pelangkah dan cakera DVD sebagai parut difraksi untuk pemilihan panjang gelombang. Keberkesanan julat UV dalam peranti telah diuji menggunakan bisphenol A (BPA) dan triclosan, manakala pewarna Reactive Orange 16 dan Reactive Red 120 untuk julat yang boleh dilihat. Peranti boleh mengesan BPA dari 10 hingga 50 ppm kepekatan (diperolehi melalui graf linear luaran yang menghasilkan R2 = 0.9970), manakala triclosan dari 1 hingga 5 ppm (R^2 = 0.9971). Had pengesanan (LOD) dan had kuantiti (LOQ) untuk BPA ialah 7.01 ppm dan 23.38 ppm, masing-masing. LOD dan LOQ untuk triclosan ialah 0.60 ppm dan 1.99 ppm, masing-masing. Keputusan yang diperoleh daripada peranti pada semua analit telah disahkan dengan spektrofotometer UV-vis komersil. Kelinearan BPA dari 10 hingga 50 ppm memperoleh korelasi R^2 = 0.9941. Triclosan menunjukkan R^2 = 0.9965 untuk lineariti dari 1 hingga 5 ppm. LOD dan LOQ masing-masing ialah 8.58 ppm dan 28.61 ppm. LOD dan LOQ pula untuk triclosan masing-masing adalah 0.66 ppm dan 2.19 ppm. Bagi julat yang boleh dilihat, spektrofotometer komersil boleh mengesan Jingga Reaktif 16 daripada kepekatan 10 hingga 50 ppm (R^2 = 0.9967) manakala Merah Reaktif 120 (R^2 = 0.9958). LOD dan LOQ untuk Oren Reaktif 16 masing-masing ialah 6.76 ppm dan 22.52 ppm. LOD dan LOQ untuk Reactive Red 120 ialah 6.94 ppm dan 23.13 ppm, masing-masing. R^2, LOD dan LOQ yang hampir sama diperolehi untuk kedua-dua peranti Arduino yang dibina sendiri dan spektrofotometer komersil. Data ini menunjukkan hasil positif dengan peratusan ketepatan 95% dan 97.2% untuk BPA dan triclosan, 98.6% dan 93.5% untuk Reactive Orange 16 dan Reactive Red 120 bagi pewarna spektrofotometer Arduino yang dibina sendiri.

Introduction

Water-soluble dye residues in particular from the chemically intensive textile industry's waste fluids have the potential to be a major source of environmental contamination because they can infiltrate several environmental compartments through soil, air, and water [1]. Several studies have shown that a sizeable portion (about 20%) of the dyes used in the textile industry each year, such as Rhodamine B, Victoria blue, Rose Bengal, Indigo Red, Caramine, Red 120, Eriochrome, Methylene Blue (MB), Black-T (EBT), and Thymol blue, are lost during the synthesis and processing processes and end up in wastewater [2]. Azo dyes are a common chemical pollutant found in environmental and water contamination. These dye-polluted effluents include colourful pigments that are toxic, non-biodegradable, and dangerous to living things [2; 3]. Thus, it is crucial to remove dyes from effluent due to being able to cause serious health related problems as well as disruption towards the ecosystems [4]. Azo dyes are typically used in a number of products, including textiles, paper, food or leather. One of the major classes of hazardous organic compounds, according to researchers, is made up of textile and industrial colourants. According to the World Bank, the textile finishing and dyeing sectors account for a significant portion of the 17–20% water pollution [2]. Owing to their toxicity and carcinogenicity, these compounds and their degradation products can be harmful [5]. Furthermore, several forms of dyes can have adverse effects on various organisms, including humans, and certain bacterial and mammalian assays that can be genotoxic [6].

A synthetic molecule known as bisphenol A (BPA) is often employed as a monomer, especially in the creation of epoxy resins and polycarbonate. Polycarbonates are used in a variety of products, including water bottles, baby feeding bottles, toys, cutlery, thermal paper, and medical equipment due to its ability to withstand high temperatures (up to 145 °C) [7]. There is growing evidence that certain chemicals, known as endocrine disrupting chemicals (EDCs), such as estradiol, nonylphenol, medicines, and some pesticides, can interact with endocrine systems if they are present in drinking water at a very low concentration [8]. One of the EDCs is BPA that may give potential threats to human beings, leading to hormonal complications, cancers, hypospadias, miscarriages, endometriosis, and infertility [9]. BPA can increase cellular response by interacting with

oestrogen receptors since its structure is similar to that of oestradiol and diethylstilbestrol. Moreover, research on lab animals demonstrated negative impacts on health even at low BPA dosages [7]. The quality and safety of marine products were negatively impacted by the pollutants found in the seawater and sediment columns, which would feed benthic and pelagic animals and enter the food chain. Due to its probable link to harmful health impacts like obesity, neurobehavioral issues, and reproductive and neurobehavioral issues like prostate cancer, bisphenol-A has drawn a lot of attention [10].

The broad-spectrum of the antibacterial agent triclosan is frequently found in pharmaceutical and personal care products (PPCPs). Many bacteria and fungi are fungicidal to TCS [11]. Triclosan is one of the most widely used biocides and it is frequently found in aquatic habitats. To protect against bacteria [11], Triclosan is frequently utilized in pharmaceutical and personal care products, hand soap, and wet wipes [12]. Direct contact with personal care items as well as other sources, such as food, water, and dust, can expose individuals to triclosan [13]. People can be exposed to triclosan as a result of its presence in aquatic and terrestrial areas which has occurred either directly through the use of PPCPs or indirectly through bioaccumulation [14]. Triclosan was discovered in bodily fluids such blood, breast milk, urine, and these substances affect the endocrine system and can cause hormonal abnormalities [14]. Triclosan may hinder the development of species in both terrestrial and aquatic habitats and potentially endanger the health of people who are exposed to these conditions. Broad-spectrum antibacterial activity is a property of triclosan. Triclosan has a negative impact on wastewater because activated sludge microbes are directly exposed to it, which inhibits bacterial growth, reduces bacterial diversity and abundance, and alters the composition of bacterial communities[15].

A device used for analysis called an Ultraviolet-visible (UV-Vis) light spectrophotometer examines the analyte absorbances of light, at specific wavelengths where different materials absorb and reflect these wavelengths differently [16]. For the analysis of pollutants, UV-Vis, atomic absorption spectroscopy (AAS), and tabletop devices with chromatographic bases are frequently utilized. In addition to these benchtop devices, on-site chemical analysis may save overall analysis costs because the result from on-site testing just needs to be validated by a simpler conclusive analysis. Thus, bringing heavy, complex instruments for on-site investigation is also impractical. There is a rising need for straightforward methods for on-site pollutants analysis in industrial wastes, leachates, landfills, and other sources of pollution due to ecological issues. Furthermore, a prospective complimentary element to a chemical analysis is the availability of an affordable and portable instrument to do the pollutant analysis on-site. For instance, applications for civil lawsuits and environmental monitoring both need quick decision-making. Low-cost, effective microcontrollers are employed as control-processing units in a variety of portable and handheld instruments. Amongst the most extensively used open-source microcontrollers is the Arduino. Arduino can be programmed with the measurement algorithms, calibration function, and drift corrections required for the entire instrument activity by using the numerical final result shown on a computer as input [17]. Prior to the previous 20 years, their increased application in industrial machines, cars, and domestic appliances made microcontrollers the top-selling products in the market for electronic chips despite their niche [18].

Portable devices based on the Arduino microcontroller are touted to have low manufacturing costs, simple operations, quick manufacture, and low power consumption [19]. To measure wavelengths for educational purposes, Widiatmoko and a colleague [20] constructed a spectrophotometer out of cardboard, a digital camera for the hardware, a photodiode sensor, and a microcontroller. They used image processing to acquire optical wavelengths with a theoretical resolution of up to 0.2 nm. However, Zhang et al. [21] developed a portable spectrophotometer for measuring the quality of water utilizing LEDs as the light source and photodiode sensors to detect specific wavelength peaks at 420 nm, 455 nm, 515 nm, 560 nm, 605 nm, and 630 nm. The created spectrophotometer was able to differentiate between ammonia and nitrite nitrogen contamination in lab-made water. In truth, the chemical structures of the contaminants in our environment vary greatly. This indicates that they must be detected in the UV band as

well, which is a feature that the majority of the portable photometers/spectrophotometers made at home lack.

This paper presents the development of a home-built spectrophotometer employing Arduino microcontroller for selected chemicals screening purpose. This brings to specific objectives which are to develop a home-built spectrophotometer equipped with Arduino platform as a microcontroller for automation. Next, to test the effectiveness and validate the UV detection of the home-built spectrophotometer device using BPA and triclosan. Lastly, to test the effectiveness and validate the visible detection of the home-built spectrophotometer device using Reactive orange 16 and Reactive Red 120. This study aims to develop a home-built spectrophotometer device based on spectroscopy principle. Different from other methods, the present device consisted of visible white LED and UV LED emitting between 190 and 600 nm spectrum. The developed device consisted of double light sources and innovative monochromator design to cater to the requirement of ultraviolet (UV) and visible ranges. A visible white LED and UV LED emitting between 190 and 600 nm spectrum were employed. Light dependent resistor (LDR) and GUVA-S12SD UV sensors were utilized as light detectors. An innovative monochromator system was incorporated with combination of stepper motor and DVD disc as a diffraction grating for wavelength selection. The effectiveness of the UV range in the device was tested using bisphenol A (BPA) and triclosan, while Reactive Orange 16 and Reactive Red 120 dyes were used for visible range. The wavelength will be detected by TSL1401CL from the sample, and it will give an output which will be displayed in a serial monitor. Afterwards, the results on all analytes from the device will be validated using commercially available benchtop UV-vis spectrophotometer.

Materials and Methods

Components and specifications

The arrangement of the hardware in the home-built spectrophotometer was based on the working principle of the benchtop instrument Shimadzu UV-1800 UV-Vis Spectrophotometer. There were two light sources used in this research namely white light LED with 8500K color temperature and UV LED with range from 190 to 380nm. Next, the "entrance slit" for the photometer was made with a piece of cardboard. The dispersion device or monochromator was made by assembling a cut up DVD with a 28byj-48 stepper motor which allows movement of the diffracted light. There was also an Edmund Optics achromatic lens that corrected chromatic distortion. Two pieces of slits with the same length were placed side by side. Furthermore, the sample holder (also known as cuvette) filled with sample solution followed by the detection using Light Dependent Resistor (LDR) sensor and GUVA-S12SD UV detector. These detectors were chosen due to their suitability of wavelength range for UV and visible analytes. Some of the detectors that were considered before were BPW34, ML8511 UV sensor, TSL1401 and TCS3200 color sensor. All of the detectors have different wavelength ranges for UV and visible but do not meet the criteria for developing the simple home-built spectrophotometer. An innovative monochromator system was incorporated with combination of step motor and disc as a diffraction grating for wavelength selection to complete the system. The schematic of a home-built spectrophotometer is shown in Figure 1 while the real device photograph is shown in Figure 2. The calibration on the distance between detector and sample cuvette was made and showed that 16cm gives the best reading of the detector. As the photoresistor detector converted the absorbed light into electrical current, the data can be transferred to the monitor via Arduino. The wavelengths were chosen by rotating the motor, and one specific visible wavelength band was chosen to pass through a handcrafted slit. The slit permits a restricted spectral bandwidth to exit the monochromator. This incident beamed on the sample held in the sample holder which was the source of this outgoing spectrum. The detectors will then read the absorbance of the samples and display the data on the serial monitor in the Arduino IDE software. Then, it will then be connected to Excel worksheet for further wavelength calculations. The wavelengths were calculated using Eq. 1:

$$n\lambda = d \sin\theta \quad (1)$$

where λ is the wavelength of a specific color; n = 1 (grating order); d = 740 (distance between slits in a DVD); and θ = diffraction angle.

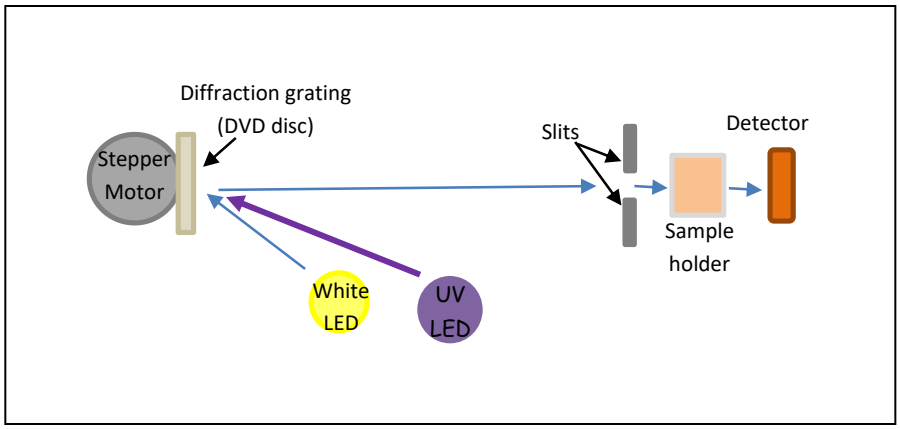

Figure 1. The schematic diagram of a portable spectrophotometer

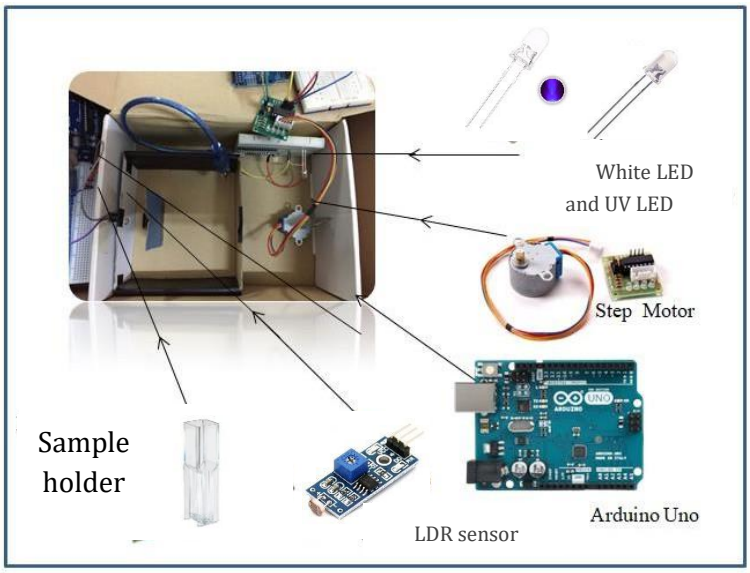

Figure 2. Portable spectrophotometer hardware arrangement

The concentration value of a chemical substance was approximately proportional to the quantity of light it absorbs when introduced to monochromatic radiation, according to Beer Lambert's law. Once the voltage readings for the light collected in the detector for the comparison and the substance being examined were gathered, the absorbance value was calculated using the following calculation in Eq.2:

$$A = \log_{10} \frac{P}{Po} = -\log_{10}(T) \qquad (2)$$

where A is absorbance; P is magnitude of transmitted light through the sample; Po is magnitude of transmitted light through the reference; and P/Po = T, which is transmittance.

Comparable to most industrial benchtop spectrophotometers, this newly built home-built Arduino spectrophotometer was small and lightweight. The home-built Arduino spectrophotometer was also very compatible with current common laboratory usage because, unlike many other home-built spectrophotometers, it can measure both UV-Vis spectrums while remaining compatible with current generic cuvettes.

Arduino programming

Arduino Uno and Arduino Nano were programmed with the system operating logic flow using the Arduino IDE 1.8.13 software as shown in Figure 3. The data of the analog transmittance signals from the UV and visible

photodetectors will transform into digital signals and can be monitored through the Arduino serial monitor.

Figure 3. Arduino sketchpad in Arduino IDE software

Experimental setup

The user can select wavelengths for the UV and visible range between 190 nm and 600 nm depending on the desired analysis. For each sample's individual spectrophotometric analysis, quartz cuvettes were employed. The cuvette was filled with a minimum of 1.5 mL of the sample solution, with the optically transparent surfaces towards the light source and detector. BPA, triclosan, Reactive orange 16 and Reactive Red 120 absorb UV and visible wavelength, peaking at 226 nm, 282 nm, 493 nm and 534 nm respectively.

Preparation for BPA sample follows the steps accordingly. Firstly, the stock solution was prepared by weighing BPA powder for 100 mg and placed in 100 mL volumetric flask. Then 5mL of 30% ethanol solution was added to dissolve the powder and filled up until it reached the mark. Then 1, 2-, 3-, 4-, and 5-mL solutions were taken into another 100 mL volumetric flask, and they were filled with 30% ethanol until the mark was reached. Thus, the concentration will be for 10, 20, 30, 40 and 50 ppm. While for triclosan sample preparation, 500 mg L^{-1} of stock solution was prepared by weighing the triclosan for 0.025 g. The triclosan was dissolved in ethanol/acetone (1:1) solution for each 10 mL. Then, it was diluted into a 50 mL volumetric flask with distilled water until it reached the mark. The stock solution was kept at -20 °C. Next, 0.02 mL of solution was taken using micropipette into a 10 mL volumetric flask. The volumetric flask was filled with distilled water until it reached the mark and labelled as 1 ppm. This step was repeated for 0.04 mL, 0.06 mL, 0.08 mL and 0.1 mL of solution respectively and the volumetric flask was labelled for 2 ppm, 3 ppm, 4 ppm and 5 ppm.

For the sample preparation of the Reactive Orange 16, a stock solution was prepared by mixing 100 mg of dry analyte in 100 mL of volumetric flask to make 1000 ppm solution. Standard working solutions which have 1, 2, 3, 4 and 5 mL accordingly of Reactive Orange 16 were made by diluting of appropriate serial dilution of the stock solution to 100 mL with distilled water. Thus, making the concentration for 10, 20, 30, 40 and 50 ppm of sample. Sample preparation for Reactive Red 120, a. stock solution was prepared by mixing 100 mg of dry analyte in 100 mL of volumetric flask to make 1000 ppm solution. Standard working solutions which have 1, 2, 3, 4 and 5 mL accordingly of Reactive Orange 16 were

made by diluting the appropriate serial dilution of the stock solution to 100 mL with distilled water. Thus, this made the concentration for 10, 20, 30, 40 and 50 ppm of sample. Measurements were taken accordingly, of all the samples data using the benchtop instrument which was the UV-Vis spectrophotometer with wavelength range from 190 nm to 600 nm. After that, the measurements of the samples were taken using the developed portable spectrophotometer device. The samples were poured in a cuvette and placed in the sample holder to record the absorbance. Table 1 included a list of the components as well as their local market prices. This spectrophotometer is estimated to cost around RM348.30 to build.

Table 1. List of components for home-built spectrophotometer

Components	**Quantity**	**Unit Price (RM)**	**Total (RM)**
Arduino Uno	1	31.90	31.90
Stepper motor and driver	1	9.50	9.50
Breadboard	1	6.80	6.80
Resistor	2	0.05	0.10
Jumper wire	1	2.50	2.50
Light Dependent Resistor	1	1.10	1.10
GUVA-S12SD UV detector	1	24.40	24.40
Push button	1	0.60	0.60
White LED	1	0.10	0.10
UV LED	1	0.30	0.30
DVD	1	1.00	1.00
Achromatic lens	1	270.00	270.00
Total cost (RM)			348.30

Results and Discussion

A home-built spectrophotometer was successfully built by equipping it with two light sources, UV and visible light detectors, and a monochromator which consisted of achromatic lens, DVD disc, and slit. The measuring method, calibration operations, and drift correction needed for the entire instrument functioning were written into the Arduino microcontroller, with the numeric result presented on screen. The data acquisition algorithm was successfully uploaded to the hardware setup of home-built spectrophotometer via the USB port. The detectors were chosen due to their suitability of wavelength range for UV and visible analytes. Some of the detectors that were considered before but not suitable due to the analyte's wavelength range were BPW34, ML8511 UV sensors and TSL1401 and TCS3200 color sensors. Calibration of the sensors were also conducted to allow the optimum detection of the sensors towards the light source, which resulted in 16 cm apart between light source and sensors to achieve the right spectrum and data reading. The difference in absorption between both devices and benchtop instruments were likely attributed to the use of different light sources, detectors and internal algorithms in the device employing Arduino microcontroller with UV-vis spectrophotometer. The Arduino microcontroller with UV-vis spectrophotometer uses were more sensitive and advanced detectors. In the device, the light source was calibrated as well as the sensors. The most accurate data obtained by the sensors was when the light source and sensors were 16 cm apart. This was demonstrated by the sensor calibration findings at various distances from the light source, which ranged from 2 cm to 22 cm with intervals of 2 cm (Figure 4). The highest reading of LDR was 16 cm, which gave the brightest spectrum detection in the home-built spectrophotometer.

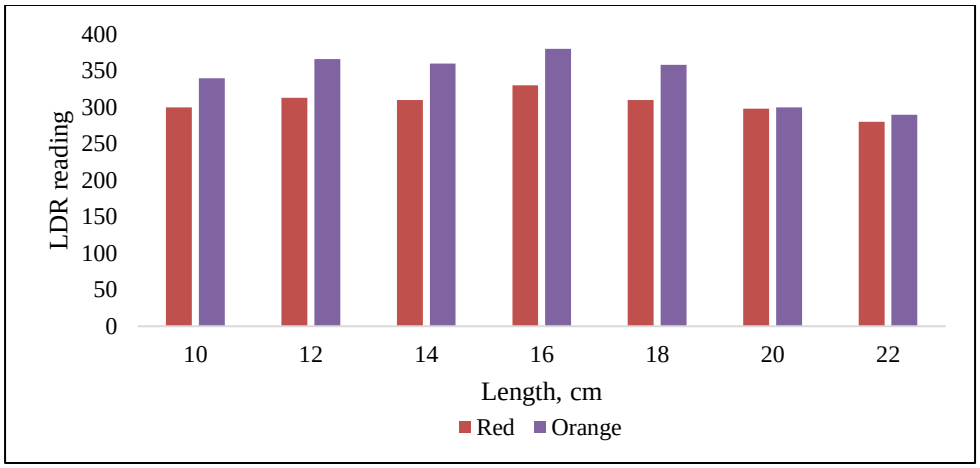

Figure 4. Calibration of different lengths between light source and sensors

To investigate whether the developed Arduino-based spectrophotometer device was functioning well, the device was applied to analyse BPA, triclosan, Reactive Orange 16 and Reactive Red 120 similar with that in benchtop UV-Visible spectrophotometer. The device could detect BPA from 10 to 50 ppm concentration (obtained through external linear graph producing R^2 = 0.9970) as shown in Figure 5a, while triclosan from 1 to 5 ppm (R^2 = 0.9971) as shown in Figure 5b. The limit of detection (LOD) and the limit of quantitation (LOQ) for BPA were 7.01 ppm and 23.38 ppm, respectively. The LOD and LOQ for triclosan were 0.60 ppm and 1.99 ppm, respectively. The results obtained from the device on all analytes were validated with a commercially available benchtop UV-vis spectrophotometer. In Figure 5c the linearity of BPA from 10 to 50 ppm obtained a correlation of R^2 = 0.9941. Triclosan showed R^2 = 0.9965 for linearity from 1 to 5 ppm as shown in Figure 5d. The LOD and LOQ were 8.58 ppm and 28.61 ppm, respectively. The LOD and LOQ for triclosan were 0.66 ppm and 2.19 ppm respectively. Different from BPA, this UV analyte triclosan, has concentration ranges 1 – 5 ppm lower than BPA due to its low concentration detection in wastewater. However, with the components used in the home-built spectrophotometer, it can only detect low concentrations starting from 1 ppm onwards.

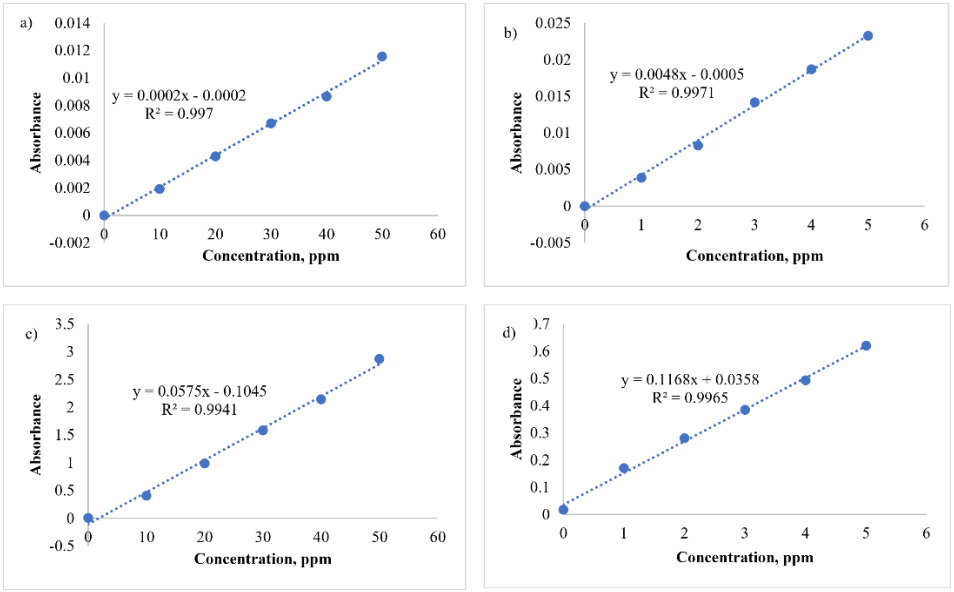

Figure 5. a) Calibration graph of BPA using the home-built spectrophotometer device b) Calibration graph of triclosan using the home-built spectrophotometer device c) Calibration graph of BPA using benchtop UV-Vis spectrophotometer d) Calibration graph of triclosan using benchtop UV-Vis spectrophotometer

As for visible range, the home-built spectrophotometer could detect Reactive Orange 16 from 10 to 50 ppm concentration (R^2 = 0.9958) as shown in Figure 6a while Reactive Red 120 (R^2 = 0.9967) in Figure 6b. The LOD and LOQ for Reactive Orange 16 were 6.76 ppm and 22.52 ppm, respectively. The LOD and LOQ for Reactive Red 120 were 6.94 ppm and 23.13 ppm, respectively. The analytes were validated with a commercially available benchtop UV-vis spectrophotometer. In Figure 6c, the linearity of Reactive Orange 16 from 10 to 50 ppm obtained a correlation of R^2 = 0.9984. Reactive Red 120 showed R^2 = 0.9974 for linearity from 10 to 50 ppm as shown in Figure 6d. The LOD and LOQ for Reactive Orange 16 were 4.43 ppm and 14.77 ppm, respectively. The LOD and LOQ for Reactive Red 120 were 3.60 ppm and 12.02 ppm respectively. As compared to the benchtop UV-Vis spectrophotometer, the home-built spectrophotometer showed lower absorbance measurement due to some factor when handling the experiment using home-built spectrophotometer. It was slightly a different spectrum color from the diffraction grating that affects the measurement.

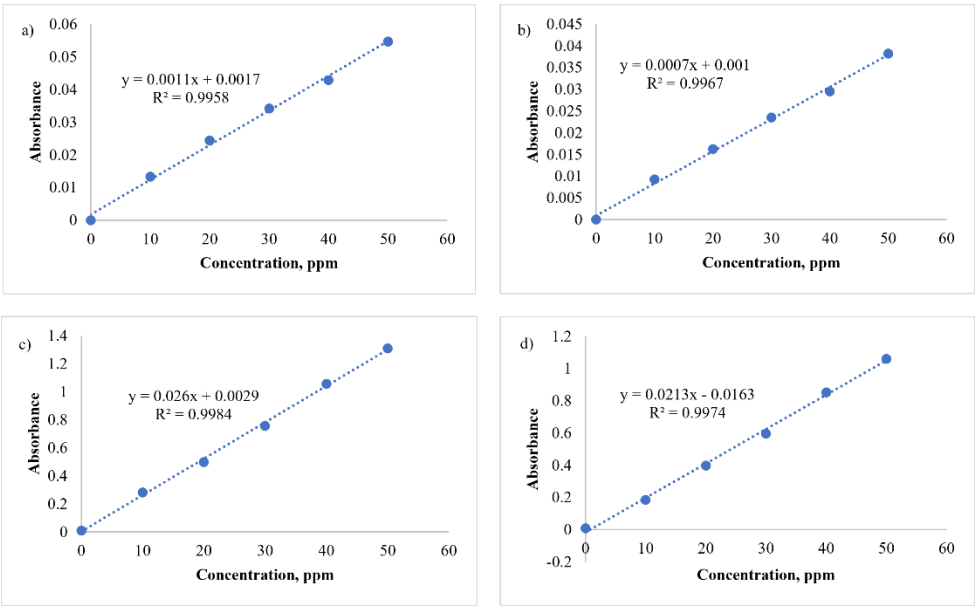

Figure 6. a) Calibration graph of Reactive Orange 16 using the home-built spectrophotometer device b) Calibration graph of Reactive Red 120 using the home-built spectrophotometer device c) Calibration graph of Reactive Orange 16 using benchtop UV-Vis spectrophotometer d) Calibration graph of Reactive Red 120 using benchtop UV-Vis spectrophotometer.

Another result that can be observed was the accuracy between the benchtop instrument and the portable Arduino device. The accuracy value was calculated using the following calculation in Eq 3:

$$y = mx + c \quad (3)$$

Nearly identical R^2, LOD and LOQ were obtained for both home-built Arduino device and the benchtop UV-visible spectrophotometer. These data indicated positive outcomes with accuracy percentage 95% and 97.2% for BPA and triclosan, 98.6% and 93.5% for Reactive Orange 16 and Reactive Red 120 dye of the home-built Arduino spectrophotometer. Comparison of the results between the benchtop instrument and home-built spectrophotometer devices showed a little difference in the accuracy percentage.

Conclusion

An automated Arduino-based semi-quantitative spectrophotometer device equipped with double light sources and innovative monochromator design for chemical analysis was developed to cater the requirement of UV and visible ranges required by a spectrophotometer for various chemical compounds. This home-built spectrophotometer device can be

further made as on-site analytical tool for dye contaminants in environment, quality control device as well as other functions in future studies. As a result, this system is reasonably priced, easy to maintain due to its small size, microcontroller-based, and amenable to further expansion for data acquisition automation via microcontroller. Other than that, this home-built spectrophotometer device development also encourages more inventions of Arduino based instrumentation for various other analytes and samples.

Abstract

In this research, molybdenum disulphide-graphene oxide (MoS_2-GO) was used as photocatalyst for the degradation of perfluorooctanoic acid (PFOA) under 12-watt light emitting diode (LED) irradiation. The photocatalyst performance was evaluated by a series of experiment; effect of contact time, trapping experiments and recyclability studies. Effect of contact time revealed MoS_2-GO degraded PFOA with 80.77% at 120 equilibrium time. Langmuir-Hinshelwood (L-H) kinetic model was applied to study the kinetic model with (R^2) of 0.8726 at half-life ($t_{1/2}$) 2.31 h under LED light irradiation. The trapping experiment shows that photocatalytic process was dominant by $\bullet O_2^-$, where $\bullet O_2^-$, supported by proton ion (h^+), is the major active species whereas •OH only played a minor part in the entire photocatalytic process. The recyclability study revealed the MoS_2-GO can be reused for up to six cycles. The employed photocatalyst in the sixth cycle was analyzed using FTIR and the FTIR spectrum shows that the peak diminishes its intensity after reusability at peaks of 1300 cm^{-1} to 1800 cm^{-1} for carbonyl (C=O), epoxy, the C=C stretching mode and carbonyl (>C=O), 750 cm^{-1} to 1250 cm^{-1} indicates the S-S bond, and at 3038 cm^{-1} that is attributed to the O-H stretching vibrations. Thus, this research proposed a performance evaluation of MoS_2-GO as photocatalyst for photocatalytic degradation of PFOA under indoor LED light irradiation.

Keywords: molybdenum disulphide, photodegradation, perfluorooctanoic acid, light emitting diode

Abstrak

Dalam penyelidikan ini, molibdenum disulfida-grafena oksida (MoS_2-GO) digunakan sebagai pemangkin foto untuk degradasi asid perfluorooktanoik (PFOA) di bawah penyinaran diod pemancar cahaya (LED) 12 watt. Prestasi pemangkin foto telah dinilai oleh satu siri eksperimen; kesan masa sentuhan, eksperimen perangkap dan kajian kitar semula. Kesan masa sentuhan mendedahkan MoS_2-GO merendahkan PFOA dengan 80.77% pada 120 masa keseimbangan. Model kinetik Langmuir-

Hinshelwood (L-H) telah digunakan untuk mengkaji model kinetik dengan (R^2) sebanyak 0.8726 pada separuh hayat ($t_{1/2}$) 2.31 h di bawah penyinaran cahaya LED. Eksperimen perangkap menunjukkan bahawa proses fotokatalitik didominasi oleh $\bullet O_2^-$, di mana $\bullet O_2^-$, disokong oleh ion proton (h^+), adalah spesies aktif utama manakala •OH hanya memainkan peranan kecil dalam keseluruhan proses fotokatalitik. Kajian kebolehkitaran semula mendedahkan MoS_2-GO boleh digunakan semula sehingga enam kitaran. Pemangkin foto yang digunakan dalam kitaran keenam telah dianalisis menggunakan FTIR dan spektrum FTIR menunjukkan bahawa puncak mengurangkan keamatannya selepas kebolehgunaan semula pada titik 1300 cm^{-1} hingga 1800 cm^{-1} untuk karbonil (C=O), epoksi, mod renggangan C=C dan karbonil (>C=O), 750 cm^{-1} hingga 1250 cm^{-1} mewakili ikatan S-S, dan di titik 3038 cm^{-1} yang mewakili ikatan renggangan O-H. Oleh itu, penyelidikan ini mencadangkan penilaian prestasi MoS_2-GO sebagai pemangkin foto untuk degradasi fotokatalitik PFOA di bawah penyinaran cahaya LED dalaman.

Kata kunci: molibdenum disulfida, fotodegradasi, asid perfluorooktanoik, diod pemancar cahaya

Introduction

Earth's surface is about 71% covered with water and over 96.5% of the Earth's water is held by oceans. In addition to these places, water may be found in air as water vapour, in water bodies such as rivers and lakes, icecaps and glaciers, Earth's soil moisture and aquifers. When harmful chemicals or microbes are released into water resources directly from industrial, commercial, or residential sources, water pollution occurs. Additionally, polluted soils can leak pollutants into streams and lead to environmental problems [2]. Therefore, non-conventional chemical emissions into water supply, surface water and drainage have resulted in significant distress.

Perfluorinated compounds (PFCs) have sparked alarm for the environment and human health because of their persistence and tendency to accumulate heavy metals. PFCs also affect hormones and induce immunotoxicity, neurotoxicity as well as developmental issues [13]. A member of PFC family, called perfluorooctanoic acid (PFOA) has raised controversy amongst the nation due to its necessity in the manufacture of Teflon, high temperature lubricants, protective coatings and surfactants [8]. Likewise, PFOA provides advantages, including improvement of stain, grease and in waterproofing. According to the US Environmental Protection Agency these pollutants are frequently found in industrial, consumer and food products. But, unlike other persistent pollutants, PFOA is easily soluble in water and readily migrated into aquifers [19]. As a result, it can bioaccumulate in the bloodstream and liver instead of fatty tissues [17].

In addition, owing to its carbon-fluorine (C-F) bond, PFOA is a remarkably stable and lasting compound which does not naturally break down. For this reason, the environment or anybody exposed to PFOA might possibly be harmed. Considering the harmful consequences that it has on the environment and to protect as well as nurture the environment for all living organisms, an innovation that can properly break down PFOA is required. The photocatalytic breakdown of PFOAs by photo-oxidative and photo-reductive degradation appears to be more suitable than the other ways outlined above. Additionally, photocatalysis oxidation has become a very promising technology due to its wide range of uses in photocatalytic process, powerful oxidising capacity, and absence of secondary pollutants. Additionally, it has advanced significantly in theory and application [7, 9, 22]. Previously, studies by Hao et al. with $BiPO_4$ photocatalyst and Sahu et al. with Ag-TiO_2 photocatalyst degraded PFOA by 72% and 57.7% when exposed to fluorescent lamp radiation for two hours and seven hours respectively. Meanwhile, Trojanowicz et al. used TiO_2 as a photocatalyst to degrade PFOA with 55.9% efficiency over the course of two hours [3, 13, 15].

Heterogeneous photocatalytic oxidation of PFOA appears as a potent, economical alternative strategy due to the ease of generating active oxygen-containing species under UV-visible irradiation, ease of photocatalyst separation and ability to recycle the catalyst. Heterostructure photocatalysts with semiconductor are employed in various fields, including electronics, catalysts, solar panels, and supercapacitor materials. According to Li et al., integrating a semiconductor with another semiconductor can enhance

light absorption and reduce photo-generated electron hole recombination [7]. Two-dimensional (2D) nanostructures have drawn attention as substitutes to photocatalytic materials in the pursuit for highly efficient photocatalytic materials due to their photocatalytic performance being driven by visible light [16]. This is because the outstanding optical and electrical features of the 2D materials demonstrate the capacity to confine electrons in their ultrathin layer. Moreover, due to their high electrochemical nature on the basal planes and edges of 2D materials in energy conversion (e.g., TMDs), well-balanced hydrogen binding Gibbs free energy on the basal sites (e.g., 1T′ MoS_2) high specific surface area, abundance of surface-active sites as well as their superior external performance, the 2D materials of MoS_2 have great structural advantages in photocatalysis [11]. Additionally, the large specific surface area of the 2D design makes surface reactions possible.

A good charge carrier for semiconductors may be found in the molecularly thick, 2D nanomaterials known as graphene, which are composed of sp2 carbon atoms that are arranged in a honeycomb structure [12]. Graphene is employed as a remarkable electron-acceptor or transport material in photocatalysis because of its capacity to decrease photogenerated electron hole recombination and increase light adsorption [6]. In addition, it has been shown that the enormous specific surface area of graphene and effective electron transport properties has made it into a fantastic co-catalyst for photocatalytic activity. [5].

While PFOA is chemically stable, photodegradation is observed to be effective when exposed to UV light. The limitations of light sources like halogen or xenon bulbs are high cost, short lifespan, poor light penetration, and low luminous efficiency. Therefore, the advantages of light emitting diode (LED) sources include the requirement for a separate water-cooling facility removal to maintain a constant temperature, flexibility of LED source placement within the designed reaction system and addition of a co-catalyst; hence, securing the enhancement of photocatalytic activity under the visible-light region. Consequently, in this work, MoS2-GO was used as a photocatalyst material to break down PFOA by using indoor LED light. As per of our knowledge, there is no attempt had been made utilizing indoor LED light as the source of light for photodegradation of PFOA.

Materials and Methods

Materials

The MoS_2-GO composites were synthesised via hydrothermal method under acidic conditions using the sodium molybdate (Na_2MoO_4) and thiourea as starting materials and successfully characterised in prior studies as outlined in literature [9].

Analytical method

The amount of PFOA in the aqueous phase was determined by using the High-Performance Liquid Chromatography (HPLC) instrument. The manual sample injector (injection volume: 20 µL), degasser, pump, and column oven (40ºC) comprised the HPLC system (Agilent 1100 series HPLC). The separating column was served by C18. The samples were isocratically eluted with acetonitrile (ACN) and aqueous NaH_2PO_4 (5 mMol, adjusted to pH 7.0) (50:50, v/v) as the eluents at a flow rate of 1.0 mL min^{-1} and 210 nm, respectively.

Contact time and kinetic study

In this work, the kinetic research of MoS_2-GO composites on the PFOA degradation was studied by using the Langmuir-Hinshelwood (L-H) kinetic model. By breaking down PFOA while being exposed to a 12-watt LED lamp's light, the MoS_2-GO photocatalytic activity was assessed. By oxidising PFOA while being illuminated by a 12-watt LED light, the MoS_2-GO photocatalytic activity was assessed. A photoreactor with several quartz tube reactors served as setting for the photocatalytic testing. In this photocatalytic experiment, 0.002 g of MoS_2-GO composite was placed in a beaker along with 20 mL of a 50 mg/L PFOA stock solution. Then, to guarantee that adsorption/desorption equilibrium was reached, the solution was stirred continuously for 30 min. At this time (t = 0), 20 mL of each solution that contained 50 mg/L (C_o) was introduced to the UV photoreactor. The mixture was subsequently centrifuged and filtered to get rid of the composite. HPLC-UV detection was used to measure

the amount of PFOA present during the photocatalytic degradation process. The C/C_o ratio was calculated by using PFOA absorption measurements for each sample, whereby C_o was the PFOA concentration at t = 0 min and C was the PFOA concentration at a specified time.

Trapping experiment

The trapping experiment was to examine the reactive species (such as h^+, •OH, e^-, and $•O_2^-$) which could be formed during photocatalysis and interact with PFOA. Trapping tests were carried out under identical experimental circumstances as those in the photodegradation experiments, with the exception that certain scavengers were introduced to the suspensions before being exposed to LED irradiation. The hydroxyl radical (•OH) scavenger was isopropanol (IPA, 1 mmol/L) [7], while the superoxide radical ($•O_2^-$) scavenger was p-benzoquinone (BQ, 0.1 mmol/L) [20].

Recyclability of the photocatalyst

Prospect of recycling and renewing the photocatalyst was examined over six cycles. After cleaning with methanol and water and drying for 12 h in a vacuum at 70˚ C, the photocatalyst was recycled. FTIR analysis was applied to check for any chemical modifications in the regenerated photocatalyst.

Results and Discussion

Photodegradation experiment: Contact time and kinetic study

To further study the impact of contact duration on the kinetic behaviour of the photodegradation process, the materials were evaluated with LED irradiation from 0 min to 120 min and in the dark for 30 min to further study the impact of contact duration on the kinetic behaviour of the photodegradation process. Figure 1 shows little deterioration in the dark area with the changing trend shown when the adsorption/desorption equilibrium was established. Between 0 and 30 minutes, there was a noticeable rapid decrease; between 60 min and 120 min, there was a gradual decline and continual stagnation. As the active sites of photocatalyst were initially unoccupied, the increase happened quickly at first. Thereafter, PFOA was instantly degraded by the photocatalysts. Most active sites were interacting, slowing the rate at which PFOA degraded since there were less opportunities for holes and electrons to join. Many research studies on heterogeneous photocatalysts in photodegradation demonstrated a finding that was consistent with the Langmuir-Hinshelwood (L-H) kinetic model for organic pollutants. (Equation 1) [9].

$$ro = -\frac{dC}{dt} = \frac{kKc}{1+Kc} \quad (1)$$

Where, *ro* is the reactant degradation rate, *k* is reaction rate constant, *K* is adsorption equilibrium constant, and *C* is reactant concentration. $Kc << 1$ in the L-H equilibrium can be simplified to a pseudo-first-order kinetic model by considering the low concentration of PFOA utilised in the experiment (Equation 2).

$$-\frac{dC}{dt} = kKc = k_{obs}C \quad (2)$$

Further set the limit of C = Go at t=0, the Equation 2 can be integrated, which resulted in Equation 3.

$$-Ln\frac{C}{C_o} = k_{obs}t \quad (3)$$

According to a plot of Ln C/Co vs irradiation time presented in Figure 1, the kinetic constants for the observed variables pseudo-first-order rate constant k, coefficient of determination R^2, and half-life $t_{1/2}$ were respectively, 0.005 min^{-1}, 0.8726, and 138.6 min. Table 1 displays the kinetic characteristics (pseudo-first order) of various photocatalyst types in the PFOA degradation. Most degrading techniques utilise the use of fluorescent, UV, visible or simulated solar radiation. By using indoor LED lighting as a source of light in the PFOA degradation process, inadequate information was found. The data revealed that PFOA was rapidly degraded under visible light without having Sb_2O_3 as the photocatalyst since Sb_2O_3/TiO_2 had a bigger k constant (0.0126 min^{-1}) and a shorter t half-life (6.612 h) than TiO_2. Further, $NaIO_4$ was shown to have better kinetic performance than Ag-TiO_2 with 0.0096 min^{-1} k constant than 0.00217 min^{-1}. While Ag-PFOA TiO_2 content was reduced by 72% under fluorescent light, $BiPO_4$ was discovered to have good degrading efficiency. Notably, kinetic results from this study showed that MoS_2-GO could break down PFOA when exposed to indoor LED light, with a 2.31-hour reduction in half of PFOA

concentration from its original concentration [1, 6, 13, 20].

Trapping experiment

Many reactive species, including proton ion (h^+), •OH, e^-, and $•O_2^-$ may be generated during photocatalysis and may react with PFOA. Trapping investigations into the active species during the photocatalytic PFOA degradation were conducted to better understand the photocatalysis process. According to Figure 3, there was no discernible difference in the photocatalytic PFOA degradation with isopropanol (IPA, 1 mmol/L, a scavenger of •OH) as compared to without a scavenger. This suggested that •OH was not the main active component. The photodegradation was completely quenched when p-benzoquinone (BQ, 0.1 mmol/L, quencher of $•O_2^-$) was added, indicating that $•O_2^-$ was the main active species and crucial to the photocatalytic activity. It was clear from this that the important oxidative species was $•O_2^-$ produced by the interaction of photogenerated electrons and O_2, while the photogenerated h^+ also supported the absolute term for PFOA degradation in the nanohybrid composite photocatalyst system. It might be presumed that $•O_2^-$ played a significant part in the photocatalytic process based on the trapping analysis (Figure 3). These findings implied that $•O_2^-$, supported by h^+, was the major active species and the fundamental mechanism for the powerful photocatalytic activity, whereas •OH only played a minor part in the entire photocatalytic process [3, 10, 18].

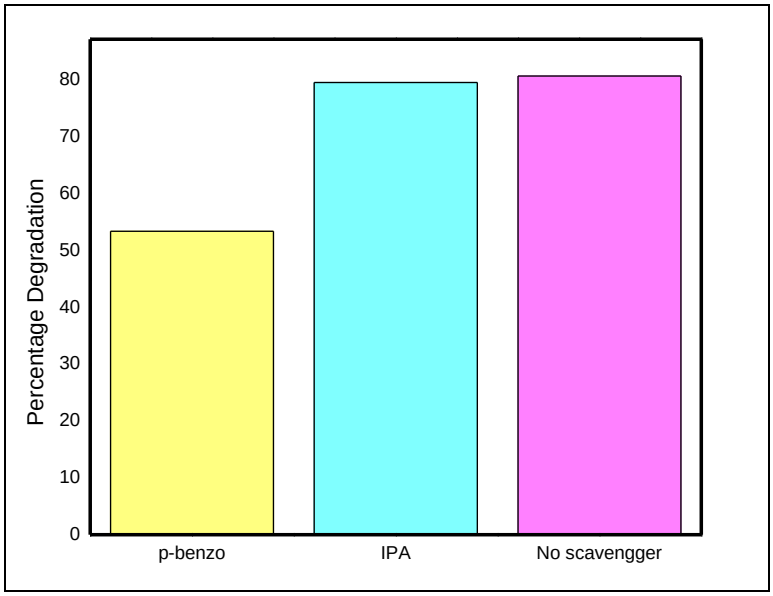

Figure 3. Trapping experiment of the active species during photocatalytic degradation of PFOA over nanocomposite alone and with the addition of BQ (quencher of $\bullet O_2^-$) and IPA (quencher of •OH) under indoor LED light irradiation

Recyclability of study

The most noteworthy aspect of photocatalytic degradation studies is a reusable, sustainable photocatalyst. After a few cycles of use, a promising photocatalyst must be able to maintain good degrading performance. The photocatalyst was cleaned with ethanol and water prior to the experiment and then dried in a vacuum for 2 h at 70 °C. Figure 4 shows that after six further experiments, the deterioration efficiency was reduced by about 30%. As a result, it was determined that the MoS_2-GO might be reused and renewed for up to six cycles. The six cycles of photocatalyst were examined by using FTIR to demonstrate the causes of MoS_2-GO's reduced degradation efficiency. According to Figure 5, the FTIR spectrum demonstrated that the peak intensity decreased after reusability due to lesser affinity as most active sites interact, reducing the production of free radicals and, consequently, the degradation process. They might be seen in the missing peaks at 1300 cm^{-1} to 1800 cm^{-1} for carbonyl (C=O), epoxy, the C=C stretching mode and carbonyl (>C=O), 750 cm^{-1} to 1250 cm^{-1} indicates the S-S bond, and at 3038 cm^{-1} is attributed to the O-H stretching vibrations that resulted from the repeated washing recyclability of the composites [14,15,21]. The recyclability of study may be extended up to seven cycles or more however, the increasing of missing peaks which indicated the availability of MoS_2-GO nanocomposites showed that the degradation process was performed by absorption of light source since the LED irradiation range was applied in a broad wavelength of 275nm to 950nm.

Conclusion

Under the 12-watt indoor LED light irradiation, GO, MoS_2, and MoS_2-GO composites were successfully fabricated, characterised and used as a catalyst for PFOA photodegradation. With increasing loading and contact duration, MoS_2-GO demonstrated the greatest PFOA degradation. The Langmuir-Hinshelwood model employed a pseudo-first order rate law to define the kinetics of PFOA photodegradation. According to the stability and reusability studies, MoS_2-GO may be used up to six times without losing its properties. The greatest degrading effectiveness of photocatalysts in PFOA had proved that MoS_2-GO was successfully used as a photocatalyst. Moreover, by adding the p-benzoquinone scavenger to MoS_2-GO composites it accelerated the breakdown of PFOA, whereby $\bullet O_2^-$ was the main active species and an important player in the photocatalytic reaction. Overall, the research findings showed that MoS_2-GO as a versatile photocatalysts that can degrade

the organic wastes by using low cost and safe indoor LED light.

Abstract

Fatty acid deep eutectic solvents (DES) became known as a promising alternative to traditional organic solvents for various extraction processes. In this study, a hydrophobic DES comprising a mixture of lauric acid (C_{12}) and pelargonic acid (C_9) at a molar ratio of 1:3, was utilized to extract 2,4-D and MCPA herbicides from aqueous solutions. FTIR and TGA were utilized in order to characterize the synthesized DES. Emulsification liquid-liquid microextraction (ELLME) technique is employed to enhance the efficiency of extraction. Furthermore, response surface methodology (RSM) was applied to optimize the extraction process of these herbicides while considering parameters such as volume of DES and emulsifying agent and pH. RSM method has various advantages, including its simplicity, fast, low cost, and great extraction efficiency. It also helps in selecting the optimum condition method to analyze the relationship between the variable, where pH 2, 265 µL volume of DES and 200 µL volume of tetrahydrofuran (THF) were the optimal conditions obtained in this study. Under these conditions, the coefficients of determination (R^2) were obtained between 65% and 79%. In addition, the results obtained from the experiment are comparable to or closely aligned with RSM, hence there was a good fit between the two methods. These results revealed that the fatty acid-based DES demonstrated remarkable efficiency in extracting 2,4-D and MCPA herbicides as well as contributing to the development of environmentally friendly extraction techniques.

Abstrak

Pelarut eutektik terdalam asid lemak (DES) dikenali sebagai alternatif kepada pelarut organik tradisional untuk digunakan dalam pelbagai proses pengekstrakan. Dalam kajian ini, DES hidrofobik yang terdiri daripada campuran asid laurik (C_{12}) dan asid pelargonik (C_9) pada nisbah molar 1:3, telah digunakan untuk mengekstrak racun herba 2,4-D dan MCPA daripada larutan akueus. FTIR dan TGA telah digunakan untuk mengenalpasti DES yang disintesis. Teknik pengekstrakan mikro cecair-cecair pengemulsi

(ELLME) digunakan untuk meningkatkan kecekapan pengekstrakan. Tambahan pula, metodologi permukaan tindak balas (RSM) digunakan bertujuan untuk mengoptimumkan proses pengekstrakan racun herba ini dan mempertimbangkan parameter seperti isipadu DES dan agen pengemulsi dan pH. Kaedah RSM ini mempunyai pelbagai kelebihan, termasuk kesederhanaan, pantas, kos rendah, dan kecekapan pengekstrakan yang hebat. RSM juga membantu dalam memilih keadaan kaedah yang optimum untuk menganalisis hubungan antara pembolehubah, di mana pH 2, 265 µL isipadu DES dan 200 µL isipadu tetrahydrofuran (THF) adalah keadaan optimum yang diperolehi dalam kajian ini. Dengan keadaan ini, pekali penentuan (R^2) diperoleh antara 65% dan 79%. Di samping itu, keputusan yang diperoleh daripada data eksperimen adalah setanding atau sejajar rapat dengan data RSM, oleh itu terdapat kesesuaian yang baik antara kedua-dua kaedah. Keputusan ini mendedahkan bahawa DES berasaskan asid lemak menunjukkan kecekapan yang luar biasa dalam mengekstrak racun herba 2,4-D dan MCPA serta menyumbang kepada pembangunan teknik pengekstrakan mesra alam.

Introduction

Providing a safe and healthy environment for everyone while concurrently reducing the hazardousness effects of current pollutants is one of the major challenges encountered by modern industry. Pesticides account for 9 of the top 12 most harmful and persistent pollutants identified by the Stockholm Convention on Persistent Organic Pollutants [1]. Herbicides, insecticides, fungicides, and other pesticides are used extensively in agriculture, and as a result, these compounds are dispersed in the environment in large quantities [2]. Therefore, the presence of pesticide residues in water, soil, and agricultural products has the potential to surpass the permitted thresholds, resulting in significant environmental contamination [2] and even human health problems [3]. Phenoxy acid herbicides are extensively employed in agricultural practices for the purpose of managing the proliferation of undesirable weeds [4]. These compounds' cost-effectiveness and high efficacy at low concentrations are widely acknowledged, albeit accompanied by potential hazards to human health [5]. Following application, these herbicides have the potential to readily infiltrate water systems as a result of their high-water solubility. They are known to have mutagenic, teratogenic, and carcinogenic properties that can lead to cytotoxicity and DNA damage after extended exposure. Detecting these substances in food and environmental samples raises significant concerns regarding their potential impact on human and animal consumption [6]. Hence, it is imperative to closely monitor the presence of these herbicides in both food and environmental samples to ensure adherence to established environmental quality standards.

Concerned with the safety of the environment and people's health, experts have been working hard to find sensitive and careful ways to test for pesticides. In order to determine these pesticides, a sample pre-treatment plays an important role during the analytical procedure. The techniques used for sample pre-treatment revolve mainly around extracting analytes from the sample matrix into a suitable solvent for the sample to be pre-concentrated and cleaned. Conventional sample pre-treatments such as liquid-liquid and solid phase extraction are commonly employed for pre-concentration of phenoxy acid herbicides [4, 6]. The use of these procedures is commonly hindered by labour and cost intensiveness, as well as the substantial consumption of toxic solvents, hence rendering these techniques incongruent with sustainable development objectives.

Microextraction techniques have emerged as a recent approach for the analysis of pesticides in environmental and food samples. These techniques have been chosen for their miniaturization, simple operation, low cost, and minimal sample and solvent consumption [3]. Solid phase micro-extraction (SPME), magnetic solid phase extraction (MSPE), emulsification liquid-liquid microextraction (ELLME), and dispersive solid phase extraction (DSPE) are the most frequently used pre-treatment methods for analysing pesticides in food samples and environmental water [7]. Out of these techniques, ELLME stands out as a widely utilized pre-treatment method for pesticide residues [7] due to its simplicity, ease of operation, rapidity, and high extraction efficiency [8]. In ELLME, sample solutions are treated with extraction solvents of high solubility

and emulsifier solvents to extract the target analytes. Among the plethora of microextraction techniques, ELLME offers several advantages, such as small amount of organic solvent consumption, time savings, and greater extraction efficiency [9].

For the development of ELLME conditions, organic solvents must be used in the determination of various types of pesticides. However, a massive number of organic solvents contribute to negative impacts on human health and the environment. The advent of green chemistry has led to the proposal of deep eutectic solvents (DES), a novel group of environmentally friendly solvents, as a potential substitute for traditional solvents, due to their green features [10]. Usually, DES is made from economical materials using simple preparation steps. It is ideal for microextraction methods due to its great thermal stability and biodegradability features. In its typical form, DES is produced by combining two substances, a hydrogen bond donor (HBD) and a hydrogen bond acceptor (HBA), which are then hydrogen-bonded to one another to produce a molecule with a low melting point [11].

Recently, researchers have proposed the utilization of hydrophobic deep eutectic solvents (DES) to extract analytes from water samples. Hydrophobic DES are formed by combining one or two hydrophobic components, resulting in DES with hydrophobic nature. Consequently, researchers have directed their attention towards the potential of hydrophobic deep eutectic solvents (DES) derived from fatty acids. Previous studies have demonstrated the efficacy of hydrophobic deep eutectic solvents (DES) as extraction media for a diverse range of analytes. Florida et al. initially reported the utilization of hydrophobic DES synthesis by combining two fatty acids, HBA and HBD, to remove bisphenol A [12]. Subsequently, DES derived from fatty acids was used for harmful industrial dye removal [13] in addition to the recognition of benzophenone and salicylate UV filters [14].

Additionally, it is crucial to optimize the extraction process in analytical methods to minimize the utilization of materials, decrease process costs, and streamline time-consuming steps. In this context, optimization studies involving chemometric modelling hold significance. Response surface methodology (RSM) is a computational approach to optimizing intricate processes [15]. The statistical technique employed in this study aims to optimize the values of a dependent variable by considering multiple independent factors. Its purpose is to facilitate a comparison between theoretical predictions and empirical observations [16]. The RSM method enables the efficient testing of all variables associated with consumer evaluation within a condensed timeframe during the optimization process. This enhances the efficiency of the laboratory testing procedure. Consequently, this leads to a decrease in expenses, utilization of resources, and the requisite number of experimental trials [11], [16]. In addition to these, using quantitative data in the context of Response Surface Methodology (RSM) enables the evaluation of relationships and interactions among multiple parameters. This facilitates the identification of the most favorable conditions in an experiment. Additionally, mitigating matrix impact and enhancing analyte extraction efficiency are supplementary benefits [11].

In light of the explanations mentioned above, this study aimed to synthesize a deep eutectic solvent composed of fatty acids, specifically lauric acid and pelargonic acid. Additionally, the fatty acids DES was analysed characterized by using thermogravimetric analysis (TGA) and Fourier transform infrared spectroscopy (FTIR). Moreover, two types of herbicides, 2,4-D and MCPA were extracted by using this DES. To achieve the best extraction effect, the application of response surface methodology (RSM) was employed to determine the optimum conditions by considering a few important variables (volume of DES, volume of emulsifier solvent, and pH).

Materials and Methods

Materials

All the pesticides used namely MCPA and 2,4-D (purity, ≥ 98.0%) were purchased from Sigma-Aldrich (St Louis, MO, USA). Lauric acid (purity ≥ 98.0%) and pelargonic acid (purity, ≥97.0%) were also supplied by Sigma-Aldrich (St Louis, MO, USA). Hydrochloric acid (37%) and acetonitrile were obtained from QRec (Auckland, New Zealand). Tetrahydrofuran (analytical

grade) was purchased from Merck (Darmstadt, Germany). The herbicide stock solutions were prepared in acetonitrile at a concentration of 1000 μg mL^{-1}. The stock solutions of each herbicide were serially diluted in acetonitrile to create working solution combinations of 10 μg mL^{-1}.

Instrumentations

The FTIR spectra were recorded using Perkin Elmer 2000 FTIR instrument (Waltham, MA, USA) to verify functional groups present in the synthesized DES. The spectra were obtained during 16 scans within the range of 400–4000 cm^{-1}. Thermogravimetric analysis (TGA) was performed using Perkin Elmer STA 6000 (Waltham, MA, USA) under 5 mL min^{-1} nitrogen flow, at temperature ranging from 30 to 600 °C and heating rate of 10 °C min^{-1}. UV-2600 Spectrophotometer (Shimadzu, Japan) was used to determine concentration of herbicides in sample by using standard quartz cells with a path length of 1 cm. The pH value was measured with a HANNA HI 5221-02 Laboratory Research Grade Benchtop pH/mV Meter with 0.001 pH resolution.

Preparation of DES

The DES was synthesized in the same way as in the previous study by Florindo et al. [12] by combining two distinct fatty acids in a sealed glass vial and it was heated in a water bath at 40°C for 30 minutes. After synthesis, a homogeneous and clear solution was observed. The DES used in this work was prepared with the following ratio: Lauric acid: Pelargonic acid (1:3).

Emulsification liquid-liquid microextraction

In this work, 10 mL of aqueous solution containing targeted analytes (1.0 μg mL^{-1}) adjusted to pH 4 to 6 using 0.1 M hydrochloric acid or 0.1 M sodium hydroxide solutions was placed in 15 mL centrifuge tube. To extract the targeted analytes, DES and tetrahydrofuran were added to the aqueous solution with a micropipette. A cloudy solution was observed after the addition of emulsifier solvent (THF) into the extraction mixture which initiates the process of the aggregation and emulsification of DES. Subsequently, the extraction process was conducted using ultrasound in an ultrasonic bath for a duration of 15 minutes. The targeted analytes were removed to the DES phase as the aggregated DES dispersed into small droplets. After 10 minutes of centrifugation at 4000 rpm, two-phase separation was observed. The upper aqueous phase was extracted using a syringe, while the bottom layer was collected. The measurements for MCPA and 2,4-D were made at 290nm and 230nm, respectively using UV-Vis Spectrophotometer.

Response surface methodology

Response surface methodology (RSM) is a method employed to optimize chemical reactions to achieve the desired outcome. The experimental design was a Box-Behnken design (BBD) for three independent factors. The volume of DES, volume of THF, and pH of solution are three independent factors influenced the microextraction. Initially, physical experiments were conducted by systematically manipulating the experimental parameters to obtain the corresponding response values. Subsequently, the relationship between the input parameters and responses was established using a second-order polynomial or exponential function. Lastly, through the examination of surface graphs and the utilization of ANOVA, the optimal points were identified. Minitab Statistical Software, version 21 (Minitab Inc., United States) was employed to perform the BBD design and statistical analysis.

Results and Discussion

Characterization of DES: FTIR analysis

The synthesis of hydrophobic DES involved the combination of two fatty acids, namely lauric acid and pelargonic acid, in a molecular ratio of 1:3. As shown in Figure 1, The confirmation of the existence of functional groups in the synthesized DES was achieved by the utilization of FTIR analysis. The spectral data for each sample was obtained via 16 scans at a resolution of 4 cm^{-1}. Data was collected at wavenumbers from 500 to 4000 cm^{-1}.

The peaks were found in the range of 2850 to 2855 cm^{-1} and 2911 to 2925 cm^{-1} which attributed to the CH_2 and CH_3 groups, respectively, represented the fatty acids. Other significant peaks were observed at 1688 and 1705 cm^{-1}, which correspond to the stretching mode of the C = O group. Then, a broad absorption band was identified as the hydroxyl group (O-H) of the fatty acids, as

detected within the range of 3000 cm^{-1} and 3500 cm^{-1}. This phenomenon occurs when the O-H stretching absorption of these dimers exhibits significant intensity and broadness, primarily due to the influence of hydrogen bonding. The O-H bond demonstrates a propensity to oscillate at different frequencies and positions, resulting in enhanced band elongation [17]. The presence of O-H stretch was also detected between 1410 cm^{-1} and 1426cm^{-1} and 926 cm^{-1} and 940 cm^{-1}. The possible DES structure from the combination of lauric acid and pelargonic acid with molar ratio of 1:3 can be predicted as in Figure 2. In this DES structure, pelargonic acid acts hydrogen bonding donor, while lauric acid acts as hydrogen bonding acceptor. Therefore, the presence of these notable peaks proves that DES was successfully synthesized.

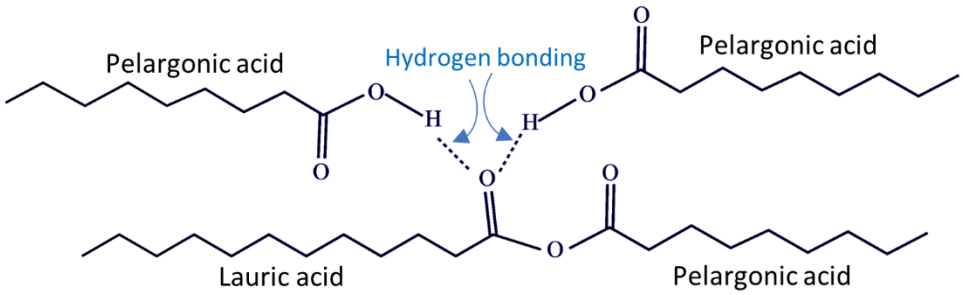

Figure 2. The possible structure of synthesized DES (combination of lauric acid and pelargonic acid with molar ratio (1:3))

Thermogravimetric analysis

As shown in Figure 3, thermogravimetric analysis (TGA) was utilized to examine the thermal properties of the synthesized DES. The TGA curve illustrates a single thermal decomposition (Td) temperature for each sample. Lauric acid, C_{12} exhibited a weight loss at 190.03 °C while pelargonic acid, C_9 showed at 166.58 °C. The weight loss for DES began at 189.97 °C. The thermal decomposition (Td) temperature determines the maximum temperature at which DES can remain liquid without decomposing. The observation of a high Td temperature indicates that a substantial amount of

energy is required to disrupts the intermolecular hydrogen bonding among the fatty acids present within the DES. Therefore, this temperature range significantly influences the applicability of DES as a solvent [18, 19]. After 200°C, the DES, and its starting materials, decomposed rapidly. There was no further degradation detected at temperatures above 200°C. This study demonstrates that DES containing lauric acid and pelargonic acid is considered thermally stable by having a high Td temperature.

Experimental optimisation of ELLME: Effect of volume of DES

The first consideration in determining the amount of the extraction solvent should be to achieve a high level of selectivity to facilitate the effective extraction of the desired analytes. Additionally, it is crucial to ensure that the solvent has minimum solubility in water [20, 21]. The DES in this work utilized a combination of lauric acid and pelargonic acid with ratio of 1:3 as described by Sazali et al. [22]. From the previous study, DES (C_{12}:C_9) exhibited highest extraction for MCPA and 2,4-D compared to other DES. The extraction capacity of this DES is influenced by the ability of fatty acids in DES to form hydrogen bonding interaction with the analytes. This phenomenon is attributed to the DES's low viscosity and high diffusivity properties. The main interaction occurred between the analytes and DES are primarily governed by intermolecular hydrogen bonding and hydrophobic interaction, which can be attributed to the hydrophobic nature of DES [12]. For optimal results in emulsification microextraction, an appropriate volume of extraction solvent must be used during the process [22]. Figure 4 showed the optimal volume of DES for MCPA was observed to be 500 µL. In contrast, for 2,4-D the optimal extraction volume is determined to be 30 µL of DES. However, it was observed that an increase in volume resulted in a decrease in the extraction efficiency of 2,4-D. The decrease in solubility of analytes within the DES phase can be ascribed to the dilution effect, which occurs when the volume of DES is increased. As a result, the loss in solubility ultimately results in a corresponding decrease in extraction efficiency [22, 24]. Contrarily, the situation differs for MCPA, as it requires a higher volume of DES. This is because the fatty acid DES used may have a high affinity for these analytes, enabling their efficient extraction [24]. Therefore, a higher volume of DES, up to a maximum of 500 µL, may be necessary to accommodate the MCPA herbicides effectively. Therefore, 500 µL and 30 µL volume of DES were chosen for MCPA and 2,4-D, respectively, for further experiments.

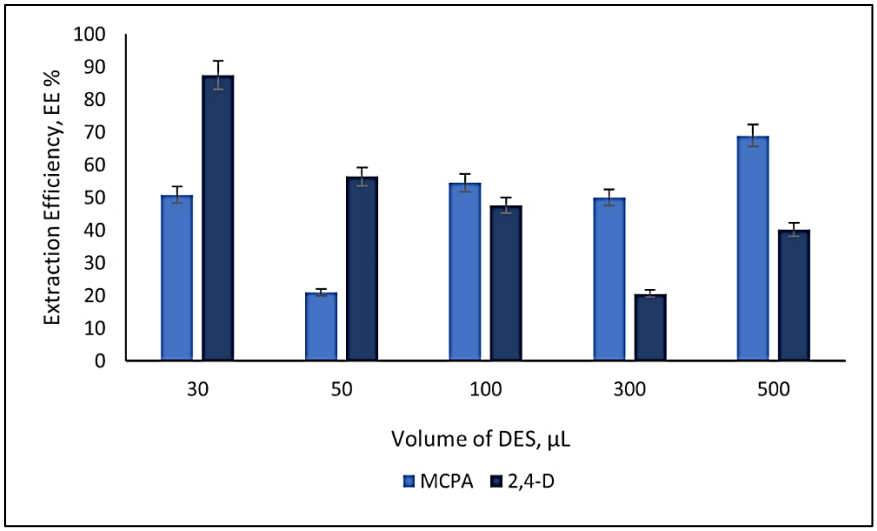

Figure 4. Effect of volume of DES. Condition: volume of THF: 500 µL; pH 4

Effect of volume of THF

The ELLME-DES approach involves the addition of an aprotic solvent as an emulsifier, resulting in the self-aggregation and subsequent separation of the DES molecules in the aqueous phase. Indeed, the emulsifier solvent tends to exhibit favourable interactions with water molecules than the DES. As a result, the DES exhibits self-aggregation, forming minute droplets that significantly enhance the contact surface area. This process facilitates the efficient mass transfer of the analytes from the aqueous phase to the DES phase [26, 27].

In this part, the impact of emulsifier solvent volume was studied by adjusting THF volume from 200 to 900 µL. Figure 5 shows the optimum value of THF was determined to be 500 µL and 200 µL for MCPA and 2,4-D, respectively. A potential reason for the observed low THF volume was achieved for 2,4-D could attributed to the high solubility of 2,4 D in aqueous phase. However, increasing the volume of THF leads to a decrease in extraction efficiency. The occurrence can be attributed to the high concentration of emulsifier, which significantly increases the solubility of both the extractant and analytes in the aqueous phase. Consequently, their distribution into the organic phase diminishes during extraction [9]. Furthermore, phenoxy acid herbicides, such as 2,4-D and MCPA, possess notable polarity and exhibit good solubility in water, thereby occasionally posing challenges in their precise extraction [28, 29]. To optimize the extraction process, it is important to control the volume of THF to maintain a sufficient concentration of the target analytes in the organic phase while minimizing their solubility in the aqueous phase. Thus, the optimal volume of emulsifier solvent was found to be 500 µL for MCPA and 200 µL for 2,4-D for further analysis.

Effect of pH solution

The pH of the sample solution is a crucial parameter as it influences the degree of ionization as well as the species of the analytes. Ionized forms of the target analytes may significantly affect the extraction efficiency [29]. In this study, the extractions were conducted at varying pH levels, from 2 to 10 adjusting using hydrochloric acid or sodium hydroxide solutions at 0.1 M. Herbicide extraction efficiency appears promising in an acidic environment (pH 2–6), as seen in Figure 6. The presence of herbicides such as MCPA and 2,4-D in their neutral form is primarily attributed to their inherent characteristics observed under acidic conditions. The effectiveness of partitioning into the hydrophobic DES is facilitated by their acidic nature [30]. The electronegative atoms of 2,4-D and MCPA form hydrogen bonds with the hydrogen bond donors (HBD) in their neutral state, thereby enhancing the solubility of the analytes in the deep eutectic solvent (DES) phase. The pH of the sample solutions was

adjusted to an acidic level for the subsequent investigations, as previous research has indicated that acidic conditions are optimal for the efficient extraction of most herbicides.

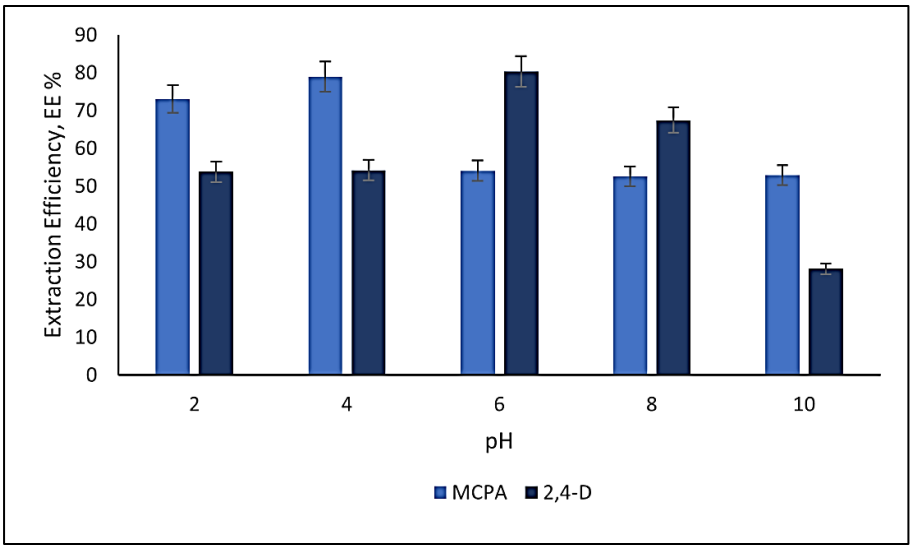

Figure 6. Effect of pH. Condition: volume of DES: 30 µL (2,4-D), 500 µL (MCPA); volume of THF: 200 µL (2,4-D), 500 µL (MCPA)

Theoretical optimization of ELLME using response surface methodology (RSM)

Response surface methodology (RSM) is a prominent statistical and mathematical technique that often aids in the systematic design of experiments [31]. Box-Behnken design (BBD) was utilized to determine the optimal combination of selected variables to conduct RSM analysis. This technique extensively analyses selected parameters and their interconnections [32]. The level of factors used in BBD are listed in Table 1. The design is based on three independent variables: volume of DES, volume of THF, and pH.

Table 1. Level of factors used in BBD.

Parameters	Unit	Lowest Value	Highest Value
Volume of DES	µL	30	500
Volume of THF	µL	200	900
pH		2	10

BBD serves as a valuable tool in minimizing the number of experiments, particularly during the initial stages. It facilitates the identification of influential factors in the response [33]. By conducting BBD (Box-Behnken Design), it is possible to identify crucial operational variables that can optimize the extraction efficiency of MCPA and 2,4-D herbicides. The variables were optimized using the two-level factorial design (low and high), as shown in Table 1. The effects of all variables on the extraction were determined through a series of 13 separate experiments. The present study utilized a statistical analysis technique known as analysis of variance (ANOVA) to investigate the impact of independent factors on microextraction efficiency. The results of ANOVA were determined by calculating the F and P-values, as shown in Table 2.

The determination of the significant association between the variables influencing the extraction efficiency, namely the volume of DES, volume of THF, and pH, and the response, represented by the peak area, was accomplished through the analysis of p-values and F-values. Models that exhibit greater F-values and lower p-values are suggestive of statistical significance. For a model term to be considered statistically significant, its p-value must be less than 0.05. Table 2 shows the F-values and p-values corresponding to the developed model, precisely 0.63 and 0.742 for MCPA, and 1.19 and 0.494 for 2,4-D herbicides, respectively. As shown, the main factors possess negligible effects, as indicated by their high p-values (> 0.05). A significant in lack of fit ($p<0.000$) was observed in both models, showing that the models inadequately specify the relationship between the variables and the response. In addition, the goodness of fit of the model was assessed by examining the coefficient of determination (R^2), which were 0.6527 and 0.7814 for MCPA and 2,4-D, respectively. These data indicated that 65.27% and 78.14% of the variability in MCPA and 2,4-D, respectively. According to the R^2 value of the model, it is possible that the connection between the variables and the response is not entirely represented. This implies that additional optimization or an alternative method may be required to attain a more accurate fit with the data. A possible explanation for this phenomenon is the presence of a weak correlation between the variables, which may hinder the model's ability to forecast the accurate relationships among the variables [34]. Besides, this can be explained by the high p-value ($p>0.05$), which suggests that none of the variables have statistical significance. Consequently, all the factors under consideration are independent, as they exhibit no mutual influence and do not significantly impact the interaction between one another. One of the variables can be changed independently without significantly impacting the response of the experiment. The following regression equation (1) and (2) represents the relationship between the variables studied (volume of DES, volume of THF, and pH) for MCPA and 2,4-D, respectively:

$$Y= 0.146+ 0.000148X_1 - 0.000090X_2 - 0.0077X_3 - 0.000001X_1^2 - 0.000000X_2^2 - 0.00024\,X_3^2 + 0.000000\,X_1\,X_2 + 0.000001\,X_1\,X_3 + 0.000011X_2\,X_3 \quad (1)$$

$$Y= 0.340 + 0.000748X_1 - 0.000800X_2 - 0.0235X_3 - 0.000001X_1^2 + 0.000001X_2^2 + 0.00055\,X_3^2 - 0.000000X_1\,X_2 + 0.000007X_1\,X_3 + 0.000022X_2\,X_3 \quad (2)$$

Where Y is absorbance, and X_1 , X_2 , X_3 are variables terms of volume of DES, volume of THF, and pH, respectively.

An interaction plot provides a visual representation of the relationship between a continuous response variable and the influence of a specific variable on another. This interaction plot shows the influence of two or more variables on the response [35]. Figure 7 and Figure 8 illustrate the interaction effect of variables on the extraction of 2,4-D and MCPA extractions.

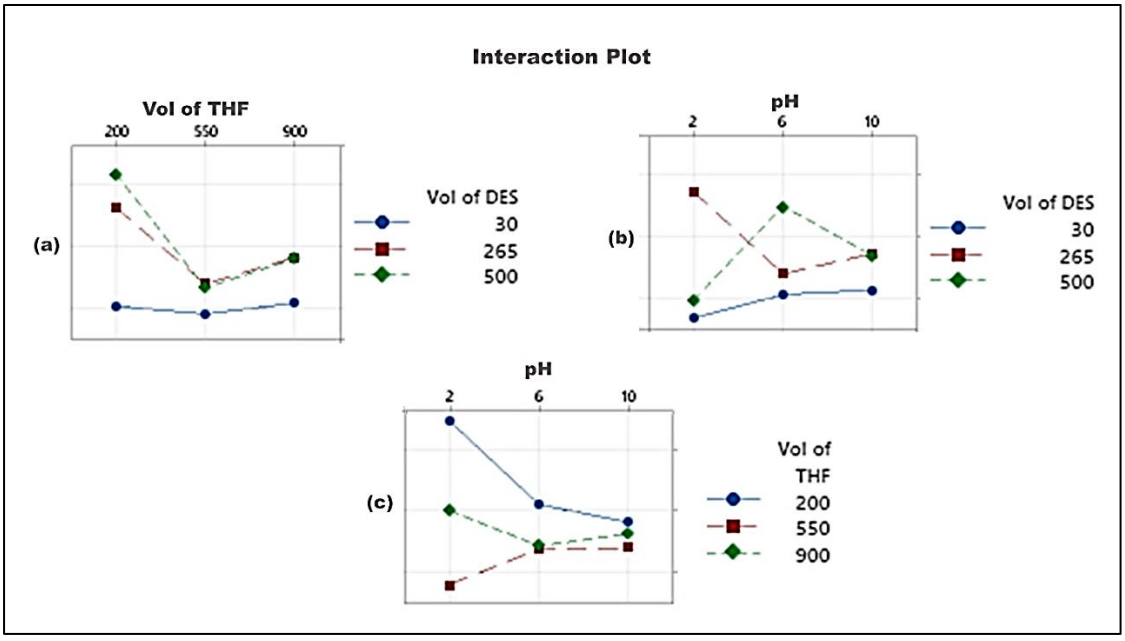

Figure 7. The interaction plot of 2,4-D sample, (a) volume of DES-volume of THF, (b) volume of DES-pH, (c) volume of THF-pH

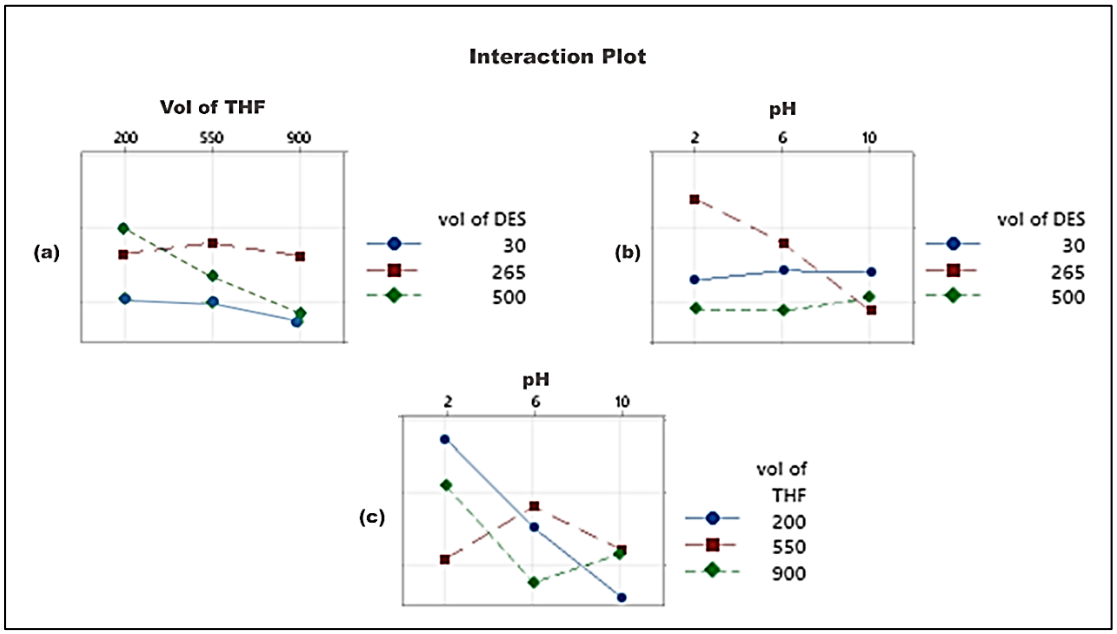

Figure 8. The interaction plot of MCPA sample, (a) volume of DES-volume of THF, (b) volume of DES-pH, (c) volume of THF-pH

As shown in Figure 7(a) and Figure 8(a), the absorbance exhibited a positive correlation with the increase in the DES volume and a decrease in the THF volume, specifically at a volume of 200 µL. The enhancement of mass transfer of 2,4-D and MCPA from aqueous phase into DES phase was observed when 500 µL of DES was utilized. This improvement can be attributed to the establishment of sufficient hydrogen bonding and

hydrophobic interactions between the analytes and DES. The effective dispersion of DES in the aqueous phase requires the addition of an appropriate volume of THF, owing to the miscibility of DES in the aqueous phase. However, an increase in THF volume caused noticeable declines in response for both analytes. This can be attributed by the challenges encountered during emulsification of DES, which subsequently enhanced the solubility of the analytes in the aqueous phase. Consequently, this leads to a decrease in the extraction efficiency [26, 37].

Furthermore, it was observed that both 2,4-D (Figure 7(b) and 7(c)) and MCPA (Figure 8(b) and 8 (c)) exhibited good responses at acidic conditions with pH 2. The acidic condition enhances the efficacy of analyte extraction. This observation is consistent with the anticipated behavior of these herbicides, as they often possess acidic properties that aid in their solubility inside the hydrophobic DES [37]. However, with an increase in pH, there was a noticeable decline in extraction efficiency. This decline in extraction efficiency can be attributed primarily to the ionization of the herbicides during the reaction [9]. The ionization results in an increase in the herbicides' water solubility, posing a difficult in mass transfer into the hydrophobic DES phase. Consequently, the extraction efficiency diminishes as the herbicides' solubility in the aqueous phase increases. This study's findings indicate that the extraction level in acidic circumstances is similar to the outcomes observed in the experimental results (Figure 6). Thus, this observation further emphasizes the importance of considering the pH of the extraction system when designing and optimizing extraction methods for analytes in achieving high extraction efficiency.

Referring to the experimental result obtained above, there are some noticeable discrepancies between the experimental data and the predicted data from BBD, specifically volume of DES and THF for both analytes. These discrepancies between the experimental data and BBD suggested the potential existence of unaccounted factors or variables that could impact the effectiveness of the extraction process. This phenomenon arises from conducting experimental investigations by systematically varying one variable at a time, whereas the other independent variables remained constant at their original levels. Consequently, the accuracy of this experiment may be compromised due to the challenge of ascertaining the relationship among all the variables [38]. This finding contradicts the BBD, which provided a simultaneous dual effect among the two variables. This feature helps the researchers in identifying the variables that make the most significant contribution to the model [39]. In order to improve the extraction, BBD suggested that high extraction efficiency can be achieved by utilizing a volume of 500 µL and 200 µL for DES and THF, respectively, for extraction of 2,4-D and MCPA.

The optimal condition determined through BBD involved 265 µL and 200 µL volume of DES and THF with pH 2 for both 2,4-D and MCPA. The optimal volume for DES was 265 µL, rather than the previously mentioned value of 500 µL. The rationale behind this decision was based on the potential diluting impact caused by an increase in DES volume, which subsequently reduces extraction efficiency. Furthermore, it has been proposed that the volume of THF should be similar to the volume of DES [9, 22]. Therefore, utilization of an equal amount of THF and DES results in better interaction and improved mass transfer of analytes to the DES phase from the aqueous solution [9].

The findings of this study demonstrate the advantages of utilizing BBD as a methodology for identifying the most favorable situations. Utilizing a BBD allows for a more complete and reliable extraction procedure by considering the combined impacts of various variables. This approach facilitates a comprehensive analysis of the relationships between variables and assists in determining the optimal circumstances for attaining a significant degree of extraction efficiency. Identifying ideal conditions provides valuable insights for future studies and can serve as a guiding principle to achieve high efficiency in similar extraction procedures.

Conclusion

In this study, a fatty acid deep eutectic solvent was successfully synthesized using lauric acid and pelargonic acid. The confirmation of DES was achieved

through FTIR spectra analysis, which enabled the identification of significant peaks associated with DES in the extraction process. The optimization of the variables influencing the ELLME method was carried out experimentally and theoretically. Furthermore, response surface methodology (RSM) based on Box Behnken design was utilized to optimize the overall extraction method, considering various factors and their interrelationships with each parameter. The findings of this study highlighted the significance of BBD as a suitable method for understanding and optimizing the complex relationship between multiple variables involved in the extraction process. The optimal conditions proposed through BBD for extraction of 2,4-D and MCPA can be achieved by applying 265 µL and 200 µL volume of DES and THF at pH 2. Thus, hydrophobic DES from a combination of lauric acid and pelargonic acid can functionally be used as an extraction solvent in the extraction process, especially for determination of pesticides. Studying BBD method provides valuable insights for future development in extraction method to be used on real sample since the extraction parameters were systematically evaluated, leading to improved extraction efficiency and accuracy.

Abstract

This study investigated the variability of ionic species and pH in rainwater chemistry during wet fallout events in Highlands (Cameron Highlands, CH) and lowlands (Petaling Jaya, PJ) in 2019. A total of 1,040 datasets were obtained from the Malaysia Meteorological Department. Descriptive analysis, Mann-Whitney U test, Spearman correlation test, and discriminant analysis were employed. The selected variables included pH, H^+, Na^+, K^+, Ca^{2+}, Mn^{2+}, Zn^{2+}, Cl^-, NO^{3-}, and SO_4^{2-}. Mn^{2+} exhibited a significant difference (p <0.05) between CH and PJ. Rainfall at PJ was more acidic due to higher concentrations of Cl^-, SO_4^{2-}, and NO^{3-}. pH in CH showed a strong positive correlation with Na^+, K^+, and Ca^{2+} as compared to PJ, attributed to atmospheric neutralizing reactions between acids (HNO_3 and H_2SO_4) and alkaline compounds ($CaCO_3$, NaCl, and KNO_3) present in suspended fine particles during wet fallout. Discriminant analysis, by using the confusion matrix, demonstrated significant differences in the overall performances of anions, cations, and pH in rainwater chemistry between CH and PJ, achieving 94.32% classification accuracy. This study highlighted the variability of ionic species and pH in rainwater chemistry between highlands and lowland areas. The findings contributed to understanding atmospheric heterogeneous reactions and factors that influenced rainwater chemistry at different geographic locations.

Keywords: wet fall-out, ionic species, statistical analysis, Petaling Jaya, Cameron Highlands

Abstrak

Kajian ini mengkaji kebolehubahan spesies ionik dan pH dalam kimia air hujan semasa berlakunya hujan di tanah tinggi (Cameron Highlands, CH) dan tanah rendah (Petaling Jaya, PJ) pada tahun 2019. Sebanyak 1,040 set data diperoleh daripada Jabatan Meteorologi Malaysia. Analisis deskriptif, ujian Mann-Whitney U, ujian korelasi Spearman, dan analisis diskriminasi telah digunakan. Pemboleh ubah yang terpilih termasuk pH, H^+, Na^+, K^+, Ca^{2+}, Mn^{2+}, Zn^{2+}, Cl^-, NO^{3-}, dan SO_4^{2-}. Mn^{2+} menunjukkan perbezaan yang signifikan (p <0.05) antara CH dengan PJ. Hujan di PJ lebih berasid sebab disumbangkan oleh kepekatan Cl^-,

SO_4^{2-}, dan NO_3^- yang lebih tinggi. pH di CH menunjukkan korelasi positif yang kuat dengan Na^+, K^+, dan Ca^{2+} berbanding dengan PJ, disebabkan oleh tindak balas peneutralan atmosfera antara asid (HNO_3 dan H_2SO_4) dengan sebatian alkali ($CaCO_3$, NaCl, dan KNO_3) yang terdapat dalam zarah halus yang terampai semasa hujan. Analisis diskriminasi, menggunakan matriks kekeliruan, menunjukkan perbezaan ketara dalam prestasi keseluruhan anion, kation, dan pH dalam kimia air hujan antara CH dengan PJ, mencapai ketepatan pengelasan 94.32%. Kesimpulannya, kajian ini mengetengahkan kebolehubahan spesies ion dan pH dalam kimia air hujan antara kawasan tanah tinggi ddengan tanah rendah. Penemuan ini menyumbang kepada pemahaman tindak balas heterogen atmosfera dan faktor yang mempengaruhi kimia air hujan di lokasi geografi yang berbeza.

Introduction

Rainwater chemistry is a heterogenous atmospheric reaction, whereby the conversion from gas to particle occurs. The gaseous and aerosol released can originate from natural (marine spray, haze, resuspension) or anthropogenic activities (industrial process, transportation, agricultural pesticide spray that can be transported by winds from elsewhere [1]. The repetitive process from dry to wet deposition in the atmosphere is important with the nutrient cycle cleansing the pollutant in our ambient air [2]. The continuity of these processes occurs through day and night, regardless of the geolocation or even the altitude, including highland or lowland. According to Li et al. [3], the chemical composition of highlands would provide us with regional information regarding atmospheric pollution as compared to what the lowland offers as the local condition. Do et al. [4] reported that industrial development has resulted in an increase of SO2 and NOx emissions that finally led to significant disruption in atmospheric conditions, and thus affected the pH value in rainwater.

In Malaysia, a lot of highland areas were spotted, but a few were explored in the tourism sector such as Cameron Highlands, Pahang, and Kundasang, in Sabah. The Highlands and lowlands are both crucial for natural ecosystems. With reference to Razali et al., areas located at more than 1,000 m above sea level are categorized as mountains and classified as reserved forests or catchment forests, which serve as major sources of hydroelectric production for lowlands [5]. Lowland areas are experiencing higher population growth than high plateau areas, as they offer greater opportunities to stimulate the economy. In this study, rainwater samples were acquired from the Malaysian Meteorological Department (MMD) from two different sites, namely Cameron Highlands (CH) and Petaling Jaya (PJ) in the year 2019. The aims of this study are: (1) to assess the difference of pH, cation, and anion in rainwater between CH and PJ, representing highlands and lowland, respectively; (2) to investigate the relationship between the contribution of chemical composition (anion and cation) toward the fluctuation of pH value throughout 2019.

Materials and Methods

The chemical composition dataset

This study selected CH as the highland area and PJ as the lowland area. The 2019 rainwater data for the two sites were acquired from the Malaysian Meteorological Department (MMD) on a weekly basis which accounted from January to December. Since this study focused on the differences between highland and lowland areas, the total days of rainfall between these sites most likely differed. PJ recorded a total of 50 weeks available for the rainwater volume, while CH only provided 44 weeks out of 52 weeks in 2019. Therefore, the total data extracted at PJ and CH were 750 (50 weeks × 15 variables) and 440 (44 weeks × 10 variables), respectively. For CH, the variables involved in this study were H^+, Na^+, Ca^{2+}, Mn^{2+}, Zn^{2+}, Cl^-, NO_3^-, SO_4^{2-}, and pH. However, PJ recorded a higher number of variables, which included H^+, Na^+, Ca^{2+}, NH_4^+, Mg^{2+}, Ca^{2+}, Cu^{2+}, Mn^{2+}, Pb^{2+}, Zn^{2+}, Fl^-, Cl^-, NO_3^- SO_4^{2-}, and pH. Only the variables available in the two domains were selected and analyzed for a better understanding of statistical analysis. From the enumerated variables, only pH, H^+, Na^+, K^+, Ca^{2+}, Mn^{2+}, Zn^{2+}, Cl^-, NO_3^-, and SO_4^{2-} were selected for additional univariate and multivariate statistical analysis for both zones.

Study area

Ghosh et al. [6] described CH as the location of the borderline between a humid rainforest climate and a subtropical upland climate. CH (4° 29’ 3’’N, 101° 22 17’’E) is situated at 912m – 1,960m above sea level with a temperature range between 16°C and 22˚C, and total average rainfall fluctuated between 1800 and 3000 mm, a perfect setting for an agricultural area [7]. The local community's commitment mainly depends on tea estate farmlands such as strawberry farms, and vegetable farms as well as flower gardens like lavender gardens and rose gardens [5]. The major drawback in air quality and rainwater chemistry was probably contributed by the uncontrolled routine application of chemical pesticides in CH. The farms and estates had the possibility of excessive consumption of pesticides, herbicides, and fertilizers that may influence the concentration of ionic species in rainwater, resulting in unstable pH readings in the rainwater.

Petaling Jaya (3° 06’ 07’’N, 101° 38; 42’’E) with location at 556m above sea level is one of the busiest cities in Klang valley, which is encircled by Kuala Lumpur, Sungai Buloh, Shah Alam, and Puchong. According to Morissey et al. [8], PJ with a size of 97.2 km^2 recorded a temperature between 31°C and 33°C, making June and July being recorded as the driest month. In rainfall volume, PJ received heavy annual rainfall which accumulated up to 3300 mm. Shabanda et al. [9] emphasized that Petaling Jaya is an urban area involved in various industries, high traffic, and commercial and residential areas. Petaling Jaya industries include manufacturing, electrical and electronics, machinery, food and beverage, plastics, and chemical industries. Unlike CH, the variability in chemical composition in PJ rainwater might differ due to higher contributions from fossil fuel combustion, municipal waste, and industrial activities, which are exacerbated by the meteorological conditions [2]. Figure 1 illustrates the variation of land use activities in CH and PJ.

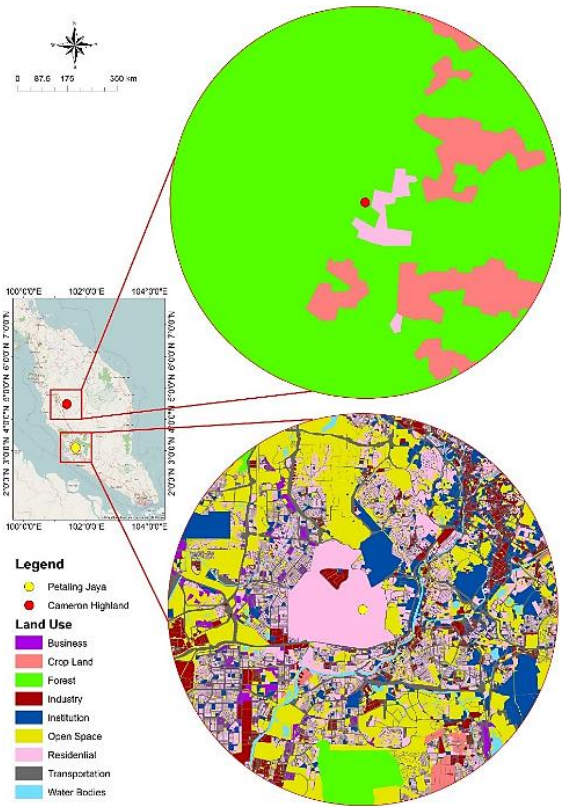

Figure 1. The illustration of land use activities in Petaling Jaya and Cameron Highlands

Statistical analysis: Pre-treatment dataset

Any missing data in this study were identified and removed from the datasets to increase data accuracy and uniformity. The data were mostly indicated as "Not Available" because an inadequate sample was recorded within that particular week. Not only that, but any variable was also recorded lower than the detection limit (LDL), and any results that showed no variation between weeks in 2019 were removed. The raw data received from MMD contained redundant and inconsistent data that had to be reduced to improve data coherence and reduce data corruption and database size. In this study, data transformation is a process of changing the format or structure of data. In this study, standardization methods were used to change the scale of data across a range. To proceed with multivariate statistical analysis like discriminant analysis, the datasets had to be standardized first. The transformation dataset process benefited this study in two ways; firstly, it canceled the unit with different variables and secondly, it reduced the range limit between variables. Data with a substantial gap such as between H^+ (e.g., 0.000005 µmol/L) and NO_3^- (100 µmol/L) could make H^+ seemed less important, yet both ions played an important role in determining the acidity in rainwater. Therefore, having a transformation dataset range (e.g., -1,1 or 0 -1) helps to reduce issues in this study [12]. Therefore, this study employed the standardization techniques, and the formula is written as below:

$$Z = \frac{x-\mu}{\sigma} \quad (1)$$

Where, x = individual data, μ = mean (average), and σ = standard deviation

Descriptive analysis

The data visualization in this study was performed by using R Studio (R development, 4.2.2). Martins et al. [10] substantiated the role of descriptive analysis in assessing activities that influence the characteristics of a given source. It entails employing techniques such as the box-whisker plot (boxplot) to draw informed conclusions. In the context of the standard boxplot, an issue arises when dealing with data that exhibit asymmetry or heavy-tailedness, resulting in an inflated identification of values as atypical. Notably, Cable and Deng [11] previously conducted a comprehensive study, quantifying the concentration of ionic species and pH in the Detroit Metropolitan area. The boxplots depicted the upper and lower limits, corresponding to 1.5 times the interquartile range (IQR) away from the box, while the median was represented by a vertical line within the box. This insightful methodology facilitated a thorough understanding of data distribution, identification of outliers, and exploration of the relations between ion concentrations and pH in CH and PJ.

Normality test, comparative, and correlation analysis

The normality test employed in this study utilized the Shapiro-Wilk test, with a sample size of less than 500 ($n < 500$), implemented by using XLSTAT (ver. 2019, USA). To visualize the Spearman Rank correlation analysis, the corrplot library function within R Studio (R development, 4.2.2) was utilized. Prabhaker et al. [12] conducted a statistical analysis and reported a *p*-value of greater than 0.05, indicating acceptance of the null hypothesis (H_0), and thus suggested a normal distribution. Conversely, for the alternative hypothesis (H_a), a *p*-value of below 0.05 was observed. In this study, the Shapiro-Wilk test rejected the null hypothesis ($p > 0.05$) for all variables, indicating that non-parametric analysis was necessary due to the non-normal nature of data. Consequently, given the non-parametric nature of the data, this study employed appropriate non-normal data analysis techniques. To compare independent datasets, the Mann-Whitney U test was employed, which utilized medians as the basis for comparison of each individual variable between the CH and PJ groups.

Spearman correlation analysis was conducted to explore the relation between pH, cation, and anion in the CH and PJ groups, with a significance level at 0.05. The strength of the correlation was classified as strong ($r > 0.70$), moderate ($0.30 \leq r \leq 0.69$), or weak ($r < 0.30$), as per the classification proposed by Ibrahim et al. [13]. The Spearman correlogram provided a visual representation of the correlations observed in the data. Positive correlations were depicted by blueish cubic representations, while inversible correlations were indicated by reddish cubic representations. Blank

(white) cell areas indicated correlations that were statistically insignificant with a 95% confidence interval (p >0.05).

Results and Discussion

Variation of pH, cations, and anions in rainwater

Figure 2 illustrates the pH fluctuated between 4.18 and 5.92 in both areas during 2019. From the times series analysis, the overall mean pH measurement for CH and PJ were 4.87 ± 0.27 and 4.59 ± 0.76, respectively. For the record, pH in CH ranged 4.27-5.58 while CH showed a greater variance of 4.18-5.92, with the lowest value being recorded in Week 8 (February). In comparison, there were only two noticeable circumstances in that CH showed a greater pH value as compared to PJ: Week 11 – Week 18 and Week 36 – Week 44. The study conducted by Park et al. [14] provided evidence which supported the significant role of precipitation quantity in influencing rainwater acidity and pH. This influence was attributed to the dilution effect on ion concentrations during precipitation events. Regions with higher rainfall, such as high plateaus of Cameron Highlands, underwent more pronounced dilution of ionic species as compared to areas with lower rainfall, like Petaling Jaya, resulting in lower total mean concentrations of ionic species in the Cameron Highlands relative to Jaya Petaling. In contrast, Payus et al. [15] postulated the occurrence of neutralizing reactions between cations and anions within rainwater, leading to an equilibrium of ionic species concentrations. Furthermore, the study highlighted the substantial impact of atmospheric scavenging, a process involving the removal of airborne particles and gases from the atmosphere through precipitation, on the concentration of ionic species in rainwater and consequent modulation of rainwater pH levels.

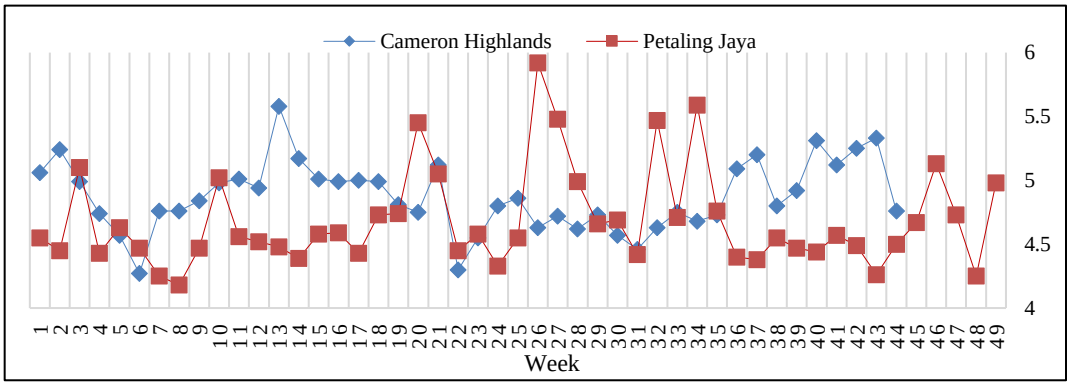

Figure 2. Time series analysis on pH variation in Cameron Highlands and Petaling Jaya during 2019.

Additionally, a higher temperature in the cloud led to an increased concentration of Cl^-, resulting in a decreased pH level of rainwater. This phenomenon was attributed to the heightened availability of gaseous molecules and high solubility of HCl in water. While the study placed considerable emphasis on pH, it was essential to direct attention toward the diverse array of cations and anions requiring investigation [14]. In the comparison of all variables, H^+ was determined to be the lowest concentration in both areas, with individual means that ranged from 0.000016 µmol/L - 0.00002628 µmol/L. The presence of H^+ ions in rainwater inflicted the rainwater acidity level. The higher the H^+ concentration present in rainwater, the lower the pH value in rainwater it gets. However, it will also depend on the influence of the external factor, including the type of anthropogenic activities and meteorological conditions, exacerbated by uncontrolled on vehicle possession in Malaysia especially in urban areas [16]. In this study, Na^+, NH_4^+, Ca^{2+}, Cl^-, NO_3^-, and SO_4^{2-} were among the abundance of species discovered in rainwater. Table 1 tabulates the rudimentary descriptive analysis which showed the min, max, mean, and standard deviation of individual species found in CH and PJ.

Together, the Mann – Whitney U test was integrated into the table to verify the differences in each individual -

species at different lowlands and highlands. NO_3-, NH_4^+, SO_4^{2-}, Cl^-, Na^+, and Ca^{2+} were the concentrated ions as compared to others, with PJ showing a higher concentration than CH. Despite having differences in terrain structure, agricultural activities, as well as industrial and urbanization effects, Khan et al. [2] confirmed that the only explanation that PJ had concentrated ions was due to fractional acidity (FA). The divergence in FA between developed and less developed areas suggested a significant variation in the neutralization of alkaline ions in rainwater, primarily due to the considerable influence of NO_3- and SO_4^{2-} on rainwater acidification. For instance, the average NO_3- found in PJ was approximately 69.7% lower as compared to what was recorded in PJ. This pattern was similar with SO_4^{2-}, Cl^-, Na^+, Ca^{2+} were all 66.7%, 53.4%, 51.9%, and 49.7% lower, respectively. Not only on the average value for individual species, but also the observation from the max values also proved that the differences between types of anthropogenic activities operated in both areas proved the hypothesis constructed in this study.

Table 1. Statistic description of rainwater anion, cation (μmol/L) and pH in Petaling Jaya and Cameron Highlands

	Petaling Jaya				**Cameron Highlands**				**Mann – Whitney U test (*p*-value)**

Asterisk (*): the individual datasets was recorded below the detection limit.
NA: The analysis can't perform due to incompatibility comparison between CH & PJ
Bolded result: The result is not significantly differed between CH and PH with 95% confidence interval.

From the result, NO_3^- and NH_4^+ were the only variables which showed a huge gap in the range. The NO_3^- in CH ranged between 0.02 μmol/L - 43.77 μmol/L, whereas PJ recorded 5.95 μmol/L - 127.57 μmol/L and 0.10 μmol/L - 140.67 μmol/L for both ions, respectively. The possible reasons that caused acid rain in urban areas were rapid industrialization, urbanization and rapid increase in automobiles, fossil fuel combustion, and the emission of SO_2 and NO_x from vehicles into the atmosphere [17]. A higher concentration of SO_2 and NO_x in the atmosphere could lower the pH of rainwater during wet falls because these were acidic species. Higher levels of Cl^- observed at Petaling Jaya may be associated with the formation of HCl in the atmosphere. Since the data showed non - parametric type, the comparison analysis was performed by using Mann – Whitney U Test. The independent comparison test between these two locations proved that there was a significant difference (p <0.05) for all variables, except for Mn^{2+}. In other words, the existence of manganese

ions in both rainwaters was found comparable even though there was fluctuation in overall concentration throughout 2019. The finding revealed in Mann – Whitney result was supported by the Discriminant Analysis (DA), whereby the classification between CH and PJ unquestionably differed with a total of 94.32% dissimilarities.

The influence of cations and anions on the pH variability

In this study, the second objective of the study was achieved as the statistical evaluation between the pH and the group of cations and anions was performed by Spearman's rank correlation analysis. It helped to characterize the effect of these ionic species concentrations in rainwater with the pH as it discovered the strength of correlation. Among all, there were a few that had a significant correlation toward pH. H^+ was the only variable that had a significant correlation (p <0.05) in both areas, with Cameron Highlands having an inverse strong correlation with CH than Petaling Jaya, with r = -1.00 and -0.88, respectively. pH and H^+ had an inversely strong proportional relationship, the higher the concentration of H^+, the lower the concentration of pH [18]. This relationship could be described in the equation of pH = -log [H^+]. Other than H^+, other variables such as Zn^{2+}, NO_3^-, and SO_4^{2-} were the ions that demonstrated a significant correlation toward pH, and these were only found in CH. Despite H^+, other variables did not possess a significant correlation in PJ.

For the record, SO_4^{2-} was the only ion which showed the highest correlation indication with r (SO_4^{2-}/pH) = -0.75, followed by r (NO_3^-/pH) = -0.53, and r (Zn^{2+}/pH) = -0.40. The observation derived from this investigation aligned closely with the research conducted by Zeng and Han, wherein the ratio of SO_4^{2-} to NO_3^- exceeded the value of 1. This noteworthy observation suggested the influence of stationary sources of pollutant emissions, such as the transportation and dispersion of pollutants emitted during coal combustion activities. An inverse–strong correlation was observed, which might probably be due to the availability of H_2SO_4 in the atmosphere, forming acidic precipitation in CH [19]. For both locations, there was a strong correlation of r (Na^+/K^+) = 0.73 – 0.82, whereby CH had a higher correlation as compared to PJ. Zeng and Han, and Zeng et al. explained that a stronger correlation of Na^+ with K^+ and Ca^{2+} was due to atmospheric neutralizing reactions between the acids (HNO_3 and H_2SO_4) with alkaline compounds ($CaCO_3$, NaCl, and KNO_3) that existed in suspended fine particles [20,21]. The strength and direction of correlation between different ions indicated the effects of ions concentration on pH concentration, which resulted in the acidity or alkalinity of the rainwater of the particular area [22]. Figure 3 illustrates the overall correlation analysis between chemical composition toward pH variability in rainwater for CH and PJ, representing highland and lowland as hypothesized in this study.

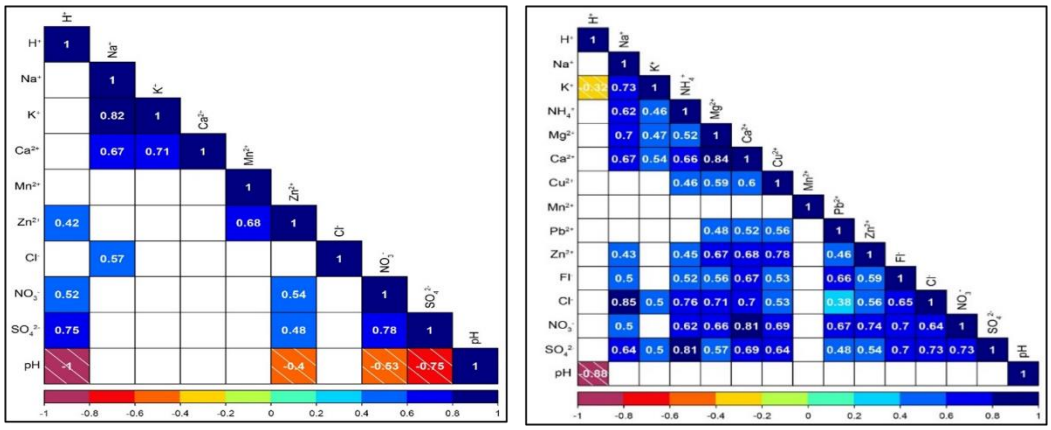

Figure 3. Spearman's correlation coefficient between pH and ionic species at Cameron Highlands (left) and Petaling Jaya (right). The colored cells denoted with a significance level of p <0.05, while white cells denote statistically non – significant correlation (p >0.05)

Conclusion

In brief, the study revealed that rainwater in both highland (CH) and lowland (PJ) regions could be classified as acidic, with the pH threshold for acid rain established at 5.6. Comparatively, the average pH value in PJ (4.59) was lower than in CH (4.87). The lowest pH values were observed in February 2019 during the Northeast Monsoon (NEM) period, characterized by increased precipitation on the Peninsula's east coast, although the study focused on the west coast, which might have been influenced by the nearby Titiwangsa mountain range. Statistical analysis demonstrated that various ions, including Na^+, NH_4^+, Ca^{2+}, Cl^-, NO_3^-, and SO_4^{2-}, significantly influenced the H^+ concentration and pH value. The Mann-Whitney U Test revealed significant differences among all variables, except for Mn^{2+}. Discriminant Analysis indicated substantial dissimilarity (94.32%) in overall performance between CH and PJ. Spearman's rank correlation analysis highlighted significant correlations between pH and ionic species, with three ionic species that affected pH value in CH, while none were significant in PJ. The fluctuation in pH variability throughout 2019 was attributed to interactions between ions such as NO_3^- and SO_4^{2-} and alkaline compounds ($CaCO_3$, NaCl, and KNO_3) during the dry deposition process. To advance research and practical applications, future studies should adopt a holistic approach, encompassing factors like climate change, trans boundary haze pollution, and monsoon patterns, conducting spatial and temporal surveys in Malaysia, considering variations in altitude, rainfall volume, population density, traffic levels, and land use types. Regular monitoring on a weekly, monthly, or annual basis would offer valuable insights.

Acknowledgements

The authors gratefully acknowledge the support of this research by Universiti Malaysia Terengganu by giving us the precious opportunity through Talent and Publication Enhancement Research Grant (TAPE-RG) (Vot No.: 55348). The authors want to thank Faculty of Science and Marine Environment for providing all technical supports throughout this study. Lastly, the authors are also thankful to the Malaysian Meteorological Department (MMD) for their full support and assistance in providing the dataset.

Abstract

Activated carbon (AC) is a versatile porous material with numerous applications in various industries. In this study, ACs with both specific surface area and mesoporous developed structure were prepared using Sarawak wild bamboos, i.e., *Gigantochloa levis* (beting) and *Bambusa vulgaris* (aur), as a carbon precursor. The bamboos were chemically activated with phosphoric acid (H_3PO_4) at various concentrations, and then carbonized using a tubular furnace at 500 °C for 3 hr under an inert nitrogen gas flow. The proximate and ultimate analyses of AC were measured. The chemical and porous structure of AC were characterized using Brunauer, Emmett, and Teller (BET), Fourier transform infrared spectroscopy (FTIR), and field emission scanning electron microscopy (FESEM). The results show that by increasing the H_3PO_4 concentration, the surface area of bamboo AC was increased. The AC yield between 58% and 62% was obtained at 1%–9% v/v H_3PO_4 impregnations. The highest surface area of 1319 and 1285 m^2/g were obtained at 9% v/v H_3PO_4 impregnation of beting and aur bamboos, respectively. Therefore, ACs can be prepared using low H_3PO_4 impregnation concentration, but high quality ACs comparable to other ACs from different biomass with good yield and textural characteristics are also producible. This could lower the production cost of ACs from bamboo due to the use of cheap and novel raw materials from different species of bamboo by using only the minimum concentration of activating agent in the production.

Keywords: activated carbon, bamboo, chemical activation, surface area

Abstrak

Karbon teraktif (AC) ialah bahan berliang serba boleh dengan pelbagai aplikasi dalam pelbagai industri. Dalam kajian ini, AC dengan kedua-dua kawasan permukaan tertentu dan struktur liang meso telah disediakan menggunakan buluh liar Sarawak; *Gigantochloa levis* (beting) dan *Bambusa vulgaris* (aur) sebagai prekursor karbon. Buluh tersebut diaktifkan secara kimia dengan asid fosforik (H_3PO_4) pada pelbagai kepekatan, dan kemudian dikarbonisasi menggunakan relau tiub pada suhu 500 °C selama 3 jam dengan aliran gas nitrogen. Analisis proksimat dan unsur karbon, hidrogen, nitrogen, sulphur ke atas AC telah diukur. Struktur

kimia dan keliangan AC dicirikan menggunakan, Brunauer, Emmett, dan Teller (BET), spektroskopi inframerah transformasi Fourier (FTIR) dan Mikroskopi elektron pengimbasan pelepasan medan (FESEM). Keputusan menunjukkan bahawa dengan meningkatkan kepekatan H_3PO_4, luas permukaan AC buluh meningkat. Hasil AC dalam julat antara 58% hingga 62% diperolehi pada impregnasi 1% - 9% v/v impregnasi H_3PO_4. Luas permukaan tertinggi 1319 m^2/g dan 1285 m^2/g diperolehi pada 9% v/v H_3PO_4 impregnasi buluh beting dan aur. Oleh itu, AC boleh disediakan menggunakan kepekatan impregnasi H_3PO_4 yang rendah, tetapi AC berkualiti tinggi setanding dengan AC lain daripada biojisim berbeza dengan hasil yang baik dan ciri tekstur juga boleh dihasilkan. Ini boleh mengurangkan kos pengeluaran AC daripada buluh kerana penggunaan bahan mentah yang murah dan baru daripada spesies buluh yang berbeza dengan hanya menggunakan kepekatan minimum agen pengaktif dalam pengeluaran.

Kata kunci: karbon teraktif, buluh, pengaktifan kimia, luas permukaan

Introduction

Activated carbon (AC) is a unique and multifunctional substance due to its high porosity and large surface area, which leads to high adsorption capability. AC pores exhibit strong van der Waals forces, which are linked to its adsorption capabilities. ACs are widely utilized in various applications, including water purification, gas storage, water treatment, as a catalyst, and as a material for double layer capacitors [1-3], environmental remediation, air purification, food processing, medicinal uses, and recovery of metals in hydrometallurgy [4]. The demand for AC will continue to rise as its applications expand.

Commercial AC is often produced from coal, which is a non-renewable resource with limited availability. Biomass has emerged as an alternate raw material for the manufacturing of AC to circumvent this constraint. Approximately 80%~85% of the total AC production is derived and explored from non-renewable coal-based resources with the remaining from renewable sources such as agricultural residues, wood [4], palm, coconut shell [4], coffee endocarp, fine cone biomass [1], hazelnut shells, olive, peach, apricot and cherry stones, grape seeds, and eucalyptus leaves [3]. Bamboo is another biomass material that has a good potential to be used as a carbon precursor to produce AC [5-8]. Bamboo is a fast-growing plant, rich with lignin (32%–33%) and alpha cellulose (45%–46%), which makes it suited to be used as a carbon precursor to produce AC. The porous structure (micropores, mesoporous, and macropores) of AC from biomass is made up of cellulose and lignin. The chemical composition of the raw material and the parameters of the manufacturing process determine the characteristics of AC [1]. In other words, the structural properties of AC, i.e., porous structure (pore size and surface area) and surface chemistry depend on the carbon precursors and the manufacturing processes.

There are two manufacturing processes of AC known as physical activation and chemical activation methods. Physical activation is recognized as a two-step method because it involves carbonization followed by activation. Chemical activation is a single-step method in the presence of chemical activator, whereby carbonization and activation take place simultaneously. Nevertheless, chemical activation has shown more advantages over physical activation because it produces ACs with higher yield and higher surface area even at moderate temperatures with only one step activation [4, 9]. Basically, carbonization is the conversion of raw materials into charcoal and the formation of initial porosity through thermal decomposition resulting in a higher carbon content without non-carbon components in the substance. Meanwhile, activation is a process to create advanced porosity by opening previously inaccessible initial holes, forming new pores, and enlarging existing pores [10].

The most common chemical activators used in chemical activation method to produce AC are H_3PO_4, alkali metal compounds such as sodium hydroxide (NaOH), potassium hydroxide (KOH), sodium carbonate (Na_2CO_3), and potassium carbonate (K_2CO_3), and zinc chloride ($ZnCl_2$) [2, 11-12]. Among the alkali metal compounds, KOH is often carried out at high temperatures of 700~900 °C with a high impregnation ratio (IR = KOH: biomass precursor) of 5:1 and very effective in creating micropores, small mesopores, and very high specific BET surface area of above 2000 m^2g^{-1} [3]. However, chemical activation using KOH activation has low carbon yield and has detrimental impacts on

human health and environment. On the other hand, H_3PO_4 can be operated at low temperatures of 400~600 °C with a low IR (weight ratio of H_3PO_4 to biomass precursor) of 3:1, results in BET surface area of approximately 1000~1500 m^2g^{-1} consisting of mainly mesopores. As a dehydrating catalyst, H_3PO_4 does not only promote bond cleavage reactions but also facilitate crosslinking via cyclization, condensation, and forming a layer of linkage such as phosphate and polyphosphate esters, which could protect the internal pore structure, and thus prevent excessive burn-off in carbon activation. With the considerations of environmental impacts, energy cost, and carbon yield, H_3PO_4 is highly attractive and has been in demand for large-scale AC production in recent decades [4].

In this paper, AC was prepared using two different Sarawak wild bamboo species, i.e., *Gigantochloa levis* (Beting) and *Bambusa vulgaris* (Aur) through the H_3PO_4 chemical activation. They can easily be found in almost all Sarawak regencies. To the best of our knowledge, there are no previous reports on the preparation of AC from Beting) and Aur bamboos using low concentration H_3PO_4 chemical activation. There is a shortage of data, particularly regarding the properties of AC. Therefore, the effects of H_3PO_4 concentration on the AC yield, porous structure, and surface chemicals of beting and aur bamboos were examined in this study.

Materials and Methods

Materials

Two different species of Sarawak wild bamboo, i.e., *Gigantochloa levis* (beting) and *Bambusa vulgaris* (aur), approximately aged 4 years old were supplied by Sarawak Timber Industry Development Corporation (STIDC). Both bamboos were originated from Kota Samarahan, Sarawak, Malaysia. Mixed portion of bamboos (top, middle, bottom) were used as the carbon precursor throughout the study. The bamboo internodes were cut and chipped into small size and oven-dried at 103±2 °C for 48 hr to remove water content. The dried bamboos were ground and sieved through a 1.0-mm sieve. The ground bamboo was known as dried bamboo particle. The analytical grade of H_3PO_4 was used as a chemical activator. The chemicals and reagents used in this study were purchased from Sigma-Aldrich.

Preparation of bamboo activated carbon

The method used to prepare the bamboo AC was adopted from Tumirah et al. [12]. Approximately 5g of dried bamboo particle was impregnated with 50 mL of different concentrations (1%, 3%, 6%, and 9% v/v) of H_3PO_4. The samples were shaken overnight using an orbital shaker at 100 rpm at 70±3 °C. Then, the samples were heated using sand bath until all the excess water was evaporated. The chemical activation of bamboo was carried out using a tubular furnace at 500 °C for 3 hr under an inert nitrogen gas flow. The resulting bamboo ACs were obtained after washing with hot water and oven-dried at 103±2 °C for 24 hr. The experimental set up for chemical activation is shown in Figure 1.

.

Characterization of bamboo activated carbon: Chemical composition

The internodes of bamboos were ground into 250 µm size and used for the chemical analysis. The resulting material was placed in a sealed plastic container and labelled for the chemical analysis which comprises holocellulose, alpha cellulose, and lignin analysis using the test method of Wise et al. [13], TAPPI 203 om-93 [14], and TAPPI T222 om-02 [15], respectively. Additionally, holocellulose is a necessary preparatory stage to determine the alpha-cellulose content.

Proximate and ultimate analysis

The proximate analysis was carried out to determine the proximate amount of moisture content, volatile matter content, and ash content using the British Standard BS EN 14774-2:2009, British Standard EN 15148:2009, and British Standard EN 14775:2009, respectively.

The ultimate analysis was performed using CHNS Analyzer, LECO Instrument Model 628 at Global Testing and Consultancy for Rubber (G-TACR), Malaysian Rubber Board (MRB). The analysis was carried out to determine carbon (C), hydrogen (H), nitrogen (N), and sulphur (S) content in the bamboo samples.

Fourier transform infrared spectroscopy (FTIR)

The sample was ground and sieved with a 150-µM mesh. Exactly 2 mg of each sample was mixed with 100 mg of potassium bromide (KBr) powder, and the mixture was further ground and pressed into a 13-mm diameter disc. The IR spectra were recorded on a Spectrum 100 FTIR spectrometer (Perkin Elmer, CA, USA), equipped with a mid-infrared deuterated triglycine sulphate (DTGS) detector. The spectra were obtained in the frequency range of 4000–450 cm^{-1} with a resolution of 4 cm^{-1} and with a total accumulation of 16 scans.

Percentage of yield

The yield of bamboo AC is defined as a ratio of weight of the resultant bamboo AC to that of the bamboo raw. The yield of bamboo AC is measured using Equation 1 as follows [16]:

$$\text{Yield of bamboo AC (\%)} = (W_1 / W_0) \times 100 \quad (1)$$

where, W_0 is the mass of bamboo raw and W_1 is the mass of carbonized bamboo after washing with hot water and oven-drying.

Surface area and porous structure characterization

The surface area and porous structure of bamboo AC were characterized using the nitrogen adsorption-desorption technique at 77 K of accelerated surface area and porosimeter analyser (Micromeritic, ASAP 2020). The porous structure of bamboo AC is referring to pore size, pore size distribution, pore volume, and surface area. The surface area of bamboo AC was analysed using the BET equation, while porous structure was calculated using the desorption Barret–Joyner–Halenda (BJH) equation. Both equations are as in the instrument software package.

Surface morphology characterization

The bamboo AC samples used for FESEM analysis were prepared by placing the dried samples onto the specimen stub. The sample surface was sputter coated with a thin film of platinum before any observation was made. The morphology structure of AC was observed under the Model: Nova NanoSEM 230, THERMO SCIENTIFIC formerly known as FEI at a magnification of 5000× at a scanning voltage of 10 kV.

Results and Discussion

Characteristics of raw material: Chemical composition

In general, biomass contains three main cellulosic components (hemicelluloses, cellulose, and lignin) and closely associated in a complex structure. Previous study reported that the range of cellulose and hemicelluloses content for various types of bamboo is from 37% to 47% and 15% to 30%, respectively [17]. The characteristics of beting and aur bamboos were evaluated and compared with other literatures. The

chemical contents of bamboos for this study were (44%–46 % cellulose, 25%–33% hemicellulose, and 32%–33% lignin. This result is close to the chemical composition of other bamboo species as depicted in Table 1. During the carbonization of biomass, the hemicelluloses and cellulose decompose mostly into volatile products, while the lignin content is more difficult to decompose and contributes to the formation of a solid residue called char. Meanwhile, the fixed carbon and ash content decreased with the increase in the volatile content [16]. The chemical composition of bamboo is almost similar to that of the woody biomass materials [18, 19]. High phenolic content in lignin compound of biomass makes it important in the AC preparation because it leads to higher carbon yields than those obtained from the other two main macromolecular compounds of biomass: cellulose and hemicellulose [20]. Thus, Beting and Aur bamboos have great potential as a precursor to produce high quality AC because the result is within the range of chemical content. The formation of micropores and macropores of AC are strongly influenced by cellulose and lignin content of raw material. Table 1 also presents that the density and thickness of beting and aur bamboos was around 706–785 kg/m^3 and 8.16–10.51 mm, respectively.

Proximate and ultimate analysis

The proximate analysis of raw bamboo is very important to determine the quality of AC produced and the distribution of its contents. Four important parameters that need to be measured comprises moisture content, volatile matter content, ash content, and fixed carbon content. The moisture content present in the sample can also be considered as water vapor when it is heated to high temperatures. Hence, the volatile matter content and moisture content tend to leave the sample when heated. In view of the proximate analysis data, beting and aur bamboos show high moisture content (32%–41%) and high percentage of volatile matter (83%–90%), while the ash content and fixed carbon content of the bamboo sample was 1.4%–3.84% and 8.58%–12.88%, respectively. This gives an overview about the properties and components of bamboo [20]. The high volatile matter and low ash content of biomass resources enable them suitable to be used as starting materials to produce ACs [21]. High volatile matter content usually reduces the solid yield in the carbonization stage, while low inorganic content is vital due to their abilities to produce low ash and high fixed carbon content [22]. Apart from ash content, fixed carbon content is very important to determine the quality of AC produced from raw bamboo. The content of fixed carbon will be increased after converting it to AC. Due to its relatively high volatile matter content and low ash content, bamboo has the potential as a suitable precursor for conversion to AC. The low ash content indicates that inorganic impurities would have little impact on pore growth during the activation process. Since minerals including silica, alumina, iron, magnesium, and calcium make up majority of ash's composition, ash is an unwanted contaminant that presents in AC [5].

The ultimate analysis shows that raw bamboo and AC has 40%–43% and 69.85% of carbon, while 1.40%–3.84% and 7.22% of ash, respectively. It was predicted that compared to the raw material, AC has higher amount of carbon and ash. Past study investigated the carbonization of Pawlonia wood with phosphoric acid and discovered another pattern that is also comparable [21]. Besides the experimental conditions of the carbonization and activation steps, the porous structure of AC is also influenced by the original nature and structure of the starting material. The results of proximate and ultimate analyses from different biomass of wood and non-wood are shown in Table 2.

Table 2. Proximate and ultimate analyses of biomass and its activated carbon

Analysis	Bamboo (This study)	Bamboo [17]	Paulownia Wood [21]	Bamboo Activated carbon [5]	Pawlonia Activated carbon [21]

Characteristics of activated carbons produced: Yield of activated carbon

In general, the bamboo-based ACs exhibit various physiochemical properties at various H_3PO_4 concentrations, including the product yield. Yield of bamboo AC is defined as the weight of carbonized bamboo after washing using hot water to remove H_3PO_4 residue or contaminants and oven dried. With the increase of H_3PO_4 concentration, the yield of beting and aur ACs were increased from 58.0% to 62.0% and 58.1% to 60.1%, respectively (Figure 2). According to Ismail et al. [23], H_3PO_4 impregnation acts as a reactant to create crosslinks and as an acid catalyst to enhance the bond breaking of the carbon precursors during the activation. Phosphate and polyphosphate species are created because of the crosslinking of the H_3PO_4 and organic components in the biomass sample, and they may persist on the AC structure even after washing. Hence, more H_3PO_4 usage led to a larger AC yield and increment of leftover solid biomass by reducing tar formation and the emission of volatile compounds during the carbonization reaction [23]. The yield of both bamboo ACs obtained was higher than that of the ACs reported from other biomasses, such as bamboo (36.8%–40.2%), coconut shell (50.84%), and durian shell (45.5%) [23-25]. This shows that bamboo is one of the potential carbon precursors to produce AC.

Surface characteristics of porous activated carbon

One of the methods to determine the surface functionalities of a material and performing qualitative analysis is FTIR spectroscopy. Therefore, by employing the FTIR spectral analysis at the mid-infrared range (4000–450 cm^{-1}), the functional groups that are present in raw bamboo and manufactured ACs can be determined. Figure 3(a) and (b) shows the results of spectrum for raw bamboo and ACs, respectively. Figure 3(a) shows that the bamboo precursor created more bands than the manufactured ACs. Beting and aur raw bamboos show a broad absorption band at 3340 to 3348 cm^{-1} due to the O–H stretching and H-bonded bond structure of the main functional groups of phenols, alcohols, and waters. The C–H stretching and O–H stretching bond structure, which contains a functional

group of alkanes (cellulose and lignin) and carboxylic acids, was attributed to a small peak at 2881 and 2889 cm^{-1}. The minor peak in the C–H stretching bond structure can also comprise methyl (CH_3), methylene (CH_2), and aliphatic saturated functional groups (CH) [20]. The C=C stretching bond structure from the functional group of alkenes (lignin) is best described by the small peak at 1605 cm^{-1}, whereas the peak at 1463 cm^{-1} defined the C–H bending bond from the functional group of alkanes (cellulose, hemicellulose, and lignin). The peak marked at 1050 cm^{-1} indicates the C–O stretching bond structure from the functional group of alcohol (cellulose, hemicellulose, and lignin), carboxylic acids, and esters. The C–O stretching bond structure of the functional group of glycosides linkage is likewise recognized by the peaks band around 1100 to 1000 cm^{-1} [26].

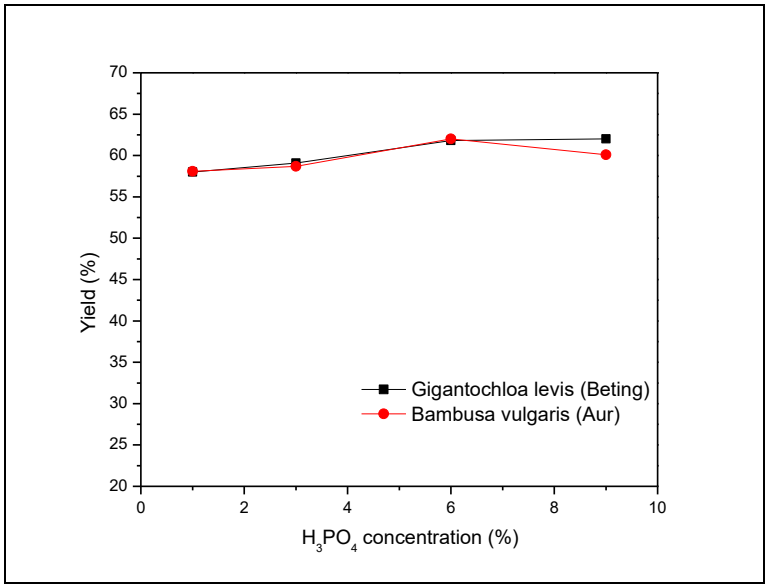

Figure 2. Effect of H_3PO_4 concentration on the yield of bamboo AC

The AC has less absorption peaks than the raw bamboo depending on the H_3PO_4 concentration used. It suggests that H_3PO_4 concentrations had less impact on the surface functionalities, while majority of the organic matter from raw bamboo was removed during the activation process [23]. Figure 3(b) reflects the results where the band at 3700 cm^{-1} is responsible for hydroxyl bonding group O–H with H-bonded vibration. The absorption band at 3340 to 3348 cm^{-1} disappeared due to the formation of polyphosphate and inorganic species in the AC [27]. Meanwhile, the stretching of C=O bands were attributed to the aromatic structures around 1540 cm^{-1}. The peak at 1210 cm^{-1} might be attributed to P=OOH, O–C stretching vibrations in the P–O–C linkage, and hydrogen-bonded P=O stretching mode. The peak at 1000 cm^{-1} can be caused by the stretching vibrations in P–O–P polyphosphate chains, and P^+–C^- in acid phosphate esters. Aromatic structures are responsible for the weaker bonds around 560 cm^{-1}. These results are in a good agreement with the study by Yorgun et al. [21]. Basically, during the H_3PO_4 chemical activation process, four main reactions will occur which are dehydration, depolymerization, the formation of aromatic ring, and the elimination of phosphate group [28]. H_3PO_4 acts as a dehydrating catalyst during acid hydrolysis to promote decomposition and depolymerization of the biopolymers (cellulose, hemicellulose, lignin). The increasing concentration of H_3PO_4 will enhance its ability as the dehydrating catalyst that removes excess water and converts the methyl group in the bamboo to AC with rich-pore structure [12, 29].

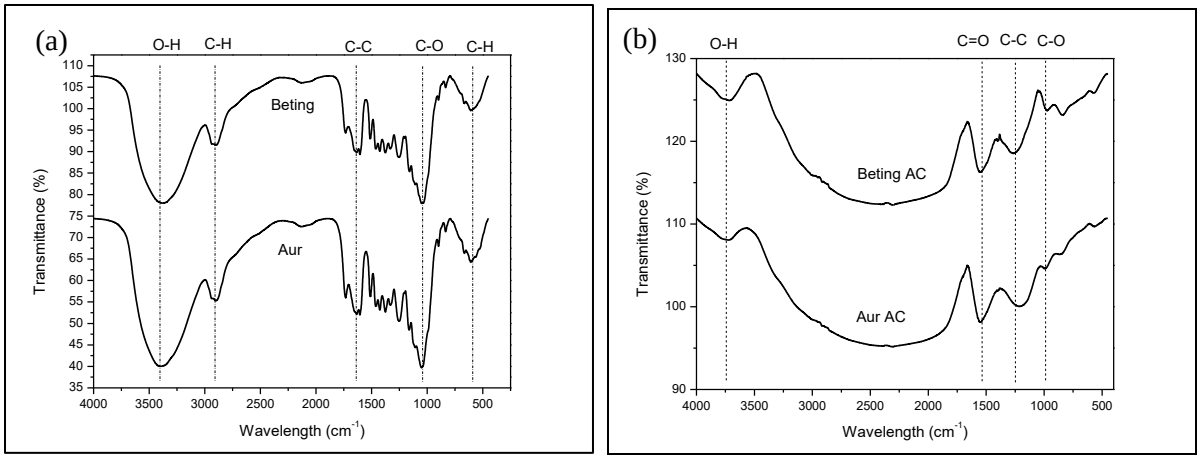

Figure 3. FTIR spectra of bamboo (a) raw precursor (b) porous activated carbon

Surface area and porous structure

Surface area and porous structure (pore size and pore volume) of bamboo AC is important to note to determine its end application. The effect of H_3PO_4 on the surface area and porous structure of bamboo AC was investigated using N_2 adsorption-desorption spectroscopy at 77 K. The effects of carbon precursor (bamboo species) on the surface area and porous structure of bamboo AC were also studied. Figure 4(a) and (b) summarizes the surface area and porous structure of ACs. The figure shows that the porous structure (pore size and pore volume) of bamboo AC increased with increasing H_3PO_4 concentration. These results indicate that high concentration H_3PO_4 impregnation benefitted the formation of pores [4, 30].

Furthermore, the surface area of bamboo AC increased with the increasing of H_3PO_4 concentration. The effect of an increased H_3PO_4 concentration on the BET surface area and pore volume was stronger at 9% v/v H_3PO_4. At this concentration, the maximum surface area of 1319 and 1285 m^2/g, total pore volume of 0.68 and 0.73 cm^3/g, and pore size of 3.6 nm were obtained in beting and aur ACs, respectively, which are comparable with that of the commercial AC (500–1500 m^2/g) [31]. The lowest H_3PO_4 concentration (1% v/v) shows the lower surface area and total pore volume of 368–381 m^2/g and 0.17 cm^3/g, respectively. The surface area and total pore volume can also be compared with the raw material of bamboo. There is no formation or presence of pores and also any increment of pore volume in the raw bamboo. The surface area and pore volume were only 0.437 m^2/g and 0.000826 cm^3/g, respectively. The effect of H_3PO_4 concentration on the surface area and total pore volume of the AC is shown in Figure 4(a) and (b). The process of thermal degradation and volatilization accelerates further when carbonization is applied to an impregnated bamboo, resulting pores forming and surface area increasing [21]. It is believed that the porosity of AC was mainly caused by the H_3PO_4 remaining in the impregnated material. The H_3PO_4 introduced into the interior of the bamboo particle during impregnation can inhibit the contraction of the structure during carbonization, thus producing a porous structure when it is extracted by washing after carbonization. The H_3PO_4 can accelerate the hydrolysis of lignocellulosic material, thus it promotes the formation bond cleavage in the biopolymer structure of bamboo. This can weaken the bonding within the structure and favouring the swelling of the biomaterial, which promotes the formation of pores and the increment of pore volume. As the H_3PO_4 dosage increases, it is reasonable to expect more potential sites could be penetrated and occupied by H_3PO_4, which enhances the pore-opening and widening processes. Besides that, during the carbonization at 500 °C using the tubular furnace, H_3PO_4 exhibits the formation of volatile cellulose products which causes the bamboo biopolymer structure begins to dilate and cross-link between the biopolymer chains through the ester linkages formation in the H_3PO_4 and OH groups. The similar findings were also reported by Feng et al. [4], Tumirah et al. [12], and Jagtoyen & Derbyshire [29].

The production of ACs with high surface areas from a low cost and renewable material is indeed of importance from the viewpoint of economic and environmental aspects. High surface area of bamboo AC is believed to provide large space to trap chemical contaminants if it is used as an absorbance. Table 4 summarizes the surface area and porous structure of bamboo ACs prepared using the H_3PO_4 chemical activation method.

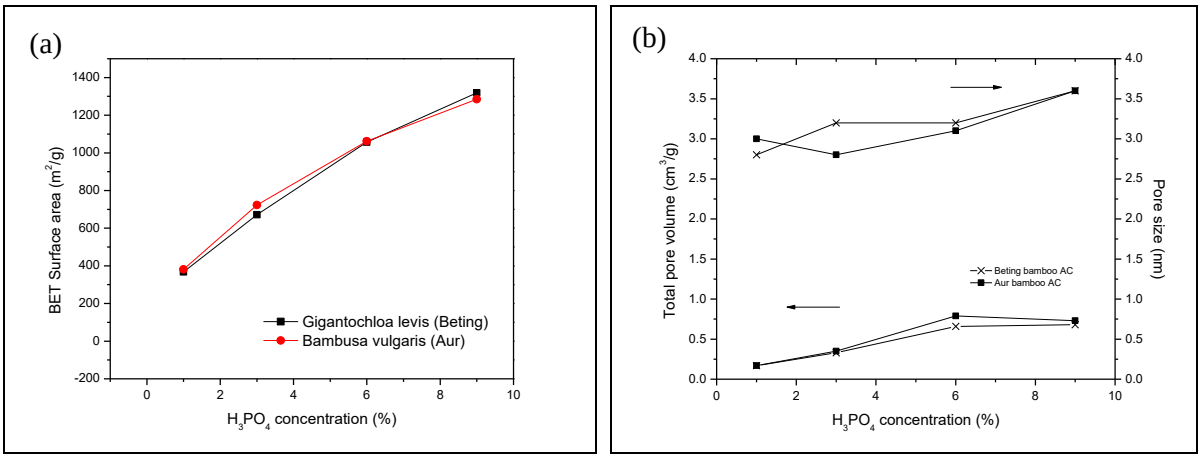

Figure 4. Effect of H_3PO_4 concentration on (a) the BET surface areas, (b) the total pore volume and pore size of activated carbons

Surface morphology of bamboo raw material and activated carbon

The FESEM analysis at the magnification scale of 5000× were carried out to confirm the textural properties and differences in the surface morphology of bamboo raw material and ACs (Figure 5). According to Figure 5(a) and (c), the micrographs of bamboo show no evidence of pore presence on the surface. The surface textures were rough, uneven, and undulating, due to the condensable volatile compounds that have gathered on the carbon surface. During activation and carbonization, most volatile matter was released thus showing surface changes of pores opening in bamboo ACs as shown in Figure 5(b) and (d). The AC's surface also generated well-developed pores because of the H_3PO_4 concentration [2]. The differences between these two carbonaceous materials' exterior morphologies can be related to the activation of H_3PO_4, which primarily involves the production of volatile chemicals and the interaction between the activating agent and the carbon precursor. The reaction between the carbon and the activating agent causes pore volume to increase as well as the formation of new pores during the chemical activation process. Similar trend was also found by Ismail and Yorgun et al [21,23]. Therefore, H_3PO_4 is a successful activation agent for producing ACs with large surface area.

Potential application of bamboo activated carbon

The performance of AC is largely depending on its surface area, porous structure, and chemical surface characteristics [32-34]. AC was used as an absorbance material because it has a massive surface area and well-developed pore structure (Table 3). These properties enable AC to have an excellent adsorption ability. Therefore, AC is widely used as a component in the water filtration system to remove contaminants. However, the adsorption effectiveness of AC is depending on the pores and pore size distribution relative to the size of adsorbent (organic matter) [35]. For example, the natural organic matter adsorption occurs in micropores and mesopores of AC [36]. However, AC with macropores is needed to filter bacteria [37]. Wang et al. [38] reported that the most suitable pore size range of AC for microbial attachment is between 2 and 5 μm. Therefore, the surface area and porous structure of bamboo AC obtained in this study indicates that it has the potential to be used as an absorbance material.

Typha orientalis leaves	1238	-	Pb(II)	The maximum adsorption capacity was found to be 7.95 mg/g	[44]
Bamboo	2237	Micropores	Ciprofloxacin	Adsorption amounts reach 613 mg/g	[45]
Coconut shell	89.09	-	Methylene blue	Adsorption amount 14.35-16.92 mg/g	[46]

Conclusion

In this work, the Sarawak wild bamboo, *Gigantochloa levis* (beting) and *Bambusa vulgaris* (aur) was used as a carbon precursor to produce ACs through the H_3PO_4 chemical activation method. The effect of H_3PO_4 concentration on the surface area, porous structure, and yield of AC was studied. The concentration of H_3PO_4 greatly influences the surface area, porous structure, and yield of AC. The maximum surface area of 1319 and 1285 m^2/g were obtained at 9% v/v H_3PO_4 impregnation

of beting and aur bamboos, respectively. Furthermore, the maximum AC yield of 62% was obtained at 9% H_3PO_4 impregnation of beting bamboo and 6% H_3PO_4 impregnation of aur bamboo. The results show that bamboo is proven to be an effective precursor and has the potential to be a promising precursor to produce ACs. The large surface area AC that was produced can be used as an extremely promising adsorbent for various environmental applications. Low cost ACs could be produced by using cheap raw materials and an appropriate production technique. Cost is the key factor in determining the potential of an adsorbent in the industry. To produce low-cost ACs, it is necessary to look at novel source materials. To our knowledge, no research has been done on using bamboo as a raw material to prepare ACs using the low concentration of H_3PO_4 chemical activation. This is to supplement the information on the properties of AC which is particularly lacking.

Abstract

This work offers a novel platform for the straightforward and low-cost manufacture of paper microfluidic devices known as gold nanoparticles modified screen printed paper electrode AuNPs/SPPE. The component can function as an electrochemical cell as well as a microfluidic device. Different paper cards were evaluated for hydrophobicity, and metallic gold card was selected due to its superior hydrophobic properties. Thus, waxing and other pretreatment steps are eliminated. The AuNPs/SPPE was created by screen printing on metallic gold card using commercial silver ink. Working electrode was modified using synthesized gold nanoparticles (AuNPs). The presence and widespread distribution of Au particles are shown by SEM and EDX study. The conductivity and resistivity study shows good conductance. The device was applied in tramadol detection, tramadol was studied electrochemically using cyclic voltammetry technique, where it was oxidized at 0.1 to 0.3 volts. Positive results obtained from electrochemical investigation suggest good and promising future applications.

Keywords: microfluidic, screen printing, paper device

Abstrak

Kerja ini menawarkan platform baru untuk pembuatan peranti mikrofluidik kertas yang mudah dan kos rendah yang dikenali sebagai nanopartikel emas yang diubah suai skrin dicetak kertas elektrod AuNPs/SPPE. Komponen ini boleh berfungsi sebagai sel elektrokimia serta peranti mikrofluidik. Kad kertas yang berbeza dinilai untuk hidrofobisiti, dan kad emas logam dipilih kerana sifat hidrofobik yang unggul. Oleh itu, waxing dan langkah-langkah pretreatment lain dihapuskan. AuNPs/SPPE dicipta melalui percetakan skrin pada kad emas logam menggunakan dakwat perak komersial. Elektrod kerja diubah suai menggunakan nanopartikel emas yang disintesis (AuNPs). Kehadiran dan pengedaran zarah Au yang meluas ditunjukkan oleh kajian SEM dan

EDX. Kajian kekonduksian dan rintangan menunjukkan kelakuan yang baik. Peranti ini digunakan dalam pengesanan tramadol, tramadol dikaji secara elektrokimia menggunakan teknik voltammetrik kitaran, di mana ia teroksida pada 0.1 hingga 0.3 volt. Hasil positif yang diperolehi daripada penyiasatan elektrokimia menunjukkan aplikasi masa depan yang baik dan menjanjikan.

Kata kunci: mikrobendalir, percetakan skrin, peranti kertas

Introduction

Microfluidic is a portable device that requires a small volume of sample and can easily be integrated into a point of care diagnostics equipment, that can be used in remote settings, with poor infrastructure [1-2]. Because of its intriguing benefits and cutting-edge platform that is still being researched, microfluidics has garnered a lot of attention. The development of fabrication techniques, novel substrates, and detection techniques is ongoing. As a result, low-cost materials and low-cost fabrication and detection designs are emerging [1-6] in response to the growing demand for low-cost devices that will greatly simplify lives all over the world. Paper substrates are now included in microfluidic systems [5-10], which is a novel development that researchers are exploring since it is portable, inexpensive, and requires a small amount of sample [7-9]. Hydrophobic and hydrophilic patterns are typically formed on the paper to create microfluidic paper devices. The hydrophilic region is produced by screen printing the ink onto the patterned paper, and the hydrophobic portion is produced by melting photoresist or wax onto the paper [1,5]. Dungchai et al. used photoresist to form the hydrophobic barrier on a filter paper [5]. The wax technique is the most popular. The wax has been applied in a variety of ways, according to reports. A fabrication technique utilizing chromatographic paper was created by Songjaroen et al. [3]. The paper was dipped into melted wax, and the wax penetrating the area not covered by the iron template created the hydrophobic region. While, Zhang and Zha employed filter paper with a paraffin copper sheet attached. When heated, the paraffin melted through the filter paper and formed the hydrophobic barriers [4].

The increasing demand for point of care testing has prompt fabrication of rapid and quantitative microfluidic paper devices [1,8-13,16] for hard drugs detection [11-13]. Rapid and quantitative microfluidic paper devices [1,8-13,16] for the detection of hard drugs [11–13] have been made as a result of the rising need for point-of-care testing. The availability of microfluidic devices can reduce the short- and long-term negative impacts of hard drugs, such as overdose, addiction, fatalities, and consumption, as the victim can be quickly identified in the general population [12-13]. Screen printing was employed due to its miniaturization ability, low cost, versatility, and ease of mass production [11,14]. This technique has been employed in the production of electrodes used in commercial electrochemical test strips [11,15-16]. The distribution of wax on the surface of the material might not be uniform depending on the application method. Thus, complete hydrophobicity of the paper cannot be assured. In order to address this problem, many paper cards were examined. And we report a novel substrate metallic gold card that has a hydrophobic nature. The fabrication is greatly facilitated by the removal of a key wax application step. Without any additional card pretreatment, the gold card can be screen-printed with Ag ink (silver ink) directly. When used as an ion selective electrode, silver ink exhibits greater sensitivity to various ions [17].

Gold nanoparticles (AuNPs) are considered to be highly stable metal nanoparticles that display a number of exceptional qualities, such as facial synthesis and surface modification, excellent biocompatibility, and strong Surface Plasmon Resonance (SPR) in the visible region of the spectrum, which make them the ideal candidate for detection of analytes with the naked eye [18]. Additionally, they have special optical and electrochemical properties that make them useful for sensing various analytes [19]. Due to the special characteristics of gold nanoparticles, which include their ability to withstand surface oxidation and chemical inertness, modification of electrode with gold nanoparticles is garnering considerable interest [20]. The sensitivity of the sensing platform can be improved by modifying the working electrode with AuNPs. In this study, a microfluidic paper device was created for tramadol detection by screen printing silver ink onto a

card and modifying the working electrode with AuNPs. Tramadol can bind to the surface of these particles through the amino group by electrostatic contact, because oxygen-containing rings of hybrid aromatics display noticeably better binding to AuNPs [18]. By coordinating interactions with the electron-deficient surfaces of metal nanoparticles, hydroxyl groups containing electron-rich oxygen atoms are more likely to be bonded to the surface of metal nanoparticles [19]. This newly fabricated microfluidic device may function as both a microfluidic system and an electrochemical sensor.

Materials and Methods

All chemicals used were of analytical grade. Chloro auric acid ($HAuCl_4$), silver acetate, carbon conducting ink and silver conductive ink from Sigma Aldrich (USA), sodium citrate dihydrate, sodium acetate, ammonia, ethylamine, acetic acid and formic acid from Kermel chemicals (China), hydroxyl ethyl cellulose (HEC) from Koch-Light laboratories (England), potassium ferricyanide, potassium chloride from Harris reagent (England).

Synthesis of silver ink

In a glass vial, 2.0 g of silver acetate and 5 mL of ethylamine were combined, and 5 mL of ammonia was then added to the mixture to create a transparent solution. Followed by dropwise addition of 0.4 mL formic acid to the clear solution, which caused it to turn from light brown to black to gray. Lastly, 0.2 g of HEC was added to the solution while being continuously stirred [21].

Synthesis of AuNPs (gold nanoparticles)

In 200 mL of deionized water, 7.0 mg of $HAuCl_4$ was dissolved to create a pale-yellow solution. 50 mL of the solution were heated to a boil while being vigorously stirred, and 5 mL of 40 mM sodium citrate were added dropwise. Till a steady deep red color was obtained after 15 minutes of continuous heating and stirring [22]. The solution was kept at or below 7 ^oC.

Fabrication of device

Two distinct patterns were created in Corel Draw. The first pattern, which is made up of circles with 1.6 cm in diameter, was printed using a printer on the card. The second pattern, the electrode layout, was printed on an A4 laser sheet using an HP laser jet 5100M. The electrode layout consists of the working electrode (WE), reference electrode (RE), and counter electrode (CE). The design on the laser sheet was exposed to a mesh, and the mesh was used to screen print silver ink onto the card as displayed in figure 1 [15]. The card was cured for 30 minutes at 120°C. Individual electrochemical cells or sensor strips were cut off. The working electrode was modified using gold nanoparticles. Gold nanoparticles modified screen printed paper electrode was prepared by drop coating the working electrode with 10 µL of AuNPs and the solution was allowed to dry at room temperature. For microfluidic system, 10 µL of AuNPs was drop coated onto the working electrode, with subsequent addition of 10 µL of 1 µM tramadol onto the AuNPs solution.

Characterization

Scanning electron microscopy (SEM) was used to examine the morphology of the AuNPs and Ag ink, and energy dispersive X-ray spectroscopy was used to examine the elemental spectra (EDX). Using a digital multimeter (DT9205A), the resistance of the manufactured devices was measured, and resistivity was computed using the formula.

$$\rho = RA/l \quad (1)$$

Where, ρ is Resistivity, R is the resistance, A is the cross-sectional area and L is the length, while conductivity was calculated using the formula

$$\sigma = 1/\rho \quad (2)$$

Where σ is the conductivity, and ρ is the resistivity [23].

Electroanalytical measurement

DropSens potentiostat (United Kingdom) coupled to a computer and the sensor strip, which has three electrodes: a working electrode, counter electrode, and reference electrode, were used to perform electrochemical measurements.

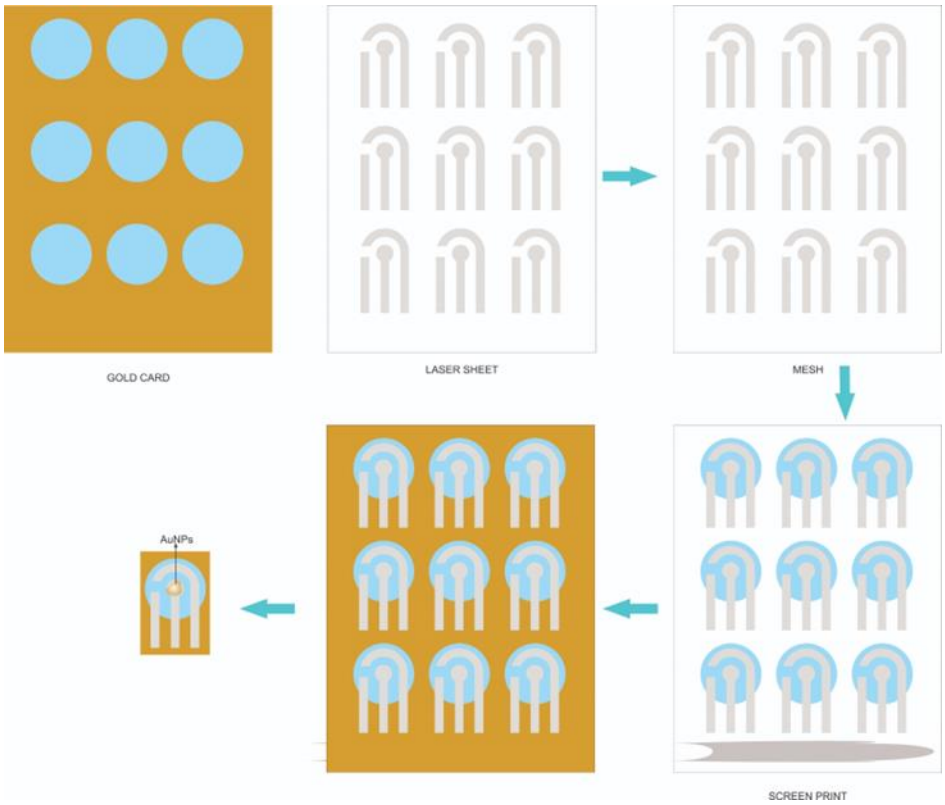

Figure 1. Schematic illustration of the fabrication steps

Results and Discussion

Scanning electron microscope

SEM Phenom Prox was used to capture the SEM imaging at 500x magnification, 100 µm interval, and 15 kV. The sample holder was created using aluminum foil as the blank. The images in Figure 2a have no particles at all dispersed across the surface. Figure 2b, on the other hand, shows an image of Ag ink with a white deposit covering the surface. Figure 2c displays image of surface without any particles at all. Figure 2d shows an image of gold nanoparticles, which are depicted as dazzling white deposits covering the surface. It has a highly distinct distribution of AuNPs dispersed widely throughout the surface.

Energy dispersive X-ray spectroscopy

The elemental spectra and value of Ag ink are shown in Figure 3a. Using the SEM image, several spectrums were captured at various distributions (Figure 2b). There is one prominent peak and several smaller peaks of silver in the spectral image, which indicates the presence of silver and the value confirms that silver is widely spread. The other elements were impurities discovered on the aluminum blank before the addition of silver, according to the elemental values obtained. The elemental spectra and value of AuNPs are shown in Figure 3b. Using the SEM image, several spectrums were captured at various distributions (Figure 2d). One sharp peak and several smaller peaks of AuNPs can be seen in the spectral image, which indicates the presence of AuNPs and the value confirms that AuNPs are widely spread. Due to the small quantity of contaminants present, the finding further supports the suitability of the process employed to create AuNPs and their purity. The aluminum blank included every element that has been seen with Ag ink and AuNPs. These are therefore impurities that are present on the blank.

Microfluidic paper device

The typical substrate for paper-based printed electronics is a paper with a hydrophobic resin coating on the surface. Hydrophilic and evenly absorbent characteristics, thus, are incompatible with the needs of printed electronics [24]. A variety of paper cards were examined to find the one with the highest hydrophobicity. When a drug sample was dropped, art card figure 4A gave a good print, but it absorbed and flowed. Figure 4B Teslin card, which is typically used to

create I.D. cards, could not produce a nice print right away. Moreover, the laser sheet figure 4C did not print well. Metallic silver and gold card figure 4D and E offered a nice print, did not absorb, and could be bent without harming the conducting part. Metallic silver and gold card were selected as the best substrates for additional examination. The image of the single sensor strip printed with commercial silver ink is shown in Figure 4F.

Conductivity and resistivity

Ag ink that had been synthesized had a conductivity of 23.1 mS. (millisiemens). The resistivity of the printed ink was calculated using the formula in equation 1. After printing with carbon ink, synthesized silver ink, and commercial silver ink on a paper card, the resistance of each ink was measured using a multimeter. The depiction of data recorded is shown in Table 1; commercial silver ink had a lower resistance. Hence, for more investigation, commercial silver ink was chosen. A lack of information from the synthesis process prevented the successful synthesis of Ag ink.

Gold and silver card printed with commercial silver ink were heated at 60 ºc. As can be seen in table 2, the resistance measurement decreased after 30 minutes, but not after an hour. As a result, 30 minutes was determined to be the ideal heating time. Resistance values obtained in table 2 were utilized in calculating the resistivity with the above resistivity formula. Gold card had a higher conductivity than silver card because it has a lower resistance than silver card. Due to the high conductivity that metal-coated papers typically display, they can perform in a variety of ways [25]

.

Electrochemical analysis

The electrochemical analysis employed the cyclic voltammetric approach, which provides data on the investigation of a reversible redox reaction. With the three-electrode sensor attached to a potentiostat, cyclic voltammetry was performed. The freshly created AuNPs/SPPE were studied using the cyclic voltammetric technique to determine their oxidation and reduction peak currents, which also shows an electron transfer reaction has taken place. Thus, indicating the feasible application of the sensor. With gold card AuNPs/SPPE in 2 mM $K_3Fe(CN)_6$ with 0.1 M KCl, a broad oxidation peak was seen at around 0.4 V to 0.55 V, whereas a minor reduction peak was seen at 0.15 V to 0.3 V in figure 5A. With the silver card AuNPs/SPPE, a broad oxidation peak was also seen between 0.3 and 0.45 V, whereas the reduction peak was shown between 0.2 and 0.45 V in figure 5B. When ferricyanide is subjected to cyclic voltammetry, ferricyanide is reduced to ferrocyanide and vice versa, demonstrating that the reaction is reversible and that a one electron transfer diffusion reaction has occurred [26]. These findings reveal that the oxidation peaks, which signify the formation of oxide, exhibit a greater current for gold card AuNPs/SPPE than for silver card AuNPs/SPPE, further demonstrating the superior conductivity of gold card.

The gold card AuNPs/SPPE was selected for further analysis. Figure 6 shows the results of the AuNPs/SPPE study in acetate buffer and tramadol. The cyclic voltammogram showed no oxidation peak but a small reduction peak in acetate buffer, while an oxidation peak current was obtained at around 0.1V to 0.3V and a reduction peak current at around 0.00V to -0.15V for acetate buffer with tramadol. As a result, AuNPs enhance detection capabilities and provide evidence of an oxidation reaction between AuNPs and tramadol.

Table 1. Resistance Measurement of different inks printed on gold and silver cards

Gold Card Electrodes	Working Electrode	Reference Electrode	Counter Electrode

Conclusion

Paper electrodes with gold nanoparticle modifications were successfully created using the screen-printing technique. The intriguing aspect of this research is that the metallic gold card we used as a substrate, which is also inexpensive, allowed us to forgo the wax phase. According to the conductivity value, the card exhibits very high conductance and produced a good print with the inks. Since the current was larger for the gold card, the electrochemical experiment further establishes the high conductivity of the manufactured sensor strip. Using cyclic voltammetry, the electrochemical method of detecting tramadol proved successful. We are certain that the manufactured sensor strip can be used in electrochemical detection based on this initial electrochemical measurement.

Abstract

As a continuous effort to discover potential neuraminidase (NA) inhibitors, two series of benzimidazole derivatives consisting of esters, **5(a–g)** and carboxylic acid moieties, **6(a–g)** were synthesised under conventional and microwave conditions. The efficiency of both methods was compared, and their ability to inhibit the action of NA enzyme was examined *in silico* and *in vitro*. The microwave synthesis of the target compounds was more efficient and convenient than the conventional method as the former accelerated the reaction from hours to minutes, giving comparable yields. All compounds obtained were confirmed by the ^{1}H, ^{13}C NMR, and mass spectroscopic data. Out of six compounds tested in the carboxylic acid series, only **6f** showed inhibitory action towards NA with 15.2%. The binding interactions of **6(a–g)** were investigated further by molecular docking on the NA active site (PDB ID: 3TI6). **6f** was found to interact in the 430-loop cavity mainly by hydrophobic interactions. **6f** interacted at different active sites compared to DANA and oseltamivir. Although the compounds showed low inhibitory action, with strategic structural improvements, the benzimidazoles have the potential to be developed as NA inhibitors.

Keywords: benzimidazole, MAOS, Neuraminidase inhibitor, Molecular docking, MUNANA

Abstrak

Sebagai usaha berterusan untuk menemukan perencat neuraminidase (NA) yang berpotensi, dua siri terbitan benzimidazola yang terdiri daripada ester, **5(a–g)** dan moieti asid karboksilik, **6(a–g)** telah disintesis dalam keadaan konvensional dan gelombang mikro. Kecekapan kedua-dua kaedah telah dibandingkan dan keupayaan mereka untuk merencat enzim NA telah diselidik secara *in silico* dan *in vitro*. Sintesis sebatian sasaran melalui gelombang mikro adalah lebih cekap dan mudah berbanding kaedah konvensional kerana proses tindak balas dipercepat dari beberapa jam ke minit, memberikan hasil yang setanding. Semua sebatian yang diperoleh adalah bertepatan dengan data ^{1}H, ^{13}C NMR, dan spektroskopi jisim. Daripada enam sebatian yang diuji dalam siri

asid karboksilik, hanya **6f** menunjukkan tindakan perencatan terhadap NA sebanyak 15.2%. Interaksi pengikatan **6(a–g)** telah dikaji dengan lebih lanjut melalui pengedokan molekul terhadap tapak aktif NA (PDB ID: 3TI6). **6f** didapati berinteraksi dalam rongga 430 gelung terutamanya oleh interaksi hidrofobik. **6f** berinteraksi di tapak aktif yang berbeza berbanding DANA dan oseltamivir. Walaupun sebatian menunjukkan tindakan perencatan yang rendah, dengan penambahbaikan struktur strategik, benzimidazola mempunyai potensi untuk dibangunkan sebagai perencat NA.

Kata kunci: Benzimidazola, MAOS, Perencat neuraminidase, Pengedokan molekul, MUNANA

Introduction

Three main types of human influenza virus (A, B, and C) were reported with both types A and B virulent to humans [1]. The H1N1 influenza attack in 2009, derived from a triple-reassortant influenza virus comprising genes from avian, swine, and human origin, had caused the first pandemic outbreak of this century, raising the influenza pandemic alert level to phase 6 [2-4] until August 2010, after which the World Health Organization declared the end of the H1N1 pandemic. Vaccination is one of the most effective ways of protecting the body against viral infection. However, several drawbacks appeared in applying vaccines, such as the requirements of a new vaccine based on predicted strains that are circulating during flu season [5] and the lack of time to produce a mass number of vaccines, especially when the outbreak strikes [6]. Therefore, an anti-influenza drug is preferably applied as a forefront target in the early treatment of influenza attack.

The M2 ion protein channel and neuraminidase (NA) are two primary targets in the development of antiviral agents for influenza infection treatment or prevention [7, 8]. The M2 ion channel inhibitors (e.g., amantadine and rimantadine (adamantanes)) act by preventing the viral to uncover inside the cell. Unfortunately, these drugs are only useful for influenza virus having the M2 protein, such as type A, but ineffective for those without, such as influenza B [9]. In addition, the drugs are also associated with several adverse effects [10] and demonstrated resistance in most strains, making them less effective for treating the disease [11, 12].

On the other hand, NA works by cleaving the terminal sialic acid from the virion progeny and the host-cell surface. In doing so, it then assists the virus's movement through the respiratory tract [13, 14]. The NA active sites are surrounded by the conserved residues of amino acids of both influenza A and B strains. Thus, these sites become the ideal target for the design of NA inhibitors. Along with the advanced development in structure-based drug design and the availability of NA crystal structure, several NA inhibitors, such as zanamivir, oseltamivir, peramivir, and laninamivir, were developed to treat influenza [15]. Zanamivir (Relenza®) is a polar compound that needs to be administered by inhalation, which makes it inconvenient especially for children and elderly people. Oseltamivir carboxylate (Tamilflu®), while available in the form of tablets, can cause nausea and vomiting. Peramivir (Rapiacta®, Peramiflu®) received a fast-track designation from the US Food and Drug Administration to be used as a drug and was approved later for intravenous administration in December 2014. However, the reported side effects of this drug include gastrointestinal problems and abnormal neutrophil counts [16]. Laninamivir, recently authorised in Japan, was found to effectively inhibit H5N1 influenza virus and oseltamivir resistance mutants by single inhalation. It was also recently reported to be as efficient as zanamivir towards children affected with the influenza virus [17], although laninamivir is much more convenient as it only requires single inhalation for the treatment [4].

Benzimidazole is a heteroaromatic compound possessing diverse therapeutic and biological properties. Its derivatives were found to act as proton pump inhibitors (e.g., omeprazole), anthelmintics (e.g., mebendazole), and inodilators (e.g., pimobendan) [17]. Compounds possessing benzimidazole scaffold were also reported to exhibit antimicrobial and antifungal activities towards *S. aureus*, *E. coli, Xanthomonas sp*., and *Salmonella sp*., [18-21], antihistamine [22-25], anticancer [24, 26], and antifungal activities [26, 27]. These interesting properties warrant benzimidazole to be considered a privileged structure as the structure can be manipulated or modified to suit many different biological targets [28, 29].

Gedye et al. [30] were the first to introduce the application of microwave in organic transformation and Giguere et al. [31] then opened up a new perspective on microwave reaction. Since then, many chemical syntheses utilising either domestic or single-mode microwave reactors have been reported [32-34]. Apart from shortening the reaction time and improving reproducibility, the percentage yield can be increased with low by-products formed [35, 36]. In contrast to the normal conventional method, the microwave method involves a conduction heating mechanism, where energy is transferred from the vessel wall to the adjacent solvent before it moves within the bulk solvent containing the reaction mixture. This process results in slow heating and thus requires a lot of energy to heat the glassware compared to the reaction mixture itself, making the temperature inside the target mixture often cooler than the outside [37].

The design of NA inhibitors mainly involves sialic acid, benzoic acid, and cyclopentane scaffolds. Only recently, benzimidazoles have also been investigated as NA inhibitors [37, 38]. Owing to benzimidazole's interesting structure and various therapeutic applications, we were interested to discover the potential of benzimidazole derivatives as NA inhibitors. In this work, the designed compounds were synthesised via microwave and conventional approaches. Both methods were compared, and the isolated compounds were evaluated by molecular docking and NA inhibition assay.

Materials and Methods

A single-mode microwave reactor (CEM™ Discover Labmate) was used for microwave experiments. ^{1}H, ^{13}C, and ^{19}F nuclear magnetic resonance (NMR) experiments were performed using an NMR spectrometer (Bruker AVANCE III 500 MHz). The chemical shifts are expressed in parts per million (ppm), and the splitting of signals are assigned as singlet (s), doublet (d), triplet (t), doublet of doublet (dd), and multiplet (m). Mass spectroscopic (MS) analyses were performed by an Agilent 1100 Series spectrometer. All chemicals purchased from suppliers were used without further purification.

Synthesis: Ethyl 4-fluoro-3-nitrobenzoate, 2

Conventional condition:

To a solution of 4-fluoro-3-nitro benzoic acid, **1** (2.00 g, 10.40 mmol) in ethanol (25 mL), 2.5 mL concentrated H_2SO_4 was added and refluxed at ~78 °C for 4–6 h. The progress of the reaction was monitored every hour by thin-layer chromatography (TLC). Upon completion, the solvent was removed under pressure. The mixture was dissolved in ethyl acetate (25 mL) and extracted with water containing 10% $NaHCO_3$. The organic layer was washed with water and dried in anhydrous Na_2SO_4. Filtered and concentrated crude product *in vacuo* was later purified using preparative thin-layer chromatography (PTLC) with ethyl acetate (EtOAc)/hexane (Hex) of 1:4 to give the ester product. The product obtained after concentrated *in vacuo* was 1.96 g (85%) of yellow solid.

Microwave condition:

Compound **2** was obtained after irradiation of a mixture containing 4-fluoro-3-nitrobenzoic acid, **1** (0.25 g, 1.35 mmol), 4% H_2SO_4 equiv. to the starting material, and 1.0 mL of ethanol. Similar work-up was carried out as in conventional procedure. The yellow solid obtained after concentrated *in vacuo* gave 0.21 g (74%).

R_f = 0.69 (EtOAc/Hex, 1:4). ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.43 (t, J = 5.0 Hz, $OCH_2C\underline{H_3}$), 4.44 (q, J = 5.0, 10.0 Hz, $OC\underline{H_2}CH_3$), 7.39 (t, J = 10.0 Hz, benzene-$\underline{H_5}$), 8.31–8.35 (m, benzene-$\underline{H_6}$), 8.74 (dd, J = 5.0, 7.0 Hz, benzene-$\underline{H_2}$); ^{13}C NMR (125 MHz, $CDCl_3$): δ 14.26, 62.13, 118.74, 127.61, 127.79, 136.49, 136.57, 158.03, 163.64; ^{19}F NMR (500 MHz, $CDCl_3$): -110.75; ESI-MS m/z calcd. for $[C_9H_8FNO_4]^+$ 213.2; found $[M + Na]^+$ 236.0.

Ethyl 4-(2-hydroxy-ethylamino)-3-nitro-benzoate, 3

Microwave condition:

4-fluoro-3-nitrobenzoic acid ethyl ester, **2** (0.25 g, 1.17 mmol) in 1 mL CH_2Cl_2 was mixed with N,N-diisopropylethylamine (DIPEA) (0.38 mL, 1.76 mmol), and ethanolamine (0.085 mL, 1.4 mmol) was added dropwise to the solution. The mixture was then irradiated in a CEM™ microwave at a temperature of 120 °C for 2 min (hold time). Upon completion, the mixture was filtered by suction and washed with hexane

to afford a yellow solid. The product was dried in a desiccator without further purification to give **3** (0.30 g, 94%).

Conventional condition:
4-fluoro-3-nitrobenzoic acid ethyl ester, **2** (1.00 g, 4.69 mmol) in 25 mL CH_2Cl_2 was mixed with DIPEA (1.51 mL, 7.0 mmol), and ethanolamine (0.33 mL, 5.63 mmol) was added dropwise to the solution. With the drying tube filled with anhydrous $CaCl_2$ attached to the round bottom flask, the mixture was stirred overnight at room temperature until a yellow precipitate formed. The precipitate was filtered by suction, washed with hexane, and dried in a desiccator without further purification to give **3** (1.18 g, 99%).

R_f = 0.60 (EtOAc/Hex, 4:1). ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.40 (t, 3H, *J* = 5.0, 10.0 Hz, $OCH_2C\underline{H_3}$), 3.57 (q, *J* = 5.0, 10.0 Hz, $C\underline{H_2}CH_2OH$), 3.99 (q, *J* = 5.0, 10.0 Hz, $CH_2C\underline{H_2}OH$), 4.37 (q, *J* = 5.0, 10.0 Hz, $OC\underline{H_2}CH_3$), 6.92 (d, *J* = 10 Hz, benzene-$\underline{H_5}$), 8.31–8.34 (m, benzene-$\underline{H_6}$, 8.89 (d, *J* = 0.0 Hz, benzene-$\underline{H_2}$); ^{13}C NMR (125 MHz, $CDCl_3$): 14.39, 44.98, 60.72, 61.09, 113.48, 117.84, 129.47, 131.58, 136.43, 147.75, 165.16; ESI-MS m/z calcd. for $[C_{11}H_{14}N_2O_5]^+$ 254.2; found $[M + H]^+$ 255.1.

Ethyl 3-amino-4-(2-hydroxy ethylamino) benzoate, 4
Microwave condition:
A mixture of 4-(2-hydroxy-ethylamino)-3-nitrobenzoic acid ethyl ester, **3** (0.60 g, 2.63 mmol), NH_4HCO_2 (0.52 g, 8.25 mmol), and 10% Pd/C (0.30 g) in 2 mL of ethanol was irradiated in a microwave at 100 °C for 2 min (hold time). The pressure profile was monitored using the Synergy^{TM} programme so that the pressure did not exceed 20 atm. Upon completion, the catalyst was filtered through Celite and washed with ethanol, while the filtrate was concentrated *in vacuo* to afford a brown solid. The product **4** (0.50 g, 94%) was used for subsequent reaction without further purification.

Conventional condition:
A mixture of 4-(2-hydroxy-ethylamino)-3-nitrobenzoic acid ethyl ester, **3** (0.35 g, 1.38 mmol), NH_4HCO_2 (0.30 g, 4.82 mmol), and 10 % Pd/C (0.18 g) in 5 mL of ethanol was refluxed at 79–80 °C for 1–2 h until all reactants were consumed, as monitored by TLC. Upon completion, the catalyst was filtered through Celite by suction and washed with ethanol, while the filtrate was concentrated *in vacuo* to afford a brown solid **4** (0.31 g, 99%). The compound was used for the subsequent reaction without further purification.

R_f = 0.69 (EtOAc/Hex, 1:4). ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.43 (t, *J* = 5.0 Hz, $OCH_2C\underline{H_3}$), 4.44 (q, *J* = 5.0, 10.0 Hz, $OC\underline{H_2}CH_3$), 7.39 (t, *J* = 10.0 Hz, benzene-$\underline{H_5}$), 8.31–8.35 (m, benzene-$\underline{H_6}$), 8.74 (dd, *J* = 5.0, 7.0 Hz, benzene-$\underline{H_2}$); ^{13}C NMR (125 MHz, $CDCl_3$): δ 14.26, 62.13, 118.74, 127.61, 127.79, 136.49, 136.57, 158.03, 163.64; ^{19}F NMR (500 MHz, $CDCl_3$): -110.75; ESI-MS m/z calcd. for $[C_9H_8FNO_4]^+$ 213.2; found $[M + Na]^+$ 236.0.

General procedure for the preparation of compounds 5(a–g)
Microwave method:
A solution of 3-amino-4-(2-hydroxy-ethanolamine)-benzoic acid ethyl ester (**4**) (1 equiv.) in CH_3CN (1 mL) was mixed with K10-montmorillonite (0.02–0.26 g) and the corresponding aldehyde (2.1 equiv. with respect to the starting material). The mixture was irradiated in the CEM^{TM} microwave at 80 °C, 150 W, 5 bar, and held for 5 min. Then, another aliquot of aldehyde (2.1 equiv.) was added, and the reaction mixture was irradiated again at the same condition as before. The reaction was monitored by TLC and was left for a few days before doing the work-up. K10-montmorillonite was removed by filtration, washed with DCM, and evaporated *in vacuo* to afford a brown precipitate. The crude product was later purified using PTLC (EtOAc/Hex, 4:1).

Conventional method:
A solution of 3-amino-4-(2-hydroxy-ethanolamine)-benzoic acid ethyl ester (**4**) (1 equiv.) in CH_3CN (5–10 mL) was mixed with K10-montmorillonite (0.30–0.50 g) and the corresponding aldehyde (2.1 equiv. with respect to the starting material). The reaction was refluxed at 78–80 °C for 4–5 h, and the progress was monitored by TLC every hour. Upon completion, K10-montmorillonite and CH_3CN were removed by filtration and under pressure, respectively, before the crude product was purified using PTLC (EtOAc/Hex, 4:1).

The product obtained in the conventional method was compared with the product obtained from microwave synthesis based on the R_f value.

5a

^{1}H NMR (500 MHz, $CDCl_3$): δ 1.31 (t, *J* = 10.0, 15.0 Hz, $CH_2C\underline{H_3}$), 1.44 (t, *J* = 10.0, 15.0 Hz, $OCH_2C\underline{H_3}$), 1.76 (br, s, $\underline{H_2}O$), 2.89 (q, *J* = 10.0, 15.0 Hz, $C\underline{H_2}CH_3$), 4.09 (t, *J* = 5.0, 10.0 Hz, $C\underline{H_2}CH_2OH$), 4.24 (t, *J* = 5.0, 10.0 Hz, $CH_2C\underline{H_2}OH$), 4.39 (q, *J* = 10.0, 15.0 Hz, $OC\underline{H_2}CH_3$), 5.09 (br, s, OH), 7.21 (d, *J* = 15.0 Hz, benzene-$\underline{H_7}$), 7.77 (d, *J* = 15.0 Hz, benzene-$\underline{H_6}$), 7.87 (s, benzene-$\underline{H_4}$); ^{13}C NMR (125 MHz, $CDCl_3$): δ 11.64, 14.43, 20.95, 46.53, 60.43, 60.74, 108.70, 120.71, 123.65, 124.31, 137.77, 141.22, 158.68, 166.86; ESI-MS m/z calcd. For $[C_{11}H_{16}N_2O_3]^+$ 262.3; found $[M + H]^+$ 263.1.

^{1}H NMR (500 MHz, $CDCl_3$): δ 1.43 (t, *J* = 10.0, 15.0 Hz, $OCH_2C\underline{H_3}$), 1.74 (br, s, H_2O), 2.11 (s, $SC\underline{H_3}$), 2.92

(t, J = 10.0, 15.0 Hz, $CH_2C\underline{H_2}SCH_3$), 3.17 (t, J = 10.0, 15.0 Hz, $C\underline{H_2}CH_2SCH_3$), 4.07 (t, J = 5.0, 10.0 Hz, $C\underline{H_2}CH_2OH$), 4.29 (t, J = 5.0, 10.0 Hz, $CH_2C\underline{H_2}OH$), 4.39 (q, J = 10.0, 15.0 Hz, $OC\underline{H_2}CH_3$), 4.57 (br, s, OH), 7.27 (d, J = 10.0 Hz, benzene-$\underline{H_7}$), 7.82 (dd, J = 5.0, 12.5 Hz, benzene-$\underline{H_6}$), 7.97 (d, J = 5.0 Hz, benzene-$\underline{H_4}$); ^{13}C NMR (125 MHz, $CDCl_3$): δ 14.41, 15.82, 27.80, 31.90, 46.76, 60.20, 60.82, 108.97, 120.66, 123.82, 124.48, 137.47, 141.00, 155.87, 166.73; ESI-MS m/z calcd. for $[C_{15}H_{20}N_2O_3S]^+$ 309.1; found $[M + H]^+$ 309.1.

General procedure for the preparation of compounds 6(a–g)

Microwave condition:

The obtained ester product **5(a–g)** in THF:H_2O (2:1) was mixed with 4 N NaOH (0.5 mL). The mixture was irradiated in the microwave at 120 °C for 2–5 min. Upon completion, THF was removed under pressure, and the product was acidified using 2 M HCl to maintain the pH at 6–7. Removing excess water *in vacuo* gave a white precipitate, which later was dissolved in butanol to separate the carboxylic acid and salt. The filtrate was again evaporated under vacuum to obtain the crude product. Purification was later carried out using PTLC (EtOAc/Hex, 4:1) by dissolving the crude product with methanol.

Conventional condition:

The obtained ester product **5(a–g)** either in THF (2 mL) or in a ratio of THF:H_2O (2:1) was added with 4 N NaOH (1–5 mL). The mixture was refluxed for 2–18 h at 66–68 °C until all reactants were fully converted to the desired acid, as observed in the TLC. Upon completion, THF was removed under pressure and acidified using 2 M HCl to maintain the pH at 6–7. Removing excess water *in vacuo* gave a white precipitate, which later was dissolved in butanol to separate the carboxylic acid and salt. The filtrate was again evaporated under vacuum to obtain the crude product. Purification was done using PTLC (EtOAc/Hex, 4:1) by dissolving the crude product with methanol.

R_f = 0.70 ($MeOH/CHCl_3$, 4:1). ^{1}H NMR (500 MHz, D_2O): δ 1.43 (t, J = 5.0, 10.0 Hz, $CH_2C\underline{H_3}$), 3.13 (q, J = 5.0, 10.0 Hz, $C\underline{H_2}CH_3$), 3.96 (t, J = 5.0 Hz, $C\underline{H_2}CH_2OH$), 4.45 (t, J = 5.0 Hz, $CH_2C\underline{H_2}OH$), 7.64 (d, J = 10.0 Hz, benzene-$\underline{H_7}$), 7.93 (d, J = 10.0 Hz, benzene-$\underline{H_6}$), 8.07 (s, benzene-$\underline{H_4}$); ^{13}C NMR (125 MHz, D_2O): δ 9.88, 19.40, 46.68, 59.17, 111.32, 115.43, 125.67, 132.57, 133.25, 134.31, 157.68, 174.02; ESI-MS m/z calcd. for $[C_{12}H_{14}N_2O_3]^+$ 234.3; found $[M + H]^+$ 235.1.

6b

^{1}H NMR (500 MHz, D_2O): δ 1.36 (d, J = 5.0 Hz, $H(C\underline{H_3})_2$), 3.39 (septet, J = 5.0, 10.0 Hz, $\underline{H}(CH_3)_2$), 3.94 (t, J = 5.0, 10.0 Hz, $C\underline{H_2}CH_2OH$), 4.41 (t, J = 5.0, 10.0 Hz, $CH_2C\underline{H_2}OH$), 7.53 (d, J = 10.0 Hz, benzene-$\underline{H_7}$), 7.84 (dd, J = 0.0, 5.0, 10.0 Hz, benzene-$\underline{H_6}$), 8.10 (d, J = 5.0 Hz, benzene-$\underline{H_4}$); ^{13}C NMR (125 MHz, D_2O): δ 20.74, 25.89, 45.52, 59.88, 109.99, 118.52, 123.69, 130.81, 136.73, 140.68, 163.71, 175.84; ESI-MS m/z calcd. for $[C_{13}H_{16}N_2O_3]^+$ 248.1; found $[M + H]^+$ 249.1.

6c

^{1}H NMR (500 MHz, D_2O): δ 1.03 (t, J = 5.0, 10.0 Hz, $CH_2CH_2C\underline{H_3}$), 1.91 (sextet, J = 5.0, 10.0 Hz, $CH_2C\underline{H_2}CH_3$), 3.20 (t, J = 5.0, 10.0 Hz, $C\underline{H_2}CH_2CH_3$), 3.99 (t, J = 5.0 Hz, $C\underline{H_2}CH_2OH$), 4.57 (t, J = 5.0 Hz, $CH_2C\underline{H_2}OH$), 7.81 (d, J = 10.0 Hz, benzene-$\underline{H_7}$), 8.08 (d, J = 10.0 Hz, benzene-$\underline{H_6}$), 8.25 (s, benzene-$\underline{H_4}$); ^{13}C NMR (125 MHz, D_2O): δ 12.69, 19.62, 27.02, 47.32, 59.04, 112.78, 115.87, 126.89, 127.87, 129.74, 134.94, 156.90, 169.12; ESI-MS m/z calcd. for $[C_{13}H_{16}N_2O_3]^+$ 248.1; found $[M + H]^+$ 249.1.

6d

^{1}H NMR (500 MHz, D_2O): δ 0.97 (t, J = 5.0, 10.0 Hz, $CH_2CH_2CH_2C\underline{H_3}$), 1.46 (sextet, J = 5.0, 10.0 Hz, $CH_2CH_2C\underline{H_2}CH_3$), 1.85 (quintet, J = 5.0, 10.0 Hz, $CH_2C\underline{H_2}CH_2CH_3$), 2.99 (t, J = 5.0, 10.0 Hz, $C\underline{H_2}CH_2CH_2CH_3$), 3.98 (t, J = 5.0 Hz, $C\underline{H_2}CH_2OH$), 4.42 (t, J = 5.0 Hz, $CH_2C\underline{H_2}OH$), 7.57 (d, J = 10.0 Hz, benzene-$\underline{H_7}$), 7.88 (d, J = 10.0 Hz, benzene-$\underline{H_6}$), 8.14 (s, benzene-$\underline{H_4}$); ^{13}C NMR (125 MHz, D_2O): δ 13.04, 21.83, 26.31, 28.98, 45.71, 59.92, 109.87, 123.65, 130.73, 140.70, 159.06, 175.84; ESI-MS m/z calcd. for $[C_{14}H_{18}N_2O_3]^+$ 262.3; found $[M + H]^+$ 263.1.

6e

^{1}H NMR (500 MHz, D_2O): δ 0.92 (t, J = 5.0 Hz,

$CH(CH_3)CH_2C\underline{H_3}$), 1.47 (d, J = 5.0 Hz, $CH(C\underline{H_3})CH_2CH_3$), 1.84–1.96 (m, $CH(CH_3)C\underline{H_2}CH_3$), 3.52 (sextet, J = 5.0, 10.0 Hz, $C\underline{H}(CH_3)CH_2CH_3$), 4.01 (t, J = 5.0 Hz, $CH_2C\underline{H_2}OH$), 4.63 (t, $CH_2C\underline{H_2}OH$), 7.80 (d, J = 5.0 Hz, benzene-$\underline{H_7}$), 8.04 (dd, J = 10.0 Hz, benzene-$\underline{H_6}$), 8.17 (s, benzene-$\underline{H_4}$); ^{13}C NMR (125 MHz, D_2O): δ 10.64, 17.72, 28.07, 32.39, 47.09, 59.02, 112.18, 114.81, 126.38, 130.71, 133.63, 133.78, 159.91, 173.48; ESI-MS m/z calcd. for $[C_{14}H_{18}N_2O_3]^+$ 262.3; found $[M + H]^+$ 263.1.

6f

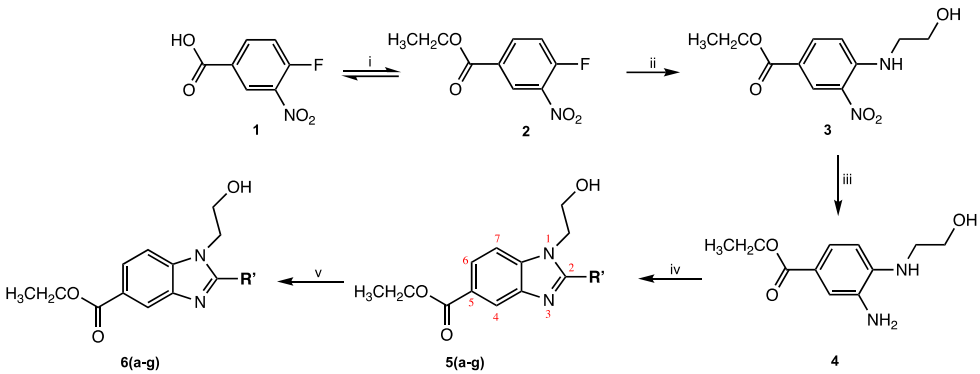
^{1}H NMR (500 MHz, D_2O): δ 0.77 (t, J = 5.0, 10.0 Hz, $CH(CH_2C\underline{H_3})_2$), 1.71–1.84 (m, $CH(C\underline{H_2}CH_3)_2$), 3.03 (m, $C\underline{H}(CH_2CH_3)_2$), 3.92 (t, J = 5.0 Hz, $C\underline{H_2}CH_2OH$), 4.42 (t, J = 5.0 Hz, $CH_2C\underline{H_2}OH$), 7.54 (d, J = 10.0 Hz, benzene-$\underline{H_7}$), 7.82 (d, J = 10.0 Hz, benzene-$\underline{H_6}$), 8.09 (s, benzene-$\underline{H_4}$); ^{13}C NMR (125 MHz, D_2O): δ 11.11, 27.37, 39.93, 45.50, 60.12, 110.08, 118.37, 123.58, 130.81, 136.72, 140.64, 161.89, 175.84; ESI-MS m/z calcd. for $[C_{15}H_{20}N_2O_3]^+$ 276.3; found $[M + H]^+$ 277.1.

6g

^{1}H NMR (500 MHz, D_2O): δ 2.10 (s, $SC\underline{H_3}$), 2.97 (t, J = 5.0, 10.0 Hz, $CH_2C\underline{H_2}SCH_3$), 3.13 (t, J = 5.0, 10.0 Hz, $C\underline{H_2}CH_2SCH_3$), 3.86 (t, J = 5.0 Hz, $C\underline{H_2}CH_2OH$), 4.21 (t, J = 5.0 Hz, $CH_2C\underline{H_2}OH$), 7.38 (d, J = 10.0 Hz, benzene-$\underline{H_7}$), 7.79 (dd, J = 10.0 Hz, benzene-$\underline{H_6}$), 8.07(s, benzene-$\underline{H_4}$); ^{13}C NMR (125 MHz, D_2O): δ 14.35, 26.60, 30.69, 45.70, 59.81, 109.81, 118.76, 123.80, 130.77, 136.66, 140.58, 156.24, 175.60; ESI-MS m/z calcd. for $[C_{13}H_{16}N_2O_3S]^+$ 280.3; found $[M + H]^+$ 281.1.

Molecular docking analysis

The structures were drawn and optimised into three-dimensional structures using Avogadro software [39]. Then, AutoDockTools (https://ccsb.scripps.edu/mgltools/) was employed to add non-polar hydrogens and merge them, define the atom types, and compute the Gasteiger charges. For the target protein, the NA protein structure (PDB ID: 3TI6) was retrieved from www.rcsb.org/pdb. Ligand, water, and ions were removed. Using AutoDockTools, polar hydrogen and Kollman charges were added before the file was saved in .pdbqt format. The size of grid points was set to 26, 30, and 40 with the grid centre to be 28.750, 14.639, and 19.556, for x-, y-, and z-coordinates, respectively. The spacing between points was set as default. Finally, Maestro 13.3 (Maestro, Schrödinger, LLC, New York, NY, 2021.) and PyMOL (PyMOL Molecular Graphics System, Version 2.0 Schodinger, LLC) were used to visualise the conformation of the best docking compounds.



Enzyme inhibition study

The NA inhibition assay protocol was taken from Potier et al. [40] and Blick et al. [41]. The assay was performed in triplicate in a 96-well microplate. Firstly, 2-(*N*-morpholino)ethanesulfonic acid (MES) buffer (25 µL) was added to well 2–12. Then, the benzimidazole derivative (50 µL) was placed in the first well, and serial dilution was performed by taking 25 µL of the drug from the first well. To the plate, NA H1N1 (25 µL) virus was mixed with the dissolved benzimidazole in each well, sealed with aluminium foil, and then incubated at 37 °C for 30 min. 2'-(4-methylumbelliferyl)-alpha-D-N-acetylneuraminic acid (MUNANA) working solution was prepared 5 min before the end of the incubation period. After 30 min, MUNANA (50 µL) was added to each well, and two positive controls were prepared by adding (25 µL NA + 50 µL MUNANA) and (50 µL NA + 50 µL MUNANA), and a blank with 50 µL MES buffer into each well separately before they were incubated again at 37 °C for another 1 h. A stop solution (100 µL) was added to each well to terminate the reaction, and the microplate was immediately inserted into the microplate reader to measure the fluorescence of absorbance. The wavelengths set for the fluorescence detection were 355 nm and 460 nm for excitation and emission, respectively.

Results and Discussion

Chemistry

The multi-step reactions to prepare alkyl benzimidazoles **5(a–g)** in conventional and microwave approaches are outlined in Scheme 1. The spectroscopic data for this series confirmed the synthesised structures with the appearance of the aliphatic substituent signals in ^{1}H NMR and the presence of quaternary carbon in ^{13}C NMR that correlates with cyclisation occurring at C-2 around 159 ppm.

Label	R'

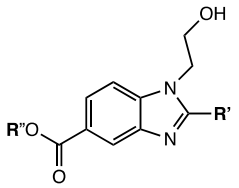

Scheme 1. Reagents and conditions: Conventional: (i) CH_3CH_2OH, H_2SO_4, 4–6 h, ~78 °C, 85%; (ii) $NH_2(CH_2)_2OH$, DIPEA, DCM, overnight, rt, 99%; (iii) Pd/C, NH_4HCO_2, ethanol, 1–2 h, 79–80 °C, 99%; (iv) K10-montmorillonite, MeCN, **R**'CHO, 4–5 h, 78–80 °C, 52–89%; (v) 4 N NaOH, THF, 2 M HCl, 4–6 h, 66–68 °C, 45–95%; Microwave: (i) CH_3CH_2OH, H_2SO_4, 15 min, 130 °C, 1–98%; (ii) $NH_2(CH_2)_2OH$, DIPEA, DCM, 2 min, 120 °C, 94%; (iii) Pd/C, NH_4HCO_2, ethanol, 2 min, 100 °C, 94%; (iv) K10-montmorillonite, MeCN, **R**'CHO, 5 min, 80 °C, 150 W, 5 bar, 29–66%; (v) 4 N NaOH, THF, 2 M HCl, 2–5 min, 120 °C, 59–90%. The numbering of the benzimidazoles is as indicated in **5(a–g)**

Due to the low solubility of the ester moieties in the buffer solution, the compounds were hydrolysed to carboxylic acids **6(a–g)** to increase their polarity. The disappearance of ester group signals in both ^1H and ^{13}C NMR spectra confirmed the formation of the products. Single crystals of **5c**, **5g**, and **6f** characterised by X-ray crystallography further confirmed their molecular structures [42-44]. The yield and duration for the preparation of the compounds from both conventional and microwave experiments are summarised in Table 1. Both techniques exhibited good to excellent conversions during esterification, S_NAr, reduction, and hydrolysis reactions, ranging from 59% to 94% for microwave and 45% to 99% for the conventional method. In contrast, during the cyclisation step, most of the compounds obtained gave low to moderate yields (23–69%), except **5f** (89%). However, there was a marked difference in terms of the duration needed to complete the reaction. In general, the reactions need 5–10 min under the microwave condition, although in some cases, the reactions can be performed in 2 min for the target compounds to yield almost similar results as under conventional conditions.

Neuraminidase inhibition assay

Benzimidazole carboxylic acid series **6(a–g)** were selected for bioassay analysis as the compounds showed good solubility in MES buffer. The NA inhibition assay was performed following the established protocols [39, 45]. One of the most potent NA inhibitors, 2,3-didehydro-2-deoxy-*N*-acetylneuraminic acid (DANA), was used as a control for comparison. Once cleaved by the NA, MUNANA substrate will release the fluorescent methylumbelliferone and will be detected by the fluorometric method. The intensity of fluorescence relates directly to the amount of NA activity. The NA inhibition results for **6(a–g)** series tested at a single concentration of 250 µg/mL are shown in Figure 1. Compound **6f** gave the best inhibition at 15.2%, while the remaining compounds were shown to give inhibition of less than 10%. The data demonstrated that branched alkyl moieties at the C-2 position, such as in **6f** and **6b**, are slightly more tolerable for the inhibitory activity. In contrast, different alkyl chain substituents (up to four carbons) at the C-2 position are not favourable even with the presence of sulphur, as observed in compounds **6a**, **6c**, **6d**, and **6g**. Compound **6e**, although also possesses branched alkyl substituent at the C-2 position, showed lower inhibition results than **6f** and **6b**. Unfortunately, we cannot provide a detailed explanation for this observation other than the unsymmetrical branched alkyl that may affect the inhibition towards the enzyme.

Table 1. Reaction time and yield of products of benzimidazole derivatives under microwave and conventional conditions

5 & **6**

Compound			Time		[a]Yield (%)

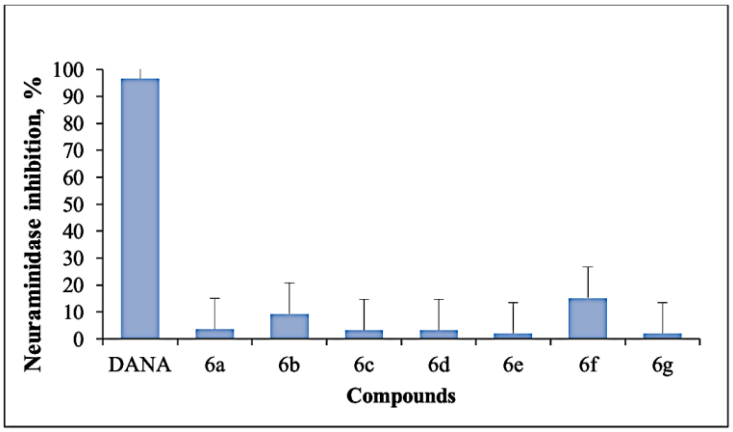

Figure 1. Percentage inhibition of **6(a–g)** analogues with DANA as a control at 250 µg/mL

Molecular docking

A molecular docking study was performed to gain a better understanding of how **6f** interacts in NA active sites at the molecular level. The NA crystal structure of 2009 H1N1 (PDB ID: 3TI6) with DANA as a reference was used in the study. The co-crystallised oseltamivir in the protein was removed and re-docked again into the NA active sites. Comparison between the co-crystallised and re-docked oseltamivir docking poses shows that the re-dock oseltamivir bound at the same location with the original ligand with slightly different conformation to give RMSD of 1.566 Å, suggesting the reliability of the docking algorithm in AutoDock VINA as the value is below the cut-off point 2.0 Å.

The NA active site of the 2009 pandemic H1N1 is unique from other N1-NA subtypes as it only consists of a sialic acid cavity and a 430-loop cavity with the absence of a 150-loop [39, 45]. In this study, DANA, which was used as a reference in the NA assay and docking study, gave the best docking energy of -6.1 kJ/mol, a slightly lower value than **6f** (-6.5 kJ/mol). Interestingly, the best docking pose of **6f** was found to bind at the 430-loop region, in contrast to DANA, which was found to bind at the sialic acid active site (Figure 2a). Further analysis on the 2D-ligand interaction between **6f** and DANA with 3TI6 was evaluated using Maestro (Schrödinger Release 2022-3, 2021).

Figure 2b(i) shows that there are nine amino acid residues take place in the binding interactions of **6f** in the 430-cavity with one hydrogen bond interaction between the carboxylic acid moiety and SER404. The remaining interactions are mostly hydrophobic interactions with ASN347, ARG371, ASN 372, ILE427, TRP403, LYS432, PRO431, ILE149, and ARG118 residues. The 3-pentanyl moiety of **6f** was found to interact with the ILE149 residues, suggesting that this type of branch alkyl group forms favourable hydrophobic interactions compared to other substituents in the carboxylic acid series. Meanwhile, DANA, which prefers to sit in the sialic acid cavity, also has one hydrogen bond interaction with THR225, while the remaining residues mainly form hydrophobic interactions. Although hydrophobic interaction is not as strong as hydrogen bonds, it can affect the docking free energy between ligand and enzyme. However, the presence of carboxylic acid group, especially for NA inhibitors, is crucial as it forms a strong hydrogen bond between the polar and charged residues of arginine with the oxygen atoms, which could give partial stability to the overall binding [46].

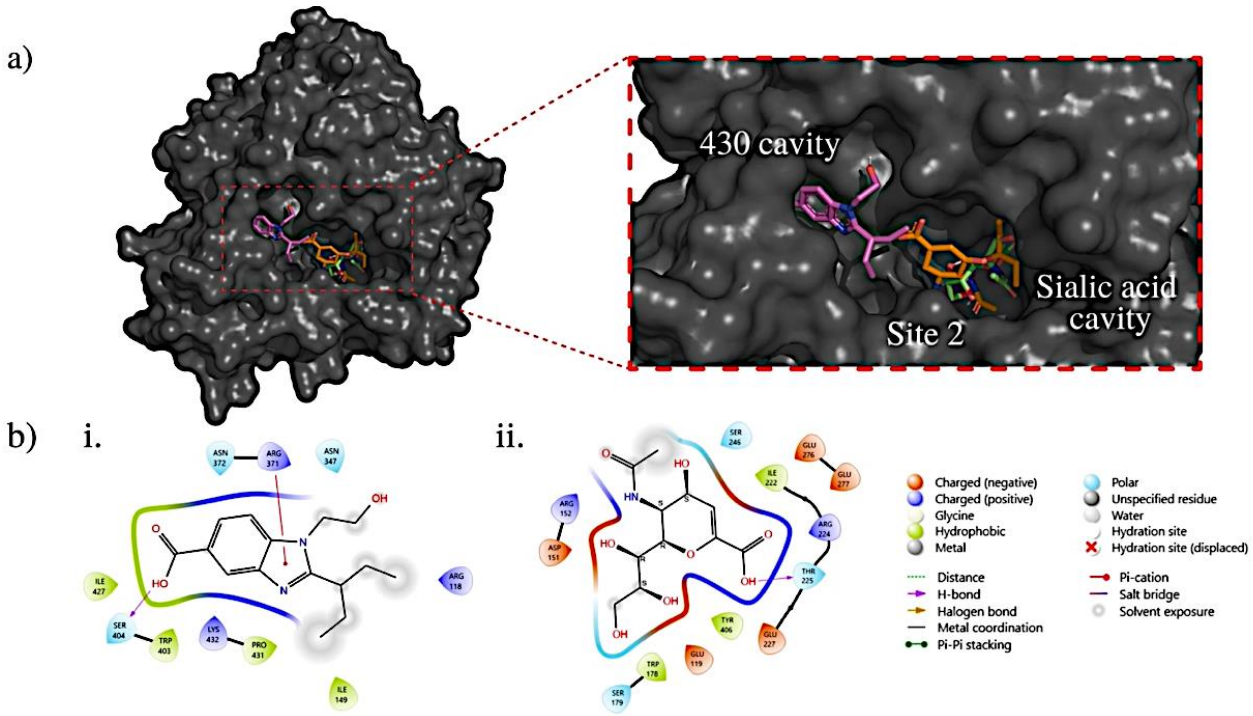

Figure 2. a) Best score docking poses of **6f** (yellow) in the 430-cavity in relation to the original ligand in the crystal structure (oseltamivir-orange) at site 2 and DANA (green) in the sialic acid region and b) the 2D-ligand interaction of i) **6f** and ii) DANA calculated in 4 Å distances from H1N1-NA (PDB ID: 3TI6) residue

Conclusion

In the present study, two series of benzimidazole analogues **5(a–g)** and **6(a–f)** were synthesised with good to excellent yields using both microwave and conventional methods. Microwave reaction was more effective than the conventional method as it can speed up the reaction time, although the yields obtained were generally slightly lower than those obtained by the conventional method. Compound **6f** was found to give the highest NA inhibition activity with 15.2% at 250 µg/mL, while others gave less than 10% inhibition. It is interesting to note that the molecular docking analysis revealed **6f** to bind at the 430-cavity of the NA active site, in contrast to DANA, which is at the sialic acid site, and oseltamivir at site 2. Despite the low inhibition data, the results show that benzimidazoles have the potential to be developed as NA inhibitors. Subsequent structural improvements of the benzimidazole scaffold could be designed towards more effective NA inhibitors.

Abstract

The synthesis of metal oxide nanoparticles with the use of plant extract is a promising alternative to chemical synthesis methods. In the study, magnesium oxide nanoparticles (MgO-NPs) were synthesized by using *Musa acuminata* Cavendish banana peel extract solution. The precursor materials used were $Mg(NO_3)_2.6H_2O$ and dried Cavendish banana peel extract solution. Different concentration of $Mg(NO_3)_2.6H_2O$, different volume of extract solution, and different calcination temperature were used to conduct this study. The green synthesized MgO-NPs were characterized by thermogravimetric analysis (TGA), Fourier transform infrared (FTIR) spectroscopy, ultraviolet-visible (UV-Vis) spectroscopy, scanning electron microscopy (SEM) and x-ray diffraction (XRD). The FTIR spectra showed O-H stretch at 3,340 cm^{-1} (peel extract solution), 3,308 cm^{-1}/3,348 cm^{-1} (pre-calcine sample), and 3,086.11 cm^{-1}/3,194.12 cm^{-1} (calcined at 600 °C). The spectra also showed Mg-O stretching at 655.80 cm^{-1} and 594.08 cm^{-1} for pre-calcine and calcined samples, respectively. The wavelength of UV-Vis obtained for 4 sets of green synthesis was around 265 nm due to the surface plasmon resonance band. Thus, confirmed the formation of MgO-NPs. SEM images of MgO-NPs samples showed a mixture of non-uniform sizes and shapes that were agglomerated with average size range of about 90 nm to 320 nm. XRD diffraction analyses displayed the MgO-NPs as a cubic structure.

Keywords: green synthesis, magnesium oxide nanoparticles, *Musa acuminata*, sustainable materials

Abstrak

Sintesis nanopartikel logam oksida dengan menggunakan ekstrak tumbuhan dapat menjanjikan kaedah alternatif kepada sintesis kimia. Dalam kajian ini, nanopartikel magnesium oksida (MgO-NPs) telah disintesis menggunakan larutan ekstrak kulit pisang *Musa acuminata* Cavendish. Bahan prekursor yang digunakan ialah magnesium nitrat heksahidrat ($Mg(NO_3)_2.6H_2O$) dan larutan ekstrak kulit pisang Cavendish yang kering. Kepekatan $Mg(NO_3)_2.6H_2O$, isipadu larutan ekstrak, dan suhu pengkalsinan yang berbeza telah digunakan untuk menjalankan kajian ini. MgO-NPs yang disintesis hijau dicirikan oleh Analisis Termogravimetrik (TGA), Spektroskopi Infra Merah Transformasi Fourier (FTIR), Spektroskopi Ultraviolet-Visible (UV-Vis), Mikroskop Imbasan

Elektron (SEM) dan Pembelauan Sinar-X (XRD). Spektra FTIR telah menunjukkan kewujudan regangan O-H pada 3,340 cm^{-1} (larutan ekstrak), 3,308 cm^{-1}/ 3,348 cm^{-1} (sampel sebelum proses kalsin) dan 3,086.11 cm^{-1}/3,194.12 cm^{-1} (MgO-NPs dikalsinkan pada 600 °C). Spektra FTIR juga menunjukkan regangan Mg-O pada 655.80 cm^{-1} dan 594.08 cm^{-1} untuk sampel sebelum dan selepas proses pengkalsinan. Panjang gelombang UV-Vis bagi keempat-empat set adalah pada 265 nm adalah disebabkan oleh jalur resonans plasmon permukaan yang membuktikan pembentukan MgO-NPs. Imej SEM menunjukkan campuran bentuk dan saiz tidak sekata yang teraglomerat dengan anggaran purata saiz sekitar 90 nm hingga 320 nm. Analisis XRD memperlihatkan MgO-NPs sebagai struktur kubik.

Kata kunci: sintesis hijau, nanopartikel magnesium oksida, *Musa acuminata*, bahan lestari

Introduction

Green chemistry has first been introduced in the America's Pollution Prevention Act of 1990 aiming to reducing pollution at its sources and producing less costly chemical products [1]. According to Murcia et al., there are 12 principles of green chemistry which are waste prevention, atom economy, less hazardous chemical synthesis, designing safer chemicals, safer solvents and auxiliaries, use of renewable feedstocks, reduce derivatives, catalysis, design for degradation, real time pollution prevention, design for energy efficiency and safer chemistry for accident prevention [2]. In synthetic chemistry, green synthesis of nanoparticles, a single-step pollution-free synthesis method [3,4] has been reported to fulfil at least five principles of green chemistry, such as waste prevention, reduce derivatives, safer solvent and auxiliaries, renewable feedstocks and less hazardous chemical synthesis [5]. This production approach is not only environmentally friendly but they are also cost-efficient as well as less toxic [6]. Green synthesis of nanoparticles which employs extracts, such as microorganisms and plant parts like leaves, fruits, and seeds [7] as a reducing and capping agent is a great alternative to the expensive physicochemical methods which poses environmental and biological threat due to the usage of toxic organic solvent and hazardous reagents [8]. Farani et al. has remarked that these natural resources contain biomolecules, polysaccharides, phenolics, vitamins and amino acids which give reducing agent properties to them [9]. Phytochemicals such as terpenoids, aldehyde, carboxylic acids and amides also contribute in the reduction and stabilization [5].

The green synthesis method is broadly used as an alternative to the chemical synthesis method in synthesizing nanoparticles [10]. In the synthesis of magnesium oxide nanoparticle (MgO-NPs), plants extract such as *Embilica officinalis* [11], Neem plant [12], Aloe vera [13] and *Trachyspermum ammi* [14] have been used in the green synthesis as this route replaces the usual conventional physicochemical techniques, such as the sol-gel method, chemical precipitation, and hydrothermal [15]. Fruit waste extract *Nepehelium lappaceum* L peels [16] *Persimmon* peels and *Citrus aurantium* peels have also been used to synthesize MgO-NPs [17, 18]. Although green synthesis of metal oxide nanoparticles by using fruit waste extracts has been extensively studied, the study on biological synthesis specifically for MgO-NPs has not been done widely [19]. The exploration of resources of potential reducing agent is necessary to ensure the efficiency of green synthesis [5].

Magnesium oxide nanoparticles (MgO-NPs) are known to exhibit the ability to withstand extreme conditions and high biocompatibility [20]. MgO-NPs have received a lot of interests for their variety kind of applications [21]. It has been found that MgO-NPs has higher surface to volume ratio and higher surface energy as compared to bulk MgO due to its small particles size [22]. They are evidenced to be great refractory and superconducting materials as they possess good optical and magnetic properties [22]. In biomedicine, MgO-NPs are applied for bone regeneration, relief of heartburns as well as antitumor [23]. They are also known as nontoxic antibacterial agents that is relatively easy to be obtained among all the metal oxide nanoparticles [24]. The properties of the nanoparticles are depending on the size and geometrical structure of the nanoparticles [25]. Therefore, the optimization of reaction conditions, such as volume of extract use, pH value, temperature of reaction, temperature of calcination and volume of starting materials is crucial as these conditions affect the

size, shape, form and stability of the nanoparticles produced [26], tailoring the properties of nanoparticles to suit different desired applications.

In this study, *Musa acuminata* or cavendish banana peel extract was used as reducing and capping agent. Phytochemical tests conducted in previous research showed the presence of secondary metabolite compounds, including alkaloids, flavonoids, saponins, and polyphenols in banana peel extract [27] making it suitable as reducing and capping agent. Previous studies have reported the usage of banana peel extract as a capping agent in the production of metal nanoparticles [28]. Banana peel utilization in the synthesis of ZnO-NPs have also been reported [27,29,30,31,32]. Abdullah et al. [30] in their comparative study of green and chemical synthesis by using cavendish banana peel in the synthesis of zinc oxide nanoparticles (ZnO-NPs) have noted that green synthesized ZnO-NPs exhibited higher crystallinity and smaller particle size. The green synthesized nanoparticles also showed high photocatalytic activity comparable to their chemically synthesized counterpart. On this note, green approach is proven compatible to that of chemical approach [30]. The optimization of metal oxide synthesis by using cavendish banana peel has been done as well [29].

While the usage of this peel in metal oxide synthesis has been explored, especially through ZnO-NPs production, the research using banana peel extract are still very limited for MgO-NPs, especially the optimization of synthesis conditions. The study using banana peel extract as reducing agent in the synthesis of MgO-NPs will further explore its potential in metal oxide nanoparticles synthesis. The optimization of conditions by using two different methods with different volume of extracts, different volume of starting materials and different concentration of starting materials were done in this study. MgO-NPs were also produced by calcination with two different temperatures. The study utilizing these parameters is important as they have major impact on the morphology and the biological applications of the nanoparticles produced. Different volume of extracts, mainly determines the yield of nanoparticles [26]. This approach differed from previous study, whereby each parameter was studied while the others were kept constant [33]. Instead of focusing on the effect of one parameter at a time on the nanoparticles, this study focused on the effect of four parameters concurrently on the nanoparticles. The produced MgO-NPs were characterized by using thermogravimetric analysis (TGA), Fourier transform infrared (FTIR) spectroscopy, ultraviolet-visible (UV-Vis) spectroscopy, scanning electron microscopy (SEM) and X-ray Diffraction (XRD) to further understand the effects of parameters on the size, surface morphology and crystallite structure of MgO-NPs.

Other than that, the utilization of the peel which contributes to a major agriculture waste [34] allows the researchers to harness renewable feedstocks as well as preventing waste and derivatives that align with the principles of green chemistry. By using banana peel as reducing agent, the researchers manage to provide safer chemicals and solvents which is better to the people and environment. In the synthesis methods, low temperature and short reaction time were operated allowing efficient energy consumption and high feasibility. Hence, the usage of banana peels extract is considered environmentally, socially and economically sustainable, making it a ‘green’ approach.

Materials and Methods

Materials

Magnesium nitrate hexahydrate ($Mg(NO_3)_2$) were purchased from Sigma Aldrich and used without further purification. *Musa acuminata* Cavendish bananas were brought from local supermarket in Petaling Jaya, Selangor. Distilled water was used to prepare all the solutions and Whatman No. 1 filter paper was used to filter MgO-NPs solution.

Synthesis of magnesium oxide nanoparticles (MgO-NPs): Preparation of banana peel extract

The *Musa acuminata* Cavendish banana peels were rinsed thoroughly with distilled water and cut into smaller pieces. The peels were oven dried at 150 ºC for 4 h and ground into powder. A total of 20 g powdered banana peel was added in a beaker with 200 mL of distilled water. The mixture was heated at 70 ºC–80 ºC for 1 h and filtered with filter paper. Excess extract solution was kept in the refrigerator (maximum 24 h).

Phytochemical tests of banana peel extract

To investigate the compounds presence in the banana peel extract, several phytochemical tests were carried out. This included saponin test, alkaloid test, tannin test, phenol test, flavonoid test, terpenoid test, and glycoside test. Table 1 shows a list of methods for each test. Each test was performed at least three times and only tests which appeared positive in two or more tests were considered to confirm the presence of the active compounds in banana peel extract.

Table 1. Phytochemical tests methods.

Tests	Methods
Saponin Test	1 mL of peel extract solution was added with 2 mL of distilled water in a test tube. The solution was shaken vigorously and was observed for a stable persistent froth for 10 min.
Wagner's Test	0.5 mL of peel extract solution were treated with a few drops of Wagner's reagent (iodine in potassium iodide). The colour changes were observed, and a brown precipitate formed to indicates the presence of alkaloid.
Mayer's Test	0.5 mL of peel extract solution was treated with a few drops of Mayer's reagent (potassium mercuric iodide). A yellow cream precipitate formed to indicates the presence of alkaloid.
Tannin Test	0.5 mL of peel extract solution was added with 1 to 2 drops of 10% iron (III) chloride solution. A dark green or blue-green coloration indicates the presence of tannins.
Phenol Test	0.5 mL of peel extract solution was put into test tube was added followed with 2 to 3 drops of 10% iron (III) chloride solution. The presence of green or blue colour indicates the presence of phenolic compound.
Flavonoid Test	0.5 mL of peel extract solution was treated with few drops of concentrated sulphuric acid. The colour changes were observed, and a formation of orange colour indicates the presence of flavonoid.
Salkowski Test	0.5 mL of peel extract solution was added with 2 mL of chloroform followed by 3 mL concentrated H_2SO_4 carefully to form a layer. Terpenoids are present if a reddish-brown colouration is observed.
Liebermann's Test	3 mL of peel extract solution was added with 2 mL of $CHCl_3$ and 2 mL of CH_3COOH. A blue colour solution changes into green colour indicated the presence of glycosides.

Green synthesis of magnesium oxide nanoparticles (MgO-NPs)

MgO-NPs were synthesized with two different set of conditions, (A) 30 mL peel extract with 150 mL $Mg(NO_3)_2$ (0.05 M) aqueous solution; (B) 25 mL peel extract with 200 mL $Mg(NO_3)_2$ (0.10 M) aqueous solution. An amount 30 mL of banana peel extract was added to 150 mL of $Mg(NO_3)_2$ (0.05 M) aqueous solution. The reaction mixture was stirred at a constant temperature of 80 °C by using a magnetic stirrer hot plate for 2 h. Color changes were noted for the reaction mixture as it indicates the formation of precipitate.

After the 2 h of constant stirring and heating, the mixture was cooled down to room temperature. The cooled mixture was centrifuged at 8,000 rpm for 20 min. The mixture was filtered and oven dried at 80 °C overnight. The fully dried precipitate was ground with mortar and pestle.

Thermogravimetric analysis (TGA) was conducted prior to calcination to determine the suitable calcination temperature. To obtain the final product, MgO-NPs, the ground samples from previous step were calcined in the furnace at the suitable temperatures for 5 h. The procedure was repeated with Condition B.

Characterization of magnesium oxide nanoparticles (MgO-NPs): Thermogravimetric analysis (TGA)

Perkin Elmer Pyris 6 TGA thermogravimetric analyzer was used to quantitatively monitor the weight change in the sample as a function of temperature. About 5 mg of pre-calcine MgO-NPs were weighed and used on each analysis to avoid any influence of sample quantity in the analysis. The analyses were performed in the presence of nitrogen gas with a constant flow rate of 20 mL min^{-1} throughout the process. The analyses were conducted within temperature range of 30 °C to 900 °C at a ramping rate of 10 °C min^{-1}. The TGA graph were obtained after the analyses.

Fourier transformation infrared (FTIR) spectroscopy

The FTIR analyses were performed by using Shimadzu model IRTracer-100 spectrophotometer in the range of 400 cm^{-1} to 4,000 cm^{-1} with the attenuated total reflectance (ATR) technique. The diamond on the sample platform was cleaned with acetone by using lens paper. A background scan without any sample on the diamond was done. A small amount (about 5 mg) of pre-calcine MgO-NPs were placed on the diamond until it was fully covered for each analysis. The pressure arm was placed into position and locked over the diamond filled with sample. Force was applied on the sample, pushing it onto the diamond surface. Finally, the sample was analyzed with the software and the FTIR spectra were obtained.

Ultraviolet-Visible (UV-Vis) spectroscopy

Shimadzu UV–Visible spectrophotometer model UV-1800 was utilized for the characterization of MgO-NPs. The baseline was set with the blank. The reference cuvette and measurement cuvette were filled with distilled water. The cuvettes were placed and aligned properly in the spectrometer. After setting the baseline, the measurement cuvette was removed and rinsed twice before filling with sample. The cuvette was ensured that it was clear from fingerprints and placed into the spectrometer for analysis. The wavelength range of the analyses were set to be within 200 nm to 800 nm with a resolution of 1 nm. The absorbance spectra were collected after the analyses.

Scanning electron microscopy (SEM)

The morphology of MgO-NPs samples was analyzed from the images generated from the TESCAN VEGA scanning electron microscope. To prepare the samples, double-sided carbon adhesives were applied onto the SEM stubs and the protective films were removed.

Then, the MgO-NPs samples were placed on the adhesives and coated them with gold (Au) by using the gold sputtering machine. The coated samples (on the stubs) were loaded onto the sample stage in the SEM chamber. Then, suitable spots for desired structure or morphology of MgO-NPs were located and the SEM images were captured at 4 magnifications, 5kx, 10kx, 15kx, 20kx.

X-ray diffraction (XRD)

To identify phases and patterns of MgO-NPs, XRD analyses were conducted by using Rigaku Miniflex II diffractometer (30 kV, 15 mA) with Cu K-α radiation (1.5418 Å) with a Bragg's angles, 2θ range of 20° to 80° with a scan rate of 2°/min.

The MgO-NPs samples were ground by using agate mortar and pestle to produce a uniform fine powder. The samples were placed onto a glass sample holder with a square hollow-ground side. The excess samples were cleared by sliding across the sample holder with a glass plate. Then, the surface of the samples was smoothed with the back of the glass plate. Any excess samples on the glass sample holder (around hollow-ground side) were wiped off. The sample holder was carefully

inserted onto the sample holder slot, ensuring no sample spills for the XRD analyses.

Results and Discussion

Several phytochemical tests were conducted on the Cavendish banana peel extract solution to confirm the bioactive compounds and the functional groups responsible for the reduction and capping of MgO-NPs. Table 2 shows that alkaloid, tannin, phenol, flavonoid, and terpenoid were present in banana peel extract solution.

The phytochemical tests were carried out in triplicate and labelled as 1, 2, and 3 for each compound to confirm the consistency and accuracy of the results. The presence of the compound of interest in the peel extract solution will only be considered if two or more positive results were obtained from the tests. The findings were mostly similar to previous studies [27, 35], however with a slight difference. In their studies, saponin and glycoside were present in banana peel extract solution while it was not present in this study. The different outcomes could be due to the drying condition of the banana peels [36].

Table 2. Phytochemical test results of Cavendish banana peel extract solution

	Tests	1	2	3

Thermogravimetric analysis (TGA)

Thermogravimetric analyses were carried out to determine the suitable temperature for calcination of the green synthesized MgO-NPs [37]. Figure 1 shows the thermogravimetric graph of two pre-calcined samples with two different sets of volume and concentration of starting materials. Based on Figure 1, the initial stage of weight loss below 100 °C was due to the evaporation of moisture and other volatile compounds [38], whereas the weight loss started at below 550 °C was due to the decomposition of the phytochemical compounds in peel extract and other organic compounds [37,39].

TGA curve for the MgO samples showed that weight loss of almost 87% from 30 °C had occurred continuously up to 600 °C as the graph showed almost a plateau thereafter. This indicated that MgO-NPs synthesized by using Method A and Method B were thermally almost stable starting at 600 °C and continuing up to the maximum temperature of 900 °C [39]. From this information, the green synthesized pre-calcine samples were subjected to calcination at 600 °C and 800 °C. It can be concluded that the formation of MgO synthesized with both Condition A and Condition B took place with heating at more than 600 °C.

Fourier transformation infrared (FTIR) spectroscopy

FTIR results were obtained for MgO-NPs synthesized with Condition A are shown in Figure 2, the broad peak centered at (a) 3340.71 cm^{-1}, (b) 3308.85 cm^{-1}, and (c) 3086.11 cm^{-1} were due to the stretching vibration of O-H group [38,39]. The presence of O-H groups is supported by the absorption peak at (a) 1635.64 cm^{-1} and (b) 1620.21 cm^{-1}, which corresponded to the bending mode of O-H bond [18].

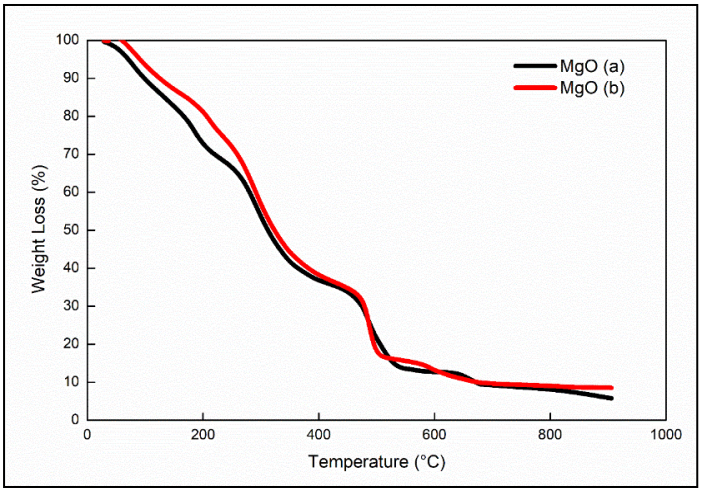

Figure 1. TGA graph of pre-calcine sample synthesised with (a) condition a (b) condition b before calcination.

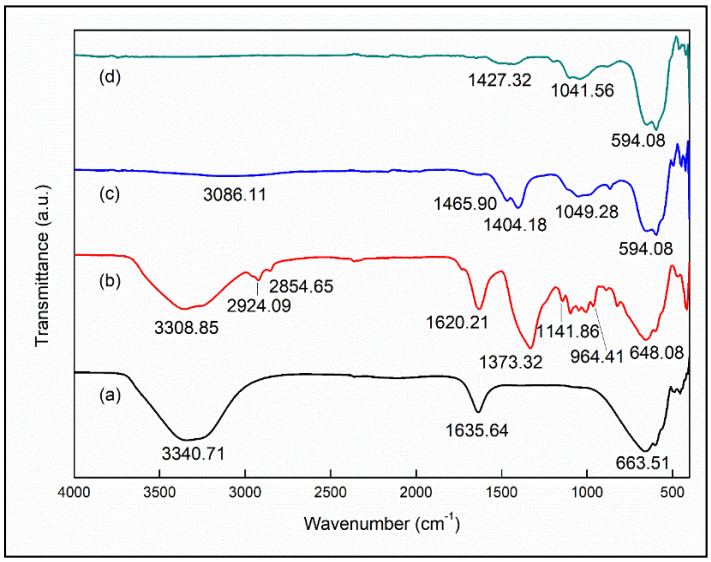

Figure 2. FTIR Spectra of MgO (Condition A): (a) banana peel extract solution (b) before calcine; (c) calcined at 600 °C; (d) calcined at 800 °C

The O-H groups located around 1630 cm^{-1} could be from the hydroxyl groups of the phytochemical compounds in the peel extract that were involved in the capping reaction [39]. Overall based on Figure 2 (b), Figure 2 (c) and Figure 2 (d), both O-H peaks became narrower and eventually disappeared with increasing calcination temperature as elimination of water molecules in the samples increased [40].

Other than O-H stretching, the broad peak centered at (a) 3340.71 cm^{-1} could also be the stretching vibration of N-H groups, which is a feature of phenolic compounds, such as glycosides, tannins, and flavonoids [41]. This finding agreed with the phytochemical test result conducted. Moreover, the two small absorption peaks at 2924.09 cm^{-1} and 2854.65 cm^{-1} shown in Figure 2 (b) represented the C-H stretching vibration in CH_2 groups which could be due to the phytochemical compounds [42]. The peaks slowly became indistinguishable as the calcination temperature increased. This meant that the capping reaction with phytochemical compounds had occurred [43].

The absorption peak at (b) 1373.32 cm^{-1} represented the C-H bending vibration. Whereas the peaks at (c)1404.18 cm^{-1} to 1465.90 cm^{-1} and (d) 1427.32 cm^{-1} were assigned to Mg-H which indicated the formation of hydride ion [44]. Besides, absorption peaks located between (b) 964.41 cm^{-1}, and 1141.86 cm^{-1} were most likely attributed to C-O and C-O-C diagnostic bonds [42]. The peaks at 2924.09 cm^{-1} and 1141.86 cm^{-1} in Figure 2 (b) proved the presence of polysaccharides, polyphenols and proteins [38] as the peaks corresponded to the functional groups contained in those phytochemicals in the pre-calcined MgO-NPs. The peaks became narrower when the samples were calcined, indicating that possibly the phytochemicals had undergone capping reaction.

The appearance of extra peaks at 3086.11 cm^{-1}, 1465.90 cm^{-1}, 1404.18 cm^{-1}, 1049.28 cm^{-1} and (d) 1427.32 cm^{-1}, 1041.56 cm^{-1} might be due to: (1) formation of crystalline inorganic compounds present in the peel extract during the calcination process; and (2) strong bonds that stabilized the formation of MgO-NPs after the decomposition of phytochemicals which remained over the surface of MgO-NPs [41]. The broad absorption peaks at (b) 648.08 cm^{-1} and (c, d) 594.08 cm^{-1} from all FTIR spectra obtained for green synthesized MgO-NPs with Condition A, indicated the stretching vibration mode for the Mg-O compound group [39]. The summary band assignment is shown in Table 3.

Table 3. Band assignment of peel extract and MgO-NPs (Condition A)

Band Assignment	**Wavenumber (cm^{-1})**			
	Banana Peel Extract	**Before Calcine**	**Calcined (600 °C)**	**Calcined (800 °C)**
O-H stretch	3340.71	3308.85	3086.11	-
N-H stretch	3340.71	-	-	-
C-H stretch	-	2924.09 & 2854.65	-	-
O-H bend	1635.64	1620.21	-	-
C-H bend	-	1373.32	-	-
Mg-H	-	-	1404.18 & 1465.90	1427.32
C-O	-	1141.86	-	-
C-O-C	-	964.41	-	-
Mg-O	-	648.08	594.08	594.08

Similar FTIR results were obtained for MgO-NPs synthesized with Condition B, as shown in Figure 3. The broad peak centered at (a) 3340.71 cm^{-1}, (b) 3348.42 cm^{-1}, and (c) ,194.12 cm^{-1} were due to the O-H stretch [18]. Also, the absorption peaks at (a) 1635.64 cm^{-1} and (b) 1,627.92 cm^{-1}, which corresponded to the bending mode of O-H bonds which came from the hydroxyl groups of the phytochemicals of peel extract solution that were involved in the capping reaction [18,39].

Similarly, based on Figure 3 (b), Figure 3 (c) and Figure 3 (d), both O-H peaks became narrower and eventually disappeared with increasing calcination temperature when more water molecules were evaporated [40]. As mentioned, the broad peak centered at (a) 3340.71 cm^{-1} could also be the stretching vibration of N-H groups other than O-H groups. N-H groups are a feature of phenolic compounds, such as glycosides, tannins, and flavonoids [41] which agrees with the phytochemical test results of the extract.

Furthermore, the two small absorption peaks observed in Figure 3 (b) at 2924.09 cm^{-1} and 2851.49 cm^{-1} represented the C-H stretching vibration in CH_2 groups. This could be attributed to the phytochemical compounds [42]. As the calcination temperature increased, the peaks became increasingly indistinguishable. This indicated that the phytochemical compound capping reaction had taken place.

The C-H bending vibration is represented by the absorption peak at (b) 1334.74 cm^{-1}. The peaks at (c)

1411.89 cm^{-1} – 1473.62 cm^{-1} were attributed to Mg-H indicating the presence of hydride ion [44]. Besides, C-O and C-O-C diagnostic bonds were most likely responsible for absorption peaks between (b) 964.41 cm^{-1}, and 1141.86 cm^{-1} [42]. When the samples were calcined, the peaks narrowed, indicating that the phytochemicals had undergone a capping reaction.

The extra peaks that appeared at 3194.12 cm^{-1}, 1473.62 cm^{-1}, 1411.80 cm^{-1}, 1056.99 cm^{-1} and (d) 1049.28 cm^{-1} could be because of: (1) the formation of crystalline inorganic compounds present in the extract solution during the calcination process; and (2) strong bonds that stabilized the formation of MgO-NPs after the degradation of phytochemicals which remained over the surface of MgO-NPs [41].

Based on all the FTIR spectra obtained for green synthesized MgO-NPs with Condition B, the broad absorption peaks at (b) 655.80 cm^{-1} and (c, d) 594.08 cm^{-1} indicated the stretching vibration mode for the Mg-O compound group [39] which confirmed the production of MgO. The summary band assignment is shown in Table 4.

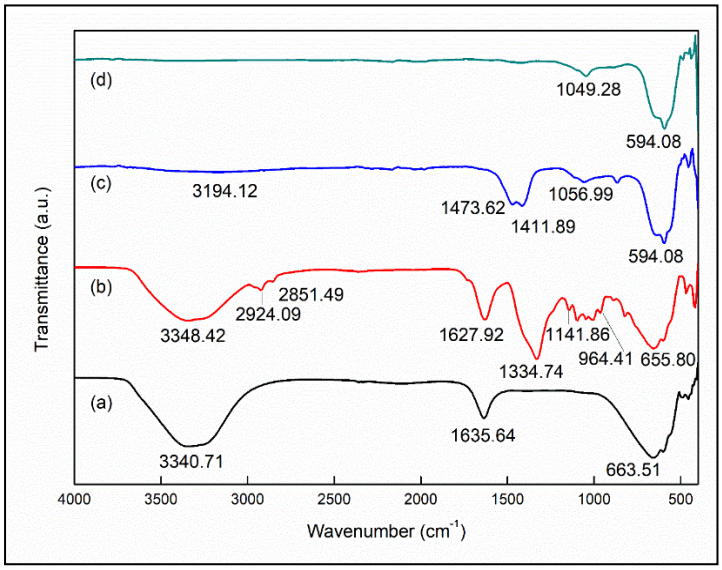

Figure 3. FTIR Spectra of MgO (Condition B): (a) banana peel extract solution (b) before calcine; (c) calcined at 600 °C; (d) calcined at 800 °C

Table 4. Band assignment of peel extract and MgO-NPs (Condition B)

Band Assignment	**Wavenumber (cm^{-1})**

Ultraviolet-Visible (UV-Vis) Spectroscopy

The synthesis of MgO-NPs was confirmed by the appearance of a maximum surface plasmon resonance (SPR) detected by UV-Vis spectroscopy. SPR located at different wavelengths can affect the shape, size and well distribution of green synthesized NPs [45].

The size of MgO-NPs produced through green synthesis tended to be small when the SPR band is located at wavelength lesser than 300 nm. However, the absorption peak shifted to larger wavelength (red-shift) with increasing particle size [46]. As shown in Figure 4, the absorption of the MgO-NPs synthesized with Condition A, calcined at 600 °C and 800 °C showed wavelengths at 264.50 nm and 265.50 nm, respectively. On the other hand, the absorption band of MgO-NPs formed with Condition B (Figure 5) was located at wavelength 264 nm for both calcination temperatures (600 °C and 800 °C).

According to previous studies, the absorption of UV-Vis spectrum of MgO-NPs was reported between 260 nm–300 nm [18, 39, 42, 47, 48]. Therefore, the absorption peak of MgO-NPs obtained with both conditions were within the accepted wavelength range. This meant that, the change in concentration of $Mg(NO_3)_2.6H_2O$ and volume of extract solution did not have a significant effect on the formation of MgO-NPs. However, MgO-NPs calcined at 800 ℃ showed a higher absorbance value indicating more yield of MgO-NPs [33]. This was due to the faster rate of crystal growth at higher temperature as thermal energy increased [49].

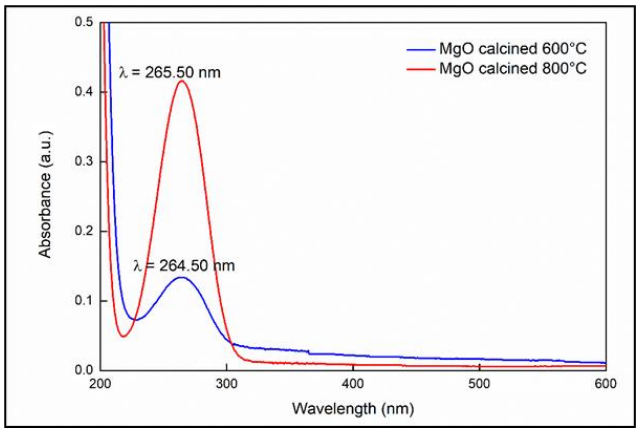

Figure 4. UV-Vis spectra of MgO-NPs (Condition A) calcined at 600 and 800 °C

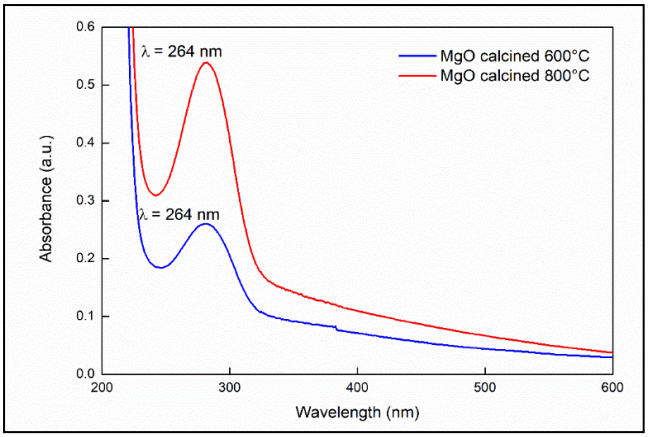

Figure 5. UV-Vis spectra of MgO-NPs (Condition B) calcined at 600 and 800 °C

Scanning electron microscope (SEM)

The morphology of the MgO-NPs is presented in Figure 6, Figure 7, Figure 8, and Figure 9. In general, the average particle size for MgO-NPs synthesized with Condition A and Condition B with different calcination temperatures varies.The products of green synthesis with Condition A, calcined at 600 °C and 800 °C, as well as products formed with Condition B, calcined at 600 °C were not within the nanoparticles size range. Whereas, the MgO-NPs produced with Condition B and calcined at 800 °C was within the nanoparticle size range of 1 nm – 100 nm [50]. The bigger particle size for MgO-NPs calcined was due to secondary phase, $Mg(OH)_2$, present in the MgO lattice causing it to be less crystalline [49]. This finding contradicts other study which stated that higher calcination temperature increases the particle size. However, the study only studied the effect of calcination temperature while other conditions were kept constant [51].

Based on previous studies, the concentration and amount of extract used, reaction temperature, and pH value could affect the variable parameters, such as size, shape, and agglomeration [52, 53]. Figure 6 shows the SEM images of MgO-NPs synthesized with Condition A with calcination temperature of 600 °C. The particles had non uniform shape with an average size of 316.78 nm, the smallest particle was about 107 nm while the largest particle was about 550 nm with some degree of agglomeration.

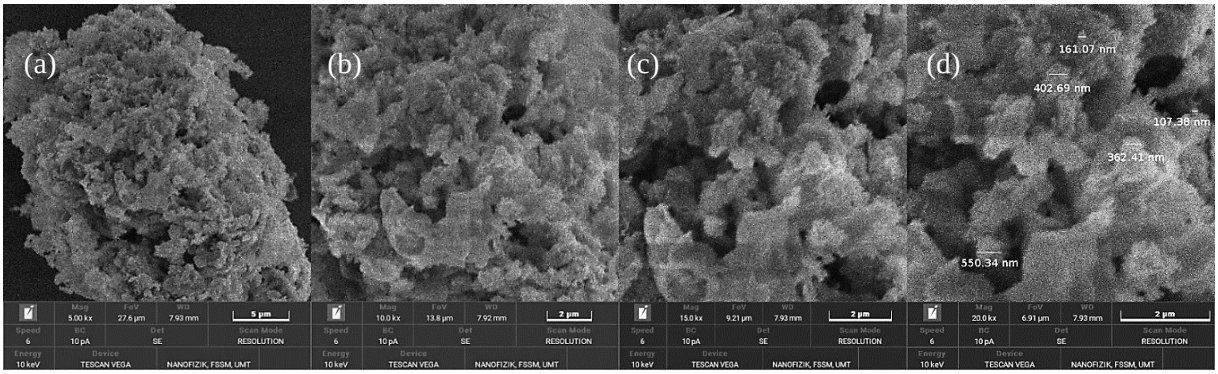

Figure 6. SEM images of MgO-NPs (Condition A) calcined at 600°C; at (a) 5,000x, (b) 10,000x, (c) 15,000x, and (d) 20,000x magnification

As shown in Figure 7, the particles synthesized with Condition A and calcined at 800 °C also had a non-uniform shape with an average size of 140.52 nm. The smallest particle was about 62 nm while the largest particle was about 255 nm with some degree of agglomeration as well.

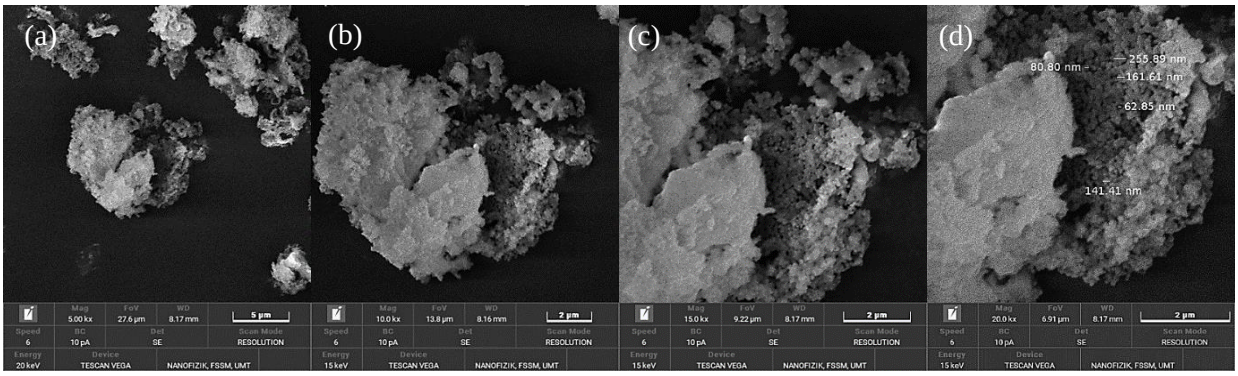

Figure 7. SEM images of MgO-NPs (Condition A) calcined at 800 °C; at (a) 5,000x, (b) 10,000x, (c) 15,000x, and (d) 20,000x magnification

Furthermore, Figure 8 shows the SEM images of synthesized MgO-NPs with Condition B and calcined at 600 °C. Most of the particles had irregular shapes with a mean particle size of 208.31 nm. The smallest particle was around 148 nm, and the biggest particle was about 255 nm. Some degree of agglomeration was observed.

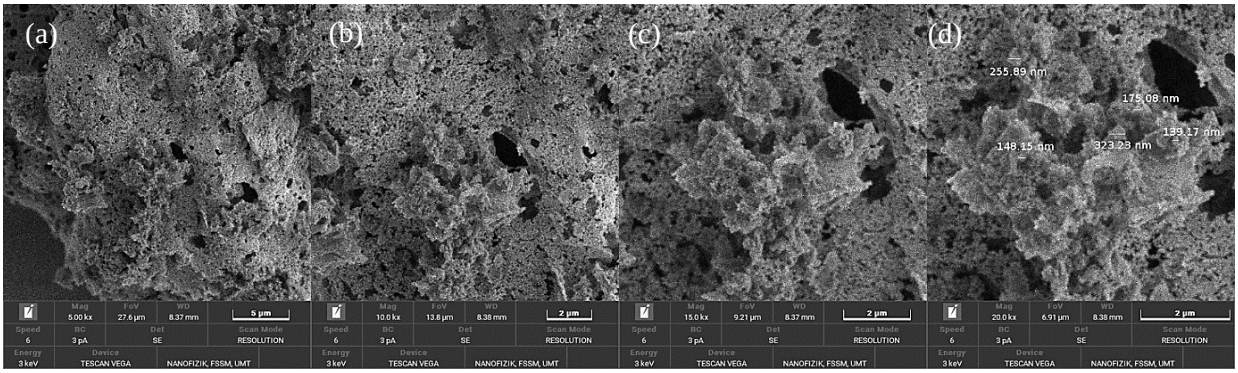

Figure 8. SEM images of MgO-NPs (Condition B) calcined at 600°C; at (a) 5,000x, (b) 10,000x, (c) 15,000x, and (d) 20,000x magnification

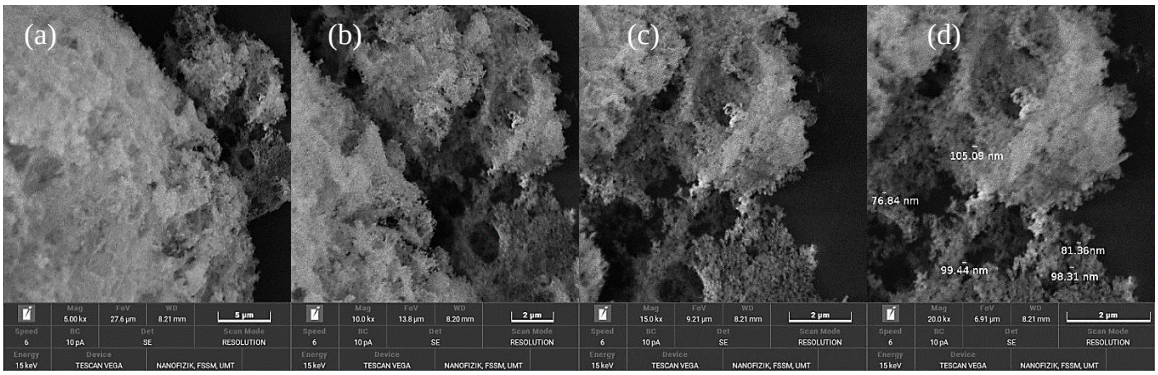

Figure 9. SEM images of MgO-NPs (Condition B) calcined at 800°C; at (a) 5,000x, (b) 10,000x, (c) 15,000x, and (d) 20,000x magnification

Lastly, Figure 9 shows the SEM images of MgO-NPs synthesized with Condition B and calcined at 800 °C. Most of the particles had non-uniform size and shapes with smaller crystallite as compared to other samples. The average particle size was 92.20 nm, with smallest particle of about 80 nm and largest particle of about 105 nm. Overall, all samples were highly agglomerated.

X-ray diffraction (XRD)

The synthesized MgO-NPs were subjected to x-ray diffraction analyses to confirm the presence and size of the NPs, obtain the crystallinity or amorphic nature, and detect possible impurities [41]. Figure 10 and Figure 11 show the x-ray diffraction pattern for MgO-NPs synthesized with Condition A and Condition B, respectively. Based on the PDF reference card No.9000493, the MgO-NPs obtained were in cubic structure with space group Fm-3m (225). Similar results were obtained for MgO-NPs synthesized with Condition A and Condition B. All the peaks observed for the MgO-NPs as listed in Table 5 and Table 6 were also in agreement with the PDF reference card No.9000493 and previous studies [45,49,51].

The presence of MgO-NPs was confirmed as all the samples (calcined at 600 °C and 800 °C) showed the presence of peaks corresponding to (111), (200), (220), (311) and (222) planes. Other than that, the sharp characteristic peaks in the diffractogram indicated the highly crystalline structure of MgO-NPs [49]. The MgO

peaks became sharper as the calcination temperature increased as evidenced in the Figures and Tables.

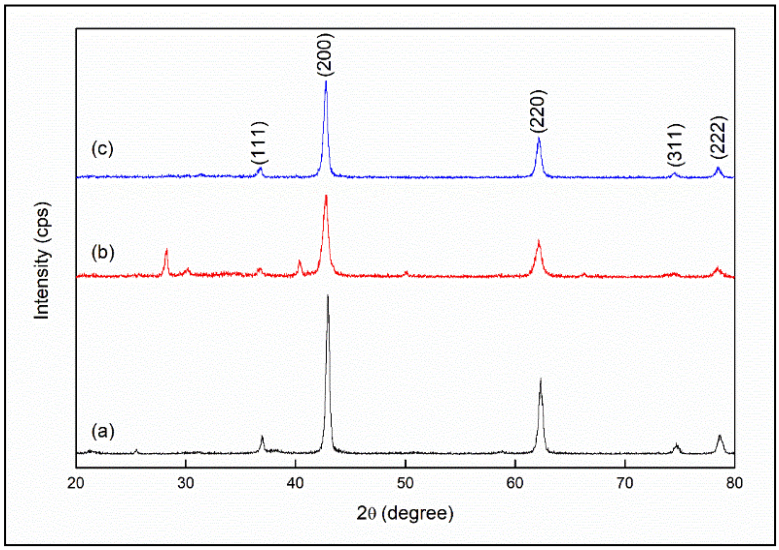

Figure 10. XRD of MgO-NPs (Condition A) (a) commercial and calcined at (b) 600 °C, and (c) 800 °C

Table 5. Crystallinity parameter of MgO-NPs synthesised with Condition A

(a) Calcined at 600 °C

2θ (°)	β (°)	Intensity (cps)	Lattice Plane	Mean Particle size (nm)
28.280	0.301	50	-	-
30.17	0.48	12	-	-
36.72	0.45	13	111	19.44
40.40	0.33	30	-	-
42.757	0.544	164	200	16.39
49.991	0.19	13	-	-
62.17	0.61	70	220	15.89
66.30	0.41	6	-	-
74.51	1.17	5	311	8.91
78.34	0.78	15	222	13.73

(b) Calcined at 800 °C

2θ (°)	β (°)	Intensity (cps)	Lattice Plane	Mean Particle Size (nm)
36.80	0.48	25	111	18.23
42.736	0.414	290	200	21.53
62.10	0.449	126	220	21.58
74.45	0.41	16	311	25.43
78.49	0.43	32	222	24.93

However, several peaks corresponded to impurities were detected for the MgO-NPs calcined at 600 °C. The extra impurities peaks detected were caused by stable crystalline inorganic compounds formed during the calcination of pre-calcine samples containing $Mg(OH)_2$ and strong bonds that remained over the surface of MgO-NPs [41]. On the other hand, no peaks other than the characteristic peaks of MgO were detected for the

MgO-NPs calcined at 800 °C, indicating that pure MgO-NPs were synthesized.

The average crystallite size of the MgO-NPs was estimated by using the Debye Scherrer's formula. When calcined at 600 °C, MgO-NPs synthesized with Condition A were approximately 9 nm–20 nm, but when calcined at 800 °C, they were roughly 18 nm–25 nm. Besides, MgO-NPs synthesized by using Condition B had a diameter of 9 nm–20 nm when calcined at 600 °C and was 17 nm–23 nm when calcined at 800 °C.

Conclusion

In summary, MgO-NPs have been successfully synthesized by using cavendish banana peel extract as reducing and capping agent, proving the concept of waste-to-wealth. The synthesis of MgO-NPs by using this banana peels with two methods of study which employed different volume of extracts and starting materials as well as different volume of starting materials were both reproducible as they both showed similar thermal stability. FTIR has shown that the mechanism of synthesis in this study were reduction and capping as the peaks of functional groups for biomolecules in the plants appeared in the pre-calcined samples for both methods. However, the peaks disappeared after calcination showing the occurrence of a full reduction and capping of the produced nanoparticles. Morphology and shapes of nanoparticles are dependent of the concentration and volume of starting materials, volume of extracts and calcination temperatures. As shown in SEM images, method A produced spherical shaped nanoparticles while method B produced irregular shaped nanoparticles. In the future, further research on the relationship between morphology of MgO-NPs and the properties of MgO-NPs can be studied in order to customizing the applications of MgO-NPs in the biological, physical and all nanotechnology-related fields. Overall, the best results obtained were from Condition B (25 mL extract with 0.1 M concentration of starting materials), thus sustainable and optimized synthesis methods have been successfully developed for future exploration of MgO-NPs. More waste products can be explored in the future providing more sustainable resources of reducing agent for the synthesis of MgO-NPs.

Abstract

In recent years, the quest to propose an ideal molecular system acting as dye-sensitised solar cells (DSSCs) bearing single molecular system have attracted great interest. This is due to their promising potential to convert solar energy into electrical energy at low cost. The alteration of molecular framework is essential to propose a rigid rod donor-π-acceptor system in enhancing its electronic properties to be applied as active layer in this type of solar cells. In recent years, mixed moieties molecules are actively being proposed as this combination proven to provide better performance of efficiency. However, the molecules bearing different moieties with different atomic features are rather scarce. The extended conjugation and the push-pull phenomenon within the molecular backbones may provide efficient electronic properties with alteration from different substituents. The development of DSSCs featuring conjugated mixed moieties are relatively new and scarce. Thus, this review article provides an insight general idea on the fundamental aspects of DSSCs as its progresses in term of its essentials features and compositions which focusing on the utilisation of these moieties. It is hope that this contribution may equip one's understanding in venturing similar work on this type of molecular system.

Keywords: DSSCs, conjugation, donor-π-acceptor, acetylene, azomethine

Abstrak

Sejak kebelakangan ini, pencarian untuk mencadangkan sistem molekul unggul yang bertindak sebagai sel suria peka cahaya (DSSC) menampilkan system molekul tunggal telah menarik perhatian yang tinggi. Ini adalah disebabkan kerana ia menjanjikan potensi untuk menukar tenaga suria kepada tenaga elektrik pada kos yang rendah. Pengubahsuaian kerangka molekul adalah penting bagi mencadangkan sistem penderma-π-penerima rod tegar dalam meningkatkan sifat elektroniknya untuk diaplikasikan sebagai lapisan aktif dalam sel suria ini. Sejak beberapa tahun lalu, molekul-molekul tercampur moiti secara aktifnya banyak dicadangkan kerana penggabungan ini telah membuktikan prestasi keberkesanan yang baik. Walau bagaimanapun, molekul-molekul yang menampilkan moiti berbeza dengan tampilan atom berlainan adalah amat jarang. Pemanjangan konjugasi dan fenomena tolak-tarik di dalam kerangka molekul mampu menyediakan sifat elektronik berkesan melalui pengubahsuian daripada pelbagai kumpulan pengganti. Pembangunan DSSC yang menonjolkan campuran moiti terkonjugat ialah agak baharu dan jarang dilaporkan. Oleh yang demikian, artikel ulasan ini menyediakan hala tuju idea secara umum terhadap aspek-aspek asas DSSC dan

kemajuannya befokuskan ciri-ciri penting dan komposisinya yang memfokuskan penggunaan moiti-moiti ini. Diharapkan agar sumbangan ini dapat menlengkapkan pemahaman seseorang dalam penglibatan kerja yang sama terhadapa sistem molekul jenis ini.

Kata kunci: DSSC, konjugasi, penderma-π-penerima, asetilina, azometina

Introduction

The sun is the single most vital energy provider for life on Earth. It provides energy to plants and planktons for photosynthesis process. In turn, the planktons and plants are then consumed by animals, providing energy for them. Almost all of the electricity that we use nowadays is also provided by the sun, albeit not in a straightforward way. Examples are wind energy caused by movement of air due to heat from the sun, hydropower energy that derived energy from water that fell as rain after being evaporated by the sun, and also fossil fuels, which are formed from the biomass of animals and plants [1]. Through the use of photovoltaic cells or solar cells, energy in sunlight can also be directly harvested to obtain electricity.

Sunlight is a form of electromagnetic radiation, consisting of 56% infrared, 36% visible and 7% ultraviolet radiation, with the remainder consisting of other electromagnetic radiations [1]. Earth received around 1.8 x 10^{14} kW of energy from sunlight. When sunlight hits the earth's atmosphere, around 40% of the sunlight is reflected back into space or absorbed by the atmosphere, so around 60 % or 1.08 x 10^{14} kW reaches the earth's surface [2]. The absorption of sunlight is due to molecules in the atmosphere such as water, carbon dioxide, ozone and oxygen. Water and carbon dioxide absorb the infrared radiation while ozone and oxygen absorb the ultraviolet radiation, thus changing the composition of the sunlight reaching the earth's surface to comprise of around 50% visible radiation and 47% infrared. The sunlight reaching earth's surface exists in two forms, direct radiation and diffuse radiation, with the latter resulted from the many scattering and absorption processes occurring when the sunlight travels through the atmosphere [1].

The total amount of energy from the sun reaching the earth's surface is around 3.4 x 10^{6} EJ [1], which is several thousand times the global energy consumption in 2019, which is 173,340 TWh [3], or around 624 EJ. Thus, there is tremendous potential in directly harnessing solar energy through photovoltaic cells for our future energy needs.

Development of dye-sensitised solar cells (DSSCs)

History of solar cells

Solar cells generate power via photovoltaic effect in which sunlight is converted into electrical current. Photovoltaic effect was first observed by Alexandre Edmond Becquerel in 1839. His cell was a wet cell, with either silver chloride or silver bromide coated electrodes immersed in acidic solution and contained within a black container. He observed that the voltage of the cell increased when its silver electrodes were exposed to sunlight [4]. In 1883, Charles Fritts as can be observed in Figure 1 created the first solar cell using selenium coated with a thin layer of gold, but its efficiency was only around 1% [5].

In 1946, Russel Ohl patented the first p-n junction silicon solar cell. He noticed that a silicon sample with a crack had current flowing in it when exposed to light. The crack formed at the boundary between the positively and negatively-doped part of the silicon, and when connected to a circuit, the photon in light imparts energy to the electron building up on the negatively-doped part to flow to the positively-doped part, thus generating electrical current. But the solar cell's efficiency was only 1% [6]. The first practical solar cell was developed by Daryl Chapin, Calvin Fuller and Gerald Pearson from Bell Labs in 1954. They first discovered that silicon with lithium and gallium impurities became very sensitive to light. They experimented with different impurities to further improve their silicon solar cells, and resulted in the use of boron and arsenic as the doping materials for their silicon solar cells, with efficiency of 6% [6].

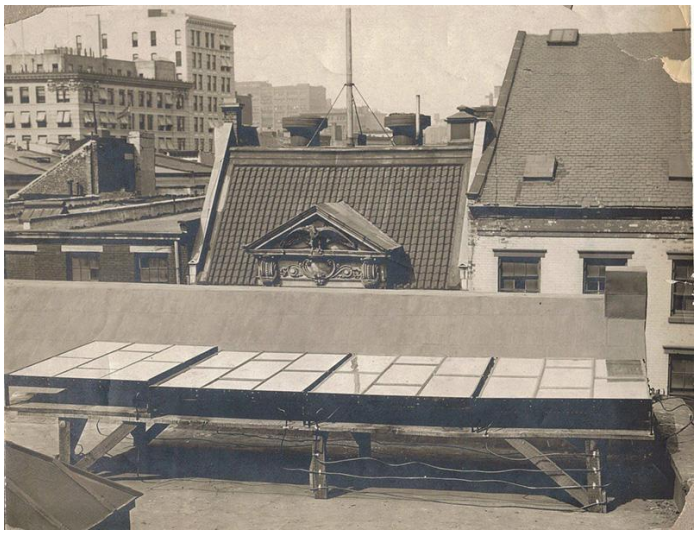

Figure 1. First solar panels installed by Charles Fritts in New York City, 1884

Solar cells were first put to practical use in 1958 when solar cells fabricated by Hoffman Electronics were used as power source for Vanguard satellite of the United States space programme [5], and solar cells were widely used in satellites afterwards. Since then, the use of solar cells has expended greatly, with it being the third most important renewable energy source after hydropower and wind power in the early 2010s and potential to overtake wind power in terms of installed power generation capacity [1].

Types of solar cells

Other than silicon solar cells, other types of solar cells have been developed. The different types of solar cells are usually grouped into three categories: first generation, second generation and third generation solar cells [7]. Silicon solar cells, or more specifically crystalline silicon wafer solar cells, are grouped in the first-generation solar cells. It is the oldest solar cells technology and currently the most widely used solar cells with around 95% market share in 2017 [8], due to silicon being cheap and abundant [7], and also due to efficient supply chain, standardisation and strongly reduced profit margins, which help to reduce the price of the solar cells [8]. There are two types of crystalline silicon wafer used in solar cells: monocrystalline silicon and polycrystalline silicon. Monocrystalline silicon wafer solar cells are fabricated through Czochralski process, which is an expensive and complicated process to produce single silicon crystal without any crystal grains. The more widely used ones are the polycrystalline silicon wafer solar cells due to their ease of fabrication and lower cost, but with the trade-off of lower efficiency [9].

The second-generation solar cells consist of thin film solar cells designed to be an alternative to crystalline silicon solar cells and achieving acceptable efficiencies with lowered costs. Some early examples are amorphous silicon (a-Si) solar cells, first prepared in 1972 by David Carlson and Christopher Wronski from RCA Laboratories with 1.1% efficiency, and the development of copper sulphide and cadmium sulphide thin film solar cells with efficiency over 10% by researchers at University of Delaware in 1980 [4].

Amorphous (a-Si) solar cells are attractive because it can be produced using low processing temperature and lower amount of energy, with possibilities of using low-cost polymer and other flexible substrates. Therefore, a-Si solar cell is comparatively cheaper than the crystalline silicon solar cells, but with caveat of lower efficiency at around 4-8 % [9]. Other promising materials used in second-generation solar cells are copper-indium-gallium diselenide (CIGS) thin film, which can reach efficiency of 20 % [9], and cadmium-telluride (CdTe) thin film. But second-generation solar cells are not as used as widely as the first-generation

solar cells due to technological problems and module stability [10].

The third generation of solar cells consists of diverse cell types such as dye-sensitised solar cells (DSSCs), organic solar cells, perovskite cells and quantum dot cells [7]. Quantum dot cells are developed with aim for the nanocrystals semiconductor material to replace bulk state semiconductor material such as Si, CdTe or CIGS [9]. Organic solar cells are solar cells with organic polymers as semiconductor materials. Thin layers of polymers consist of mixture of amorphous and crystalline regions, which can have major role in the carrier transport in the bulk material [7]. Perovskite cells are solar cells consisting of perovskite material with formula of ABX_3, where A represents a protonated amino group, B stands for Pb or Sn, and X stands for halides [11]. They have low bulk-trap density, ambipolar charge transport, wide band absorption and long charge carrier diffusion lengths, making them a highly promising candidate for solar cells as proposed by Akinoglu and team [7] with highest efficiency of 22% have been achieved, but with major drawback such as stability and reproducibility issues that prevents them from being commercialised widely [11]. DSSC was first successfully developed by Brian O'Regan and Michael Grätzel [12], with efficiency of around 7% under direct sunlight by utilising a nanoporous titanium dioxide (TiO_2) as thin layer semiconductor material with dye molecules adsorbed on its surface to absorb photons and converting it into electricity.

O'Regan and Grätzel's DSSC

The successful development of efficient DSSC by was spearheaded by Michael Grätzel and Brian O'Regan from 1988 until 1991 [12]. Although there were multiple attempts for creating DSSC previously, but all of it were of very low efficiency [13]. Previous attempts only achieved low absorption of incident monochromatic light via a layer of sensitiser on smooth surface, and using several layers of sensitiser to overcome the problem was unsuccessful.

There were also attempts to increase the dye molecules that could be adsorbed on the semiconductor surface via increasing the roughness of the semiconductor, but the conversion efficiency of the cells remains under 1%. Furthermore, the dye previously used were lacking in stability. Gratzel and O'Regan's device consisted of TiO_2 nanoparticles with average size of 15 nm deposited on a conducting glass surface to form a thin film with thickness of 10 μm as the photoanode, while the dye they used was a trimeric ruthenium complex, with iodide/triiodide redox mediator. The absorption spectrum of the thin film sensitised with the dye was redshifted and it achieved almost 100 % absorption of light in the visible spectrum under 550 nm. The conversion efficiency of the cells at one tenth and full sunlight were at 7.9 % and 7.12 % respectively, with the performance increasing to 12 % under diffuse sunlight. The cell performance was also considerably more stable compared with previous cells, with less than 10 % change in photocurrent produced by the cell after two months of testing [13]. The DSSC as invented by O'Regan and Grätzel was a significant development in DSSC history, and their device is still being studied and continuously improved by other researchers to this day.

Advantages of DSSCs

DSSCs have been gaining interest from researchers because they offer several advantages compared to the conventional silicon crystalline solar cells that are widely used today. Among the advantages of DSSCs is their capability to perform well under low light condition, as showcased by O'Regan and Grätzel in 1991 [12] when they obtained DSSC efficiency of 12% under diffuse sunlight compared to DSSC efficiency of 7.1-7.9% under direct sunlight. Unlike the silicon wafer solar cells, the performance of DSSCs is less affected by light intensity and the angle of incident, which makes DSSCs suitable for light harvesting under indoor lighting and low-level outdoor lighting [14]. Thus, DSSCs have potential for widespread application in portable electronics capable of self-powering without the need for power source from batteries, which is crucial as the Internet of Things (IOT) becoming more popular [15].

Another advantage is that DSSCs can possibly be offered with various design options, such as varying their transparency and colours. They also can be flexible and lightweight [16], which makes them

suitable for applications in small, portable electronics for indoor use, and also for application through integration in buildings and automobiles, thus helping to reduce their energy use carbon footprint. Furthermore, DSSCs are simpler and less energy intensive to produce compared to the conventional silicon wafer solar cell, which makes them possibly more practical and cost-efficient for large scale production [17]. With low energy use for DSSCs production, the energy payback time for DSSCs can be achieved in less than a year [16], which is much shorter than energy payback time for silicon solar cells [18]. Through molecular engineering of the dyes used in DSSCs, the optical properties of DSSCs can be transformed.

Challenges for widespread adoption of DSSCs

There are still several challenges that need to be overcome or mitigated before the DSSCs can be applied in large scale like the silicon crystalline solar cell. One of them is the relatively low efficiency of DSSCs. The highest cell performance achieved with DSSC is 14.3% [19]. Meanwhile, the efficiency of conventional crystalline silicon solar cells used are usually around 14-18% [10]. Other challenge is the price-competitiveness of DSSCs. At the time the first efficient DSSC was invented by Gratzel and O'Regan in 1991, the price of silicon crystalline solar cells was still high. But now, as of 2022, their price has dropped tremendously [7]. In fact, the cost effectiveness of using silicon solar cells for electrical generation have become higher than producing electricity at power plants using coal, oil or natural gas, which could possibly reduce interest for research in to improve efficiency of alternative solar cells such as DSSCs.

Commercialisation of DSSC

As for 2020, there has been penetration of DSSCs in the solar cell market, but the global solar cell market is still dominated with silicon wafer solar cell, with around 95 % market share [20]. The applications for DSSCs are as shown in Figure 2 below:

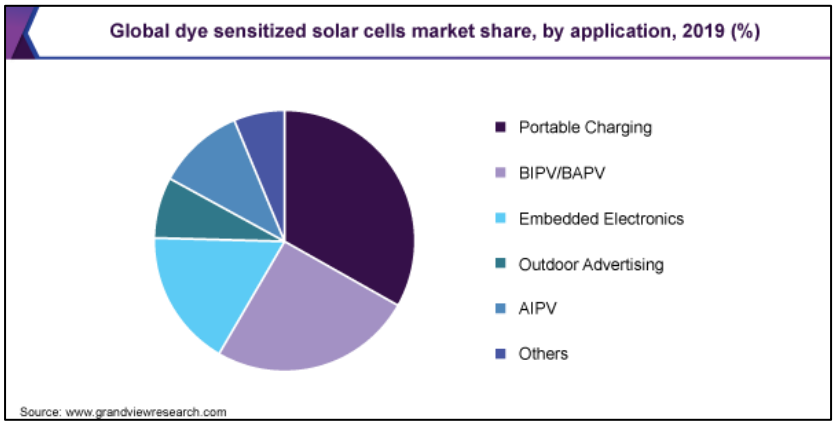

Figure 2. Global market share of DSSCs by application as for 2020

The value of the global DSSCs market is at USD 90.5 million in 2019 [21]. It was forecasted to continue growing in the future, due to the increased concerns about energy sustainability and impacts of the energy generation from non-renewable resources on the environment. DSSCs are mainly used in portable charging, building integrated photovoltaics/building applied photovoltaics (BIPV/BAPV), embedded electronics, outdoor advertising and automobile integrated photovoltaics (AIPV). Although DSSCs can have hard time to compete against the dominance of silicon based solar cells in large scale, outdoor application, but it has significant potential for indoor use [22] due to its excellent performance under low-light condition, variable design in their colour and transparency, lightweight and flexible material.

There are a number of companies involved in the DSSCs market. One of the notable companies is G24 Power, previously known as G24i. It was the first company to

produce DSSC for commercial application, with their products being used in backpacks and bags [23]. Their DSSC products are marketed under the brand name GCell (gcell.com). The next company is 3GSolar. Their products are advertised to eliminate the need for constant battery changing and charging in wireless electronic devices for the lifetime of the devices (3gsolar.com). Another player in the DSSC market is Solaronix. The company is deeply involved in the market because it not only offers DSSC kits, but it also offers the materials needed for making DSSC, such as the electrolytes, dyes, and TiO_2 paste for photoanode [24].

Main components of DSSC

A typical DSSC consists of four main components:

a) Electrolyte/redox mediator
b) Counter electrode
c) Photoanode/working electrode
d) Metal oxide nanoparticles (commonly TiO_2) with dyes molecules adsorbed on its surface

A diagram of typical DSSC as coined by Nazeeruddin [17] is depicted in Figure 3 below.

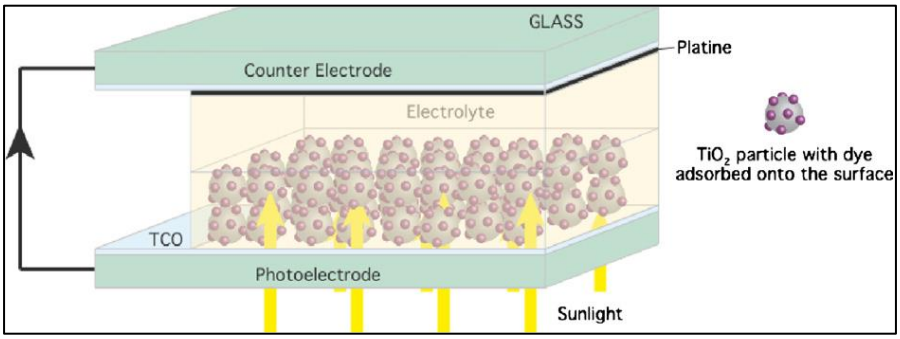

Figure 3. Schematic diagram of a DSSC

Electrolyte/redox mediator

The function of electrolyte is providing medium for the flow of electrons from the counter electrode (cathode) to the dye molecules adsorbed on the semiconductor layer (usually TiO_2) surface at the photoanode. There are several types of electrolytes used in DSSC, which are:

a) Liquid electrolyte, example is I^-/I_3^- electrolyte
b) Solid state electrolyte, example is spiro-OMeTAD
c) Quasi solid state electrolyte, example is I^-/I_3^- absorbed in PET matrix

The most commonly used type of electrolyte in DSSC is liquid electrolyte. A good liquid electrolyte needs to be chemically stable, has low viscosity to enhance electron transport capability, capable of good dissolution of the redox couple but does not significantly dissolve the dye and the semiconductor layer [16]. Among the liquid electrolytes, I^-/I_3^- electrolyte is commonly used because it demonstrated favourable kinetics. The I_3^- reacted slower with the electrons in TiO_2 than the time needed for electron injection from the dye into TiO_2 conduction band, while I^- reacts more favourably with the oxidised dye molecules than the injected electrons in TiO_2 [25]. Thus, recombination reaction could be slowed, and high efficiency can be achieved.

Other liquid electrolytes have been used in DSSC, such as Br^-/Br_3^-, $SCN^-/(SCN)_2$, $SeCN^-/(SeCN)_3^-$, $Fe(CN)_6^{3-}$ /$Fe(CN)_6^{4-}$ and Co(II)/Co(III) complex. Another type of liquid electrolyte that has been developed is ionic liquid electrolyte. It is basically a room temperature molten salt, unlike earlier liquid electrolytes in which the redox couples are dissolved in an organic solvent. But, ionic liquid electrolytes can and still have some additional solvent in it, albeit in lower amount. The salts used consists of organic cationic parts, such as alkylimidazolium, trialkylsulfonium, phosphonium and tetraalkylammonium, while for the anionic parts, halides such as iodide, and other types of anions such as PF_6^-, BF_4^- and CF_3COO^- were used [26]. Ionic liquid

electrolytes' advantage compared to the earlier liquid electrolytes is their low volatility, which ensure the electrolyte possess higher stability, but in turn, they usually have low viscosity, and thus low ion mobility [27].

The main drawback with most liquid electrolyte is their long-term stability, due to the volatility of the solvent used and prone to leakage. Thus, solid state electrolyte has been developed to overcome the issues. Solid state electrolyte consists of hole transporting materials (HTM) that function via the movement of positive charge between neighbouring molecules, as opposed to liquid electrolyte where charge transport is due to movement of redox mediators [16]. The most successful solid-state electrolyte that has been developed was the organic molecule spiro-OMeTAD. It is capable of achieving incident photon to electron conversion efficiency (IPCE) of 33%, originally yielding efficiency of 0.74 % [28]. However, the efficiency of solid-state electrolytes is still lacking compared to liquid electrolytes, mainly due to the very fast recombination between electrons in TiO_2 with holes in the HTM [29], and also the poor contact between the dye and electrolytes [12].

Another alternative electrolyte that has been developed is quasi solid-state electrolyte that can show the properties of liquid and solid simultaneously. The advantages of quasi solid-state electrolyte are their stability from leakage and vaporization of the electrolyte, close interfacial contact with the TiO_2, and relatively good ambient ionic conductivity [25]. An example of quasi solid-state electrolyte is from the work of Sun and co-workers [30], where they used polyethylene terephthalate to act as matrix for the iodide/triiodide liquid electrolyte by absorbing the liquid electrolyte to become quasi solid-state electrolyte.

Counter electrode

Counter electrode accepts electrons from the external circuit and utilise it to catalyse redox reactions in the electrolyte. A counter electrode consists of a conductive substrate (usually glass) that is coated with a thin layer of catalytic material. Among the properties for a good counter electrode are high catalytic activity, good conductivity, high reflectivity, large and porous surface area, suitable thickness of the coated catalytic layer, good stability against degradation, compatible energy level with the potential of the redox couple electrolyte, and good adhesion of the catalytic layer with conducting substrate [31].

The conductive substrate is coated with catalytic materials to reduce the charge transfer overpotential by increasing the speed of the reaction. Charge transfer overpotential originates from the electrolyte/counter electrode interface, and high charge transfer overpotential causes the output voltage of the DSSC to be significantly reduced. The magnitude of the charge transfer overpotential is dependent upon the electrocatalytic properties of the counter electrode surface towards mediator reduction [32], and coating the surface of the conducting substrate with catalytic material helps to increase conductivity and improve electrocatalytic activity of the counter electrode [33].

As for the catalytic layer, the most commonly used material is platinum. It was used in the pioneering work of O'Regan and Grätzel DSSC in 1991. It is widely used because of its ideal properties such as high catalytic activity, high electrical conductivity, good stability and high reflectivity [33]. In the DSSC fabricated by O'Regan and Grätzel, the conducting substrate used was the FTO coated glass, but it has high charge transfer resistance in iodide/triiodide electrolyte, and its surface is also very unconducive for the reduction of triiodide to iodide. Due to the ideal properties of platinum, it was chosen as the catalytic layer for the counter electrode of DSSC, and it has been popular since 1991 [33].

The platinum layer's thickness on the DSSC may significantly affect its performance. Nearly two decades ago Fang and team found out that the different layer thickness ranged from 25 nm to 415 nm did not prominently affect the charge transfer resistance at the electrolyte-counter electrode interface. They also discovered that increasing the thickness from 2 nm to 415 nm decreases the sheet resistance of the counter electrode, but no significant difference was observed in the DSSC performance. Thus, 2 nm of platinum layer

was sufficient for the DSSC to obtain good efficiency [34].

Other factors, such as the size and shape of the platinum particles also affect the performance of the DSSC. Platinum nanoparticles perform better than bulk platinum in DSSC due to their large surface area, high electrical conductivity, low charge transport resistance, good resistance against corrosion, and high transmittance [35]. Platinum nanoparticles with variety of shapes have been developed to increase their surface area and improve their properties in counter electrode.

One example is platinum nanocup developed by Jeong and co-workers [36]. In their work, they synthesised two platinum nanocup in different sizes and compared their performance with planar platinum for the counter electrode. The platinum nanocups have larger surface area than the planar platinum, so more sites are available for catalytic process on the platinum nanocup surface. Thus, it enables more electrochemical reduction by reducing the charge-transfer resistance at the counter electrode/electrolyte interface. The lowering of internal resistances of RCT helps in increasing the fill factor and short circuit current of the DSSC. The DSSC with the platinum nanocup array with a diameter of 300 nm at a 400 nm pitch size showed a power conversion efficiency of 9.75%, which is 24% higher than the 7.87% power conversion efficiency of DSSC with the planar platinum.

Although platinum has ideal properties for counter electrode, it also has several disadvantages, such as its high price, low abundance, and weak corrosion resistance against the commonly used iodide/triiodide electrolytes, so many researchers have been developing alternatives material for platinum in counter electrode. One of the alternative materials is carbon. It possesses suitable properties for counter electrode material, such as good catalytic activity, high conductivity, large and porous surface area, and chemical resistance against electrolyte and dye solution. More importantly, it is also available abundantly on earth and also cheaper to obtain than platinum, so it is a promising material [31]. There are different types of carbon materials used for counter electrode materials, examples are graphene, carbon nanotubes, carbon nanofibers, activated carbon, graphite, and carbon black [33].

Photoanode/working electrode

Photoanode, also called as working electrode, receives electrons from the excited dye molecules, which then would flow to the counter electrode through external circuit. A photoanode consists of transparent conducting substrate deposited with a layer of metal oxide semiconductor material. The conducting substrate must be high transparency for the dye molecule to be able to absorb light, and low electrical resistivity to minimise energy losses and facilitate electron transport process. The transparent conducting substrate is usually made of glass substrate for physical support, with a layer of transparent conducting oxide (TCO) on it. Examples of TCO materials are fluorine doped tin oxide (FTO), indium doped tin oxide (ITO), aluminium doped zinc oxide (AZO) and antimony doped tin oxide (ATO).

Among them, FTO is the most widely used TCO because of their suitable properties such as good light transmittance, good electrical conductivity, good adhesion with the glass substrate, high Mohs hardness, good resistance against corrosion, chemically stable, and can resist heat up to 600 °C [33]. The high heat resistance is important because the catalytic layer deposited on the conductive glass substrate needs to be solidified by calcination at high temperature. Other than glass, polymers and metals also have been used for the physical support, with polymers such as polyethylene terephthalate and polyethylene naphthalate, and metals such as stainless steel, titanium and tungsten.

For the semiconductor metal oxide layer, it should have several properties to make it an ideal material [37]:

a) Large surface area so more dye can be adsorbed on it
b) Facilitates fast electron transport from the excited dye to the external circuit
c) Optimum pore size for good diffusion of dye and electrolyte on it
d) High resistance against photo-corrosion
e) Capable of absorbing and scattering light to facilitate the dye functioning efficiently

f) Good electron acceptor
g) Good interfacial contact with the dye molecules and also the TCO layer on the substrate

The semiconductor material also must have band-gap of more than 3 eV [30]. The higher the band-gap, the UV light absorbed from the sun would be lower, thus reducing reactive holes formed in the semiconductor when it is excited by the sunlight. The reactive holes are undesirable because they can disturb and damage the organic compounds in DSSC, such as the dye molecules, via oxidation reaction [28]. Examples of materials that have been used for photoanode are titanium dioxide (TiO_2), zinc oxide (ZnO), tin oxide (SnO_2) and zinc stannate (Zn_2SnO_4). Their band-gaps are as depicted in Figure 2.4 below as proposed by team of Gong in 2012 [25].

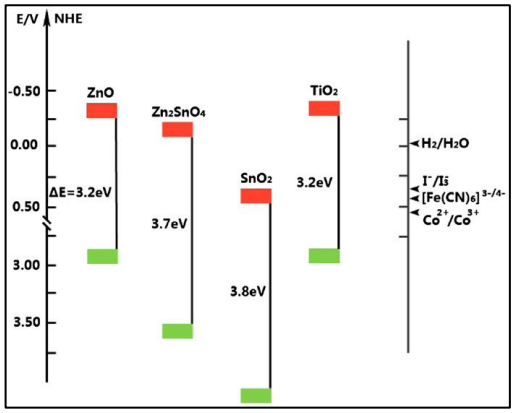

Figure 4. Band-gaps of materials for photoanode

The most widely used material for photoanode is TiO_2. In their 1991 work, O'Regan and Grätzel pioneered the use of it in DSSC, and to this day, it is still popular due to its low cost, easy availability and non-toxic [12]. It usually exists in three crystalline forms, which are rutile, anatase and brookite, with band-gaps of 3.05 eV, 3.20 eV and 3.28 eV, respectively [31]. Among the three, anatase-form TiO_2 is the most preferred form for use in DSSC. In comparison to the anatase-form TiO_2, rutile-form has smaller band-gap. DSSC using the rutile-form TiO_2 has lower photocurrent due to the lower amount of dye molecules adsorbed on the TiO_2 film surface, which is because of their smaller surface area than anatase-form TiO_2. In addition, electron transport is also slower in the rutile form than in the anatase form due to differences in the extent of inter-particle connectivity associated with the particle packing density [38]. As for the brookite-form TiO_2, although it has wider band-gap than anatase-form TiO_2, the brookite-form has lower dye loading due smaller surface area for the dye on the brookite surface compared to anatase surface. The conduction band edge in brookite-form is similar or below that of the anatase-form photoanode. Undesirable recombination side reaction is lower in brookite cell, thus enabling it to obtain higher open circuit voltage than anatase cell. But, the electron transport is significantly slower in brookite cell compared to the anatase cell due to its lower electrical conductivity, thus tremendously reducing its electron collection efficiency compared to anatase cell [39].

Other than TiO_2, other photoanode materials that have been frequently used are ZnO. In fact, ZnO has been studied for semiconductor use in DSSC since 1972, way earlier than TiO_2 [40]. Although it has been overtaken by TiO_2, ZnO can still be considered as a suitable alternative to anatase-form TiO_2, due to their nearly similar conduction band edge and same band-gap, and higher electron mobility in ZnO than TiO_2 [25], which facilities electron transportation by decreasing the recombination loss [40]. It is also relatively easy to synthesise highly crystalline ZnO (wurtzite-form) with different morphologies, such as nanoparticles, nanowires, nanorods, nanotubes, tetrapods, nanoflowers, nanosheets, and branched nanostructures [16]. However, ZnO have several disadvantages such as low carrier concentration, low fill factor, poor stability in acidic dyes and slow electron injection kinetics [41]. The highest DSSC efficiency achieved using ZnO photoanode is 8.03% [42], which is still low compared to the highest DSSC efficiency achieved with TiO_2 photoanode at 14.3% [19]. Even with many other metal oxide alternatives, TiO_2 is still the superior material of choice for photoanode.

The performance of TiO_2 and any other photoanode material is mainly affected by three factors, which are the size/surface area of the particles, the morphology/shape of the particles, and the

composition/purity of the photoanode material [31]. Nanoparticle-sized material is better than bulk size material, due to the higher surface area provided by the nanoparticles, which enable it to adsorb more dye molecules on it. O'Regan and Grätzel achieved high efficiency DSSC by using TiO_2 nanoparticles with average size of 15 nm. But smaller particle size does not guarantee better performance, [43]. They compared the performance of several TiO_2 nanoparticles films, and they observed that the films with larger particle size achieved higher short-circuit current density and better conversion efficiency. They concluded that even though the surface area of the smaller particles is larger than of the bigger particles, the bigger particles may have better dye adsorption properties by providing easier access for the dyes to its surface, resulting in a higher number of electrons and holes produced. The size distribution range of the nanoparticles also plays a role. In a study by Dhungel and Park [44], TiO_2 film with smaller size distribution range have poor interconnection between the nanoparticles, so its porosity is increased, which in turn increased the area available for the adsorption of dye after sintering. So, the size of the nanoparticles, their size distribution and surface area need to be optimised to ensure higher dye adsorption on the surface.

The next main factor is morphology or shape of the particles. There have been numerous studies on tuning the morphology of the TiO_2 nanoparticles to improve their performance. A study by Wang et al. [45] compared the performance between monolayer, double layer and multilayer TiO_2 photoanode. Small nanoparticles have large surface area, thus capable of adsorbing more dyes than large particles, but they have poorer light scattering ability than large particles. Poor light scattering ability leads to weaker absorbance of longer wavelength red light.

To overcome that, Wang and co-workers [45] have developed a multilayer photoanode structure incorporating nanoparticles layer (23 nm), followed by nanoparticles-scattering particles (50 nm) mixture layer and nanoparticles-scattering particles (100 nm) mixture layer, and lastly with scattering particles (100 nm) layer, with purpose to balance the surface area for dye adsorption with light scattering ability. Their multilayer cells achieved higher light harvesting efficiency (10.2%) than the monolayer and double layer cells. However, the mesoporous nanostructure still suffers from low electrical conductivity and the pores facilitate recombination reactions to occur. Thus, many researchers have been focused on developing new nanostructured photoanode material to obtain high conductivity and also high dye loading. Examples are nanowires, nanotubes and hollow spheres [37].

The last main factor is composition/purity of the photoanode material. Electronic band structure of semiconductors can be altered by substitutional doping, which is done by substituting some of the semiconductor atoms with different atoms of similar atomic radius [46]. TiO_2 photoanode has been doped with several materials, such as copper [47], sulfur [48], and calcium [49], and all of them successfully obtained higher cell efficiency compared to the undoped TiO_2 photoanode. Other than doping, semiconductor material has been used as composite within combination with other component, in which the mixture can be in the form of core-shell or layered frameworks [46]. Examples of TiO_2 composites are TiO_2-ZnO composite [50], TiO_2-SnO_2 composite [51], and TiO_2 nanorod-nanoparticle composite [52].

Dye/photosensitiser

Dye, also called as photosensitiser, absorbs light, resulting in excited electron which is then injected into the conduction band of the metal oxide semiconductor layer (usually TiO_2) in photoanode. The oxidised dye would then be reduced to its normal state by receiving electron from the electrolyte. The dyes used can be either metal based dyes, most commonly using ruthenium (Ru) metal, or metal-free organic dyes, which are either synthetic dyes or natural dyes extracted from plants. A good dye is vital to achieve DSSC with high conversion efficiency. Characteristics of a good dye are as follows [16]:

a) The dye should strongly absorb wavelength ranging from the visible region to the near-infrared region
b) The dye should have anchoring groups such as carboxylic acid (COOH), phosphonic acid

(H_2PO_3) or sulfonic acid (SO_3H) groups for it to be able to bind onto the semiconductor surface

c) The excited state level of the dye should be higher in energy than the conduction band edge of n-type semiconductor, so that an efficient electron transfer process between the excited dye and conduction band (CB) of the semiconductor can take place

d) For dye regeneration, the oxidized state level of the dye must be more positive than the redox potential of electrolyte

e) Unfavourable dye aggregation on the semiconductor surface should be avoided through optimization of the molecular structure of the dye or by addition of co-adsorbers that prevent aggregation

f) The dye should be stable against degradation by light, in addition to possessing electrochemical and thermal stability

By having a wide and intense absorption spectrum both the visible and the near-IR, the dye can absorb lighter, which in turn can lead to more photocurrents being produced [53]. Approximately 46% of total energy from sunlight is in the infrared region [1], which is only weakly absorbed by the commonly used crystalline silicon solar cell. The weak absorbance is compensated by using relatively thick silicon layer (~100 μm), but this led to increased material cost and some losses in power conversion efficiency due to recombination reaction [54]. Thus, DSSC has an advantage over crystalline silicon solar cell due to its cheaper material, much thinner structure (~20 μm), and higher potential capability to absorb light in the near-infrared region. And by utilising strong light absorbing dye (i.e., high molar absorption coefficient), the semiconductor layer can be made thinner, thus reducing the material used and also minimising the unwanted recombination reactions from occurring [55].

Anchoring groups bind the dye molecules to the semiconductor metal oxide surface, with carboxylic acid, cyanoacrylic acid and phosphonic acid being among the most frequently used anchoring groups [56-57]. They bind to the metal oxide by reacting with the hydroxyl group on it to form ester linkage. Anchoring groups can profoundly affect the operating parameters of DSSC, such as light absorption, molecular orbital distribution, frontier orbital energy levels, band structures of the photoanode, electron transport between the dye and photoanode, charge recombination, and overall solar-to-electron conversion efficiencies of the DSSC [57].

In order to ensure efficient charge injection, the energy level of lowest unoccupied molecular orbital (LUMO) of the dye molecule should be slightly above (i.e. more negative) the conduction band (CB) edge of the semiconductor metal oxide, while the energy level of highest occupied molecular orbital (HOMO) should be lower (i.e. more positive) than the redox potential of redox mediator. The difference between E_{LUMO} and E_{CB} acts as an enthalpic driving force for electron injection from the excited dye to the semiconductor by ensuring the injection process is kinetically favourable. And by having the dye's highest occupied molecular orbital (HOMO) to be below the electrolyte redox potential, this induces the process of electron transfer to the excited dye, which regenerates the dye in its ground state. This separates the charges and is the major mechanism for charge separation in the DSSC [58].

Dye aggregation on semiconductor surface is generally unwanted because it can cause low conversion efficiency of the DSSC via reduction of electron injection yield from the dyes to the CB of semiconductor due to intermolecular energy transfer [59]. The common structure is that the dyes would form a homogenous monolayer on the semiconductor surface with relatively uniform spacing between the dye molecules. There are several ways in which the dye molecules could aggregate either laterally or longitudinally on the semiconductor surface as depicted in Figure 2.5. Longitudinally, the dye molecules could clump together haphazardly, resulting in unequal spacing between them. Another way is the dye molecules also could cluster too close to each other, thus forming an aggregate layer. While for lateral aggregation, instead of being adsorbed on the semiconductor surface, a dye molecule could interact with the tip of another dye molecule that is adsorbed on the semiconductor surface [57] (Figure 5).

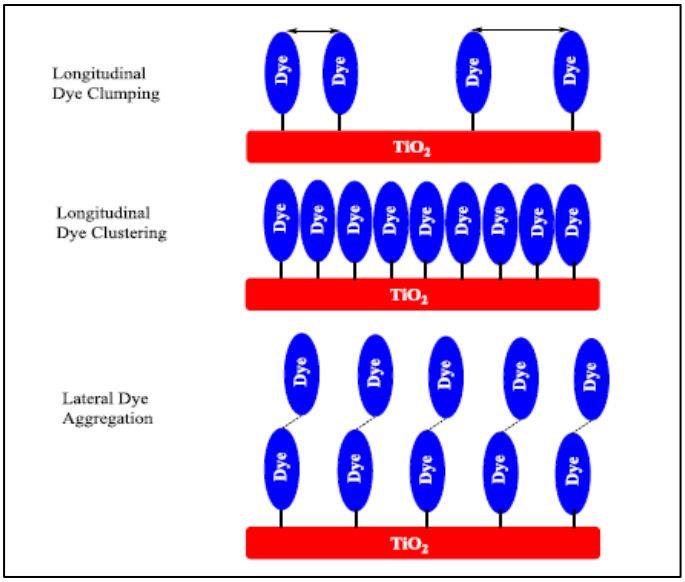

Figure 5. The possible dye molecules' arrangement on TiO_2 surface

The methods that have been used to prevent dye aggregation were tuning the molecular design of the dye molecule, using co-adsorbent in tandem with the dye, or using a different dye compound as co-sensitizer. The dye can become degraded due to seepage of moisture or oxygen in DSSC, and exposure to UV light in sunlight, which could directly excite the semiconductor and may lead to irreversible oxidation of the dye [60]. Under illumination, degradation can occur during the excited state dye or the oxidised state dye. The electron injection from excited dye state to the CB is extremely fast, so light induced degradation is thought to mostly happen at the oxidised state dye. For widespread DSSC utilisation to be become viable, other than improving the power conversion efficiency, it is vital to also increase the stability of DSSC. One way to achieve that is by using a dye possessing good light, electrochemical, and thermal stability, so the dye is capable of operating consistently without significant degradation and performance loss for at least for 20 years [55].

As mentioned previously, the three dye types that have been used in DSSC are either metal based dyes, most commonly using ruthenium (Ru) metal, metal-free synthetic organic dyes, or natural dyes extracted from plants. Metal based dyes have been frequently studied for DSSC application because of their broad absorption spectra and favourable photovoltaic properties. The structure of metal-based dye generally consists of complex with a central metal ion and auxiliary ligands with one or more anchoring group. The metal complex is able to absorb light in the visible spectrum of sunlight due to metal to ligand charge transfer (MLCT) process. Substituents such as alkyl, aryl or heterocyclic alkyl can be used to modify the photophysical and electrochemical properties of the ligands, and thus helps to improve the DSSC performance via tuning the energy levels of the MLCT states, optimisation of electron injection process and improvement of dye regeneration kinetics [16].

Among the metal-based dyes, Ru based dyes have the best performance record, with their broad absorption spectrum, optimum excited and ground state energy levels, relatively long excited-state lifetime, and good electrochemical stability [16]. The first DSSC with high efficiency developed by O'Brian and Grätzel in 1991. They used ruthenium complex dye. In 1993, Nazeeruddin et al. managed to fabricate DSSC with conversion efficiency of 10% by using cis-RuL_2-$(NCS)_2$ dye that incorporates 2,2'-bipyridyl-4,4'-dicarboxylic acid as ligands, with codename N3 dye. It was the first time a DSSC device managed to achieve conversion efficiency of 10 % and above [16].

N3 dye possess superb qualities, such as broad visible light absorption spectrum with threshold up to 800 nm, relatively long excited state lifetime, and excellent adsorption to the TiO_2 semiconductor surface via four carboxylates anchoring groups that are linked to the two bipyridyl moieties. The four carboxylates anchoring groups also facilitates improved electronic coupling between the charge-transfer excited state and the conduction band wave function manifold of the semiconductor [61]. Later on, the team studied the effects of protonation on the several Ru complex dyes also with 2,2‘-bipyridyl-4,4‘-dicarboxylic acid as ligands. One of the synthesised dyes, the doubly protonated $(Bu_4N)_2[Ru(dcbpyH)_2(NCS)_2]$ with codename N719, exhibited a higher power conversion efficiency than the other dyes [62]. Since then, the N3 and N719 dyes are considered as reference dyes for DSSC, and are also used by other researchers as template for designing other Ru based dyes by modifying its ligand moieties [16].

Other than Ru, other metals such as osmium (Os), copper (Cu), and platinum (Pt) have been investigated for their potential application in metal complex dye. Os complex dyes have been studied because it exhibited excellent photosensitisation, with better MCLT than that of Ru complex dyes [63]. The synthesis of several Os polypyridyl complexes for comparison with Ru polypyridyl complexes, and they discovered that the Os polypyridyl complexes exhibited broadening of the light absorption and extended the spectral response of nanocrystalline TiO_2 photoelectrodes to higher wavelength values while still maintaining the same performance as Ru polypyridyl complexes [64]. However, Os based dyes suffers from poor reduction of adsorbed dyes by the iodide/triiodide redox couple due to the process being kinetically unfavourable in comparison with the charge recombination process, thus limiting its photocurrent efficiency [65-66]. Among the earliest Pt complex dyes used in DSSC were square-planar platinum(II) diamine dithiolate dyes [67], and they managed to achieve efficiency of 2.6%. Other examples of Pt complex dyes are phenothiazine-based platinum(II)–acetylide dyes developed by Siu et al. [68] and platinum(II) bis(aryleneethynylene) dyes [69]. They managed to achieve highest efficiency of 5.78% and 1.57%, respectively. Still, there are much more studies need to be done for improving the performance of non-Ru complex dyes to become comparable to Ru complex dyes.

Although Ru based dyes have excellent properties, there are several drawbacks associated with it, such as the high cost of Ru metal, non-abundant supply, and the sophisticated synthesis and purification steps [25]. Recently, metal-free organic dyes have been subject to numerous studies in hope of developing promising alternatives comparable or superior in performance to Ru based dyes. Organic dyes have several advantages over Ru and also other metal-based dyes, such as easier to synthesise and purify, lower material cost, low concern of supply limitations, higher molar absorption coefficients, and wider variety of structural design modification of the organic dyes are possible to tune their properties [59].

The usually high molar absorption coefficients of organic dyes in comparison to the metal-based dyes allows the use much thinner semiconductor layer, thereby facilitating the charge transport in the photoanode and minimising energy loss, and also improving the pore filling properties for quasi-solid-state or solid-state electrolyte in porous dye-sensitized TiO_2 films [70]. Usually, organic dyes are designed with the template of donor-π bridge-acceptor (D-π-A) structure, as shown in Figure 6 below which in this particular work carried out by Shalini et al. [55] involved D-π-A structure adsorbed on TiO_2. By adjusting the design template, it is possible to broaden the absorption spectra, shift the HOMO and LUMO energy levels, and improve the intramolecular charge separation of the organic dye [16]. When a dye absorbs light, electron is transported from the donor part through the π-bridge to the acceptor part, which is then injected into the CB of semiconductor. D-π-A structure ensures that the majority of electron transport occurs in one direction.

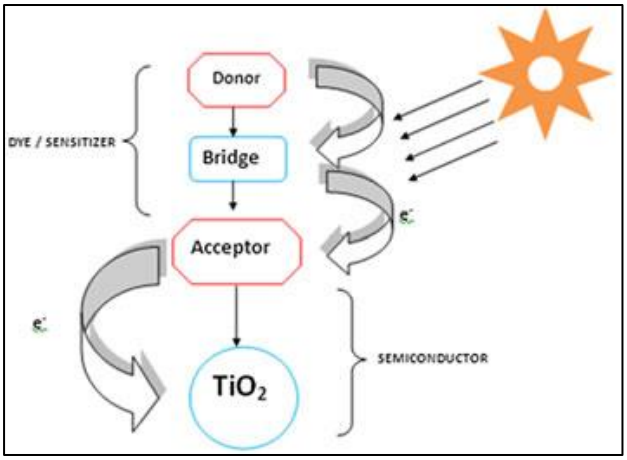

Figure 6. Schematic diagram of dye with D-π-A structure adsorbed on TiO_2

Working mechanism of DSSC

When a dye (S) is exposed to sunlight, it absorbs a photon to become photoexcited state (S*), in which an electron becomes excited and moved from HOMO to LUMO of the dye (Eq. 1). The photoexcited dye then injects an electron from its LUMO into the CB of photoanode (i.e. TiO_2), thus becoming oxidised dye (S^+) in the process (Eq. 2). The oxidised dye is then reduced to its normal state (S) by accepting electron from the redox mediator, i.e. I^- in I^-/I_3^- redox couple, thus regenerating the dye (Eq. 3). Meanwhile, the electron injected into the CB of TiO_2 travels through the interconnected TiO_2 nanoparticles and arrived at the TCO coated glass (i.e. FTO glass), and then it enters the external circuit and transported to the counter electrode (i.e. Pt-coated FTO glass), in which it reduced the I_3^- ion to regenerate I^- ion (Eq. 4) and thus completing the circuit. However, there are also other unwanted reactions that can interfere with the electron transport process, which are recombination reaction of the injected electron in the CB of semiconductor with the oxidised dye (Eq. 5), reaction of the injected electron with the electrolyte at the semiconductor/electrolyte interface, referred as dark current (Eq. 6), and also relaxation of the photoexcited dye (Eq. 7). The unwanted reactions can reduce the performance of DSSC if not mitigated or overcome. The electron cycle process is pictured in Figure 7 below as proposed by Ooyama & Harima [59].

Parameters of DSSC performance

The performance of DSSC is evaluated via several parameters: incident photon to current conversion efficiency (IPCE), photocurrent/voltage curves (J/V curves), open-circuit photovoltage (V_{oc}), short circuit photocurrent density (J_{sc}), fill factor (ff), and solar energy conversion efficiency (η) [59].

IPCE, also referred as external quantum efficiency, is defined as the photocurrent density produced by the electrons flowing in the external circuit under monochromatic illumination of the cell divided by the photon flux hitting the DSSC [16]. The equation to calculate IPCE is as shown in Eq. 8:

$$\%\ \text{IPCE} = 1240\ (\text{eV nm})\frac{J_{ph}(\text{mA cm}^{-2})}{\lambda\ (\text{nm})\times I\ (\text{mW cm}^{-2})} \quad (8)$$

Where J_{ph} is the short-circuit photocurrent, density generated by monochromatic light, and λ is the wavelength while I is the intensity of the monochromatic light. IPCE provides information the monochromatic quantum efficiency of the DSSC [16].

J/V curves for DSSC is usually measured under standard AM 1.5 simulated sunlight (100 mW cm^{-2}). From the J/V curves, four values can be obtained directly: J_{sc}, V_{oc}, J_{mp} and V_{mp}, where J_{mp} and V_{mp} are the photocurrent and photovoltage at maximum power, respectively. A typical J/V curves is depicted in Figure 8 below [64].

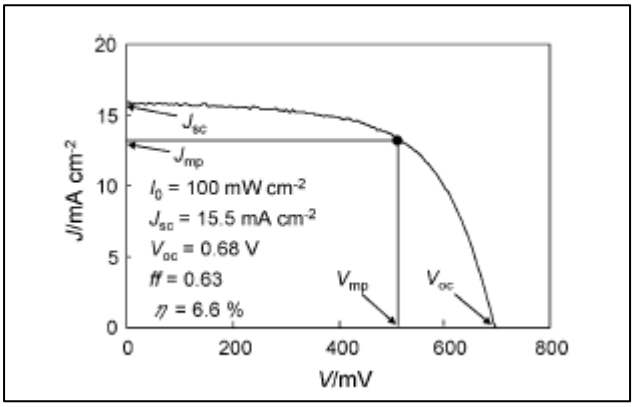

Figure 8. Typical J/V curves of a DSSC

V_{oc} is the difference in potentials between the two terminals of the cell when the circuit is being illuminated and in open state (J=0) [71]. V_{oc} can be derived from Eq. 9 shown below.

$$V_{oc} = \frac{E_{cb}}{e} + \frac{k_B T}{e}\ln\left(\frac{n}{N_{cb}}\right) - E_{redox} \quad (9)$$

Where E_{cb} is the energy level of the CB of the semiconductor, E_{redox} is the redox potential of the redox mediator, n is the number of electrons in the semiconductor, and N_{cb} is the effective density of states [59]. The maximum V_{oc} value can be defined as the difference between the E_{cb} of the semiconductor and the redox potential of redox mediator. However, the actual V_{oc} is usually lower than theoretical due to the inefficiency in electron cycle process causing losses of electrons through reactions such as recombination and dark current. The V_{oc} value could be enhanced via increasing the E_{cb} of semiconductor or lowering the E_{redox} of the redox couple [72].

J_{sc} is the photocurrent density measured when the DSSC is short-circuited, i.e. no opposing voltage that inhibits electron flow [71]. Its value is dependent upon absorption coefficient of the dye, in addition to the interaction between photoanode and the dye. To obtain

high J_{sc} value, the dyes should be capable of intense light-absorption over broad wavelength of sunlight, the electron injection process from the excited dye to the photoanode should be highly efficient, and the oxidised dye should be effectively reduced by the redox mediator [59].

Fill factor (ff) is defined as the ratio where product of current and voltage at maximum power is divided by the V_{oc} and J_{sc} as shown in Eq. 10.

$$\mathrm{ff} = \frac{J_{mp} \times V_{mp}}{J_{sc} \times V_{oc}} \quad (10)$$

The ff is determined from the J/V curve. It is essentially a comparison of how much the rectangular area defined by J_{sc} and V_{oc} is filled by rectangular area as defined by J_{mp} and V_{mp}. Thus, if the J_{mp} and V_{mp} rectangle completely fill the J_{sc} and V_{oc} rectangle, the ff value becomes unity [59]. However, the ff value is usually around 0.6 – 0.8 due to charge recombination and electron loss [71]. Electron loss are caused by the combination of series resistance in the DSSC, such as sheet resistances of the substrate and counter electrode, electron transport resistance through the photoanode, ion transport resistance, and the charge-transfer resistance at the counter electrode.

Energy conversion efficiency (η) is calculated by dividing the maximum electrical output of the DSSC divided by incident power from the sunlight as defined in Eq. 11.

$$\eta = \frac{J_{sc} \times V_{oc} \times \mathrm{ff}}{P_{in}} \quad (11)$$

Where η is the power conversion efficiency, J_{sc} is the short circuit photocurrent density, V_{oc} is the open circuit photovoltage, ff is the fill factor, and P_{in} is the incident light intensity. The incident power is usually set to the irradiance of the AM 1.5 spectrum with value of 100 mW/cm^2. From the energy conversion efficiency, it provides information about the generated power of DSSC and the light conversion into electricity and photovoltaic parameters. To improve the energy conversion efficiency, all of the components of DSSC must be optimised, with the dye as the most important component to be optimised. Numerous scientists have conducted studies to adjust their photophysical and electrochemical properties of the dyes by molecular design to improve their properties [59]. External factors, such as overall light intensity, spectral intensity distribution and temperature also affect the performance of DSSC [71].

Organic dyes as photosensitiser

There has been intense interest in research and development of organic dyes for application in DSSC due to their potential advantages against ruthenium and other metal complex dyes, such as higher molar extinction coefficient, flexibility in designing the molecules, lower material costs, and being relatively easy to prepare [59, 73]. But organic dyes also have several drawbacks compared to ruthenium complex dyes, such as narrow absorption in the visible spectrum, dye molecules aggregation, short electron lifetime in the excited state, and low stability in the long term. These drawbacks need to be overcome for organic dyes to become more efficient as photosensitisers in DSSC. The structural design of an organic dye is commonly based on the donor-pi-acceptor (D-π-A) structure as shown in Figure 9. According to Ooyama and Harima [59], an organic dye should fulfil several requirements:

a) The organic dye must have at least one anchoring group for adsorption onto the TiO_2 surface, for example –COOH group. A carboxyl group can form an ester linkage, a chelating linkage, and a bidentate bridging linkage with the TiO_2 surface to provide a strongly bound dye and good electron communication between the dye and the surface

b) For efficient electron injection from the excited dye to the CB of TiO_2, the energy level of the LUMO of the dye must be higher (more negative) than that of the CB of the TiO_2 electrode, while for efficient regeneration of the oxidized state by electron transfer from the I^3-/I^- redox couple in the electrolyte, the energy level of the HOMO of the dye must be lower (more positive) than that of the I^3-/I^- redox potential

c) Have high molar absorption coefficients over the wide range of sunlight for high light harvesting efficiency

d) The flow of electrons in the excited state of a dye should be highly unidirectional with path from the donor part to the acceptor part to provide efficient electron injection from the excited dye to TiO_2 through good electronic coupling between the LUMO of the dye and the CB of TiO_2.

e) Possess chemical stability in its photoexcited state and in the redox reactions throughout the reaction cycle so the DSSC can last longer

f) The dyes should not excessively aggregate on the TiO_2 surface because it could cause low conversion efficiency of the DSSC. Aggregated dyes reduce the electron-injection yield from the dyes to the CB of TiO_2 owing to intermolecular energy transfer between the dyes through the stacked π-bridge, especially dyes with long conjugation

g) Recombination of injected electrons with dye cations and I^{3-} ions in the electrolyte should be suppressed. Wide spatial separation between the moieties of positive charge density on the exited dye and the TiO_2 surface facilitates efficient charge separation, thus inhibiting the recombination process. Hydrophobic substituents on the dye skeleton act as barriers to prevent hydrophilic I^{3-} ions from approaching the TiO_2 surface, thereby retarding charge recombination.

D-π-A dyes consisting of electron-donating and electron–accepting groups linked through π-conjugated bridges featuring broad and intense absorption spectrum are expected to be one of the most promising classes of organic sensitizers that meet the above requirements, because D-π-A structure offers flexible designs that make it possible to obtain desirable dye properties with molecular engineering for various designated function of interests.

D-π-A dye design

As mentioned previously, the D-π-A structure consists of three parts, which are the donor part (D), π-bridge, and acceptor part (A), with donor part conjugated with the acceptor part though the π-bridge. Requirements a) to c) can be fulfilled by adjusting the photophysical and electrochemical properties of the dyes via the inclusion of electron-donating and electron-accepting groups onto the chromophore skeleton and extending the length of π-conjugation, which causes shift in the energy levels of the HOMOs and LUMOs [59]. By increasing the electron-donating ability of the donor part and electron-accepting ability of the acceptor part, the energy gaps between the HOMO and LUMO are reduced, thus resulting in redshifting of the absorption peaks. So, the dyes can absorb more sunlight in the visible region. Redshifting is vital because compared with metal complex dyes, organic dyes exhibited sharp and narrow absorption bands in the visible region, which impairs light-harvesting capabilities [75].

For requirements d)–f), they should be fulfilled through the introduction of sterically hindered substituents, such as hydrophobic long alkyl chains and aromatic units, onto the chromophore skeleton [59]. One of the main drawbacks of these D-π-A dyes is the formation of strong π-stacked aggregates between dye molecules on TiO_2 surfaces, which tends to reduce electron-injection yields from the dyes to the CB of TiO_2, due to intermolecular energy transfer between dyes. The sterically hindered substituents (bulky groups) help to prevent the aggregation of dye molecules on TiO_2 surfaces by inhibiting the π-π stacking between the dyes, and also prevent the ions in electrolyte from approaching the TiO_2 surface, thus reducing the electron recombination between the electrolyte ions and electrons in TiO_2 [76].

Utilisation of mixed moieties of D-π-A system as dyes for DSSC

In this section, several selected prior studies involving application of different selected mixed moieties featuring numerous substructures of D-π-A system in DSSCs have been focused, reviewed and discussed in relation to the scope of mixed moieties system. Thorough discussion on their characteristics and

molecular build-up are presented in respect to the unique highlights on their functionalities and performances.

Acetylene

The moiety of acetylene has been known over the years as active materials in numerous applications, synthesised in recent decades via Sonogashira cross coupling reaction [77-78]. Over a decade ago, Song et al. [79] had synthesised four dyes with triphenylamine as donor part, cyanoacrylic or carboxylic acid as acceptor part, with phenylacetylene moiety as linker. They varied the structure of the phenylacetylene linker part and the acceptor part while keeping the donor part unchanged (Figure 9).

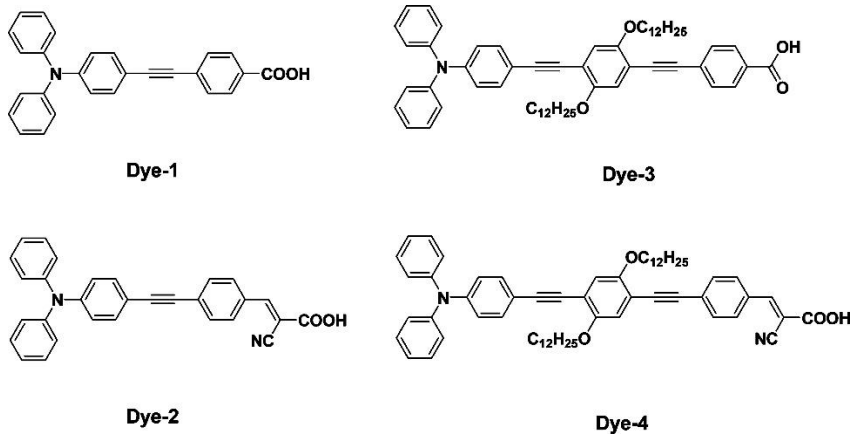

Figure 9. Structures of dyes bearing four dyes with triphenylamine as donor part, cyanoacrylic or carboxylic acid as acceptor part, with phenylacetylene moiety as linker

In recent years some alternatives have been proposed involving rather similar motifs and expected to behave fairly equal as acetylenes involving thiourea [80] and chalcone [81] derivatives with the focus in optoelectronics interests. The properties of the dyes and their DSSC performance were compared with that of the reference Ru complex N719 dye. In general, Dye-3 and Dye-4 with longer conjugation length of the double phenylacetylene moiety exhibited red-shifting in their absorption spectrum compared to the Dye-1 and Dye-2 with only one phenylacetylene moiety. It is also almost the same with their emission spectrum, except that Dye-2 and Dye-4 with cyanoacrylic acid moiety as donor part, in which the trend is reversed. The molar absorption coefficient of Dye-3 and Dye-4 are also higher than that of Dye-1 and Dye-2, but all of the values are still overwhelmingly higher than that of the reference dye N719 (1400 dm^3 mol^{-1} cm^{-1}). The performance of the dyes in DSSC is tabulated in Table 1 below as synthesised by Song et al. [79].

Table 1. Performance of DSSCs using dyes

Dye	V_{oc} (V)	J_{sc} (mA/cm^2)	ff	η (%)
N719	0.66	14.82	0.47	4.54
Dye-1	0.70	4.62	0.62	2.00
Dye-2	0.71	8.56	0.47	2.89
Dye-3	0.79	6.64	0.59	3.06
Dye-4	0.73	9.30	0.49	3.61

The V_{oc} of all the organic dyes are higher than N719 dye, which is theorised to occur due to inhibition of the charge recombination at the photoanode/dye/redox electrolyte interface and the semirigid phenylacetylene spacers. Dye-3 and Dye-4 with longer conjugation length achieved higher energy conversion efficiency than Dye-1 and Dye-2. The investigation on the effects of acetylene moiety as π-spacer on their properties and

DSSC performance also have been investigated prior [82]. They designed and synthesised four organic dyes containing acetylene moiety for comparison with five dyes without acetylene moiety (Figure 10). The dyes incorporating acetylene moiety exhibited red-shifting in their absorption spectrum due to the increased conjugation length, but the degree of re-shift in dyes with acetylene moiety is quite weaker compared to dyes with ethylene (double bond) moiety. Introduction of acetylene moiety only barely influenced the HOMO level of the dyes, but the dyes with ethylene moiety experienced negative shifting of its HOMO level.

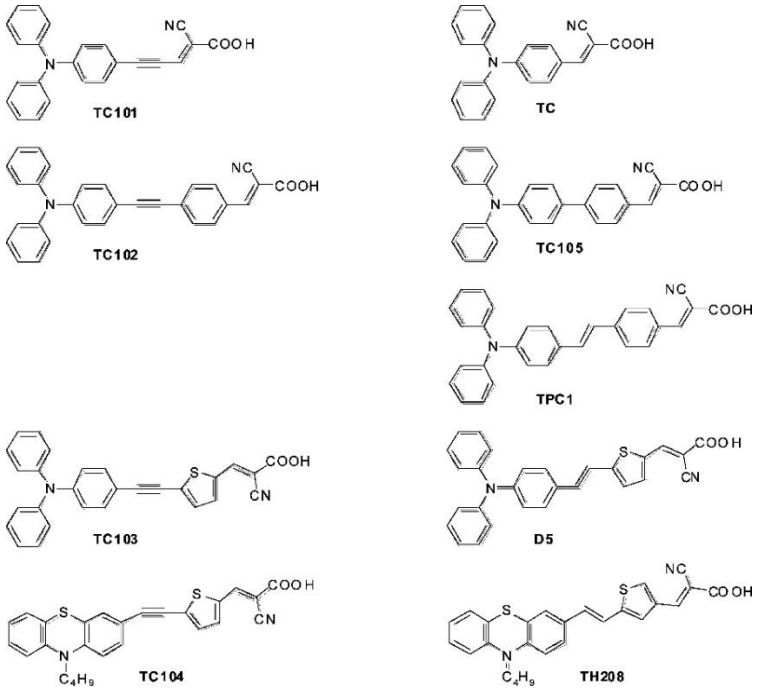

Figure 10. Dyes synthesised by Teng et al. [82] investigated the effects of acetylene moiety as π-spacer on their properties and DSSC performance.

Their designated DSSC performance of the dyes is tabulated in Table 2 below. Dyes with acetylene moiety only showed slight improvement in their energy conversion efficiency, compared to ethylene moiety which significantly improved the energy conversion efficiency, which is due to the lower J_{sc} of dyes containing acetylene moiety than dyes with ethylene moiety. But, DSSC using acetylene-based dyes showed improvement in their IPCE, due to the enhanced electron transfer yield of DSSC with introduction of triple bond.

Based on the selected studies, incorporation of acetylene moiety in dyes can induce red-shifting in their absorption spectrum via extension of conjugation length, which is important for the dye because more sunlight can be absorbed. Acetylene moiety also helped to improve the energy conversion efficiency of DSSC, but ethylene moiety showed much higher improvement in energy conversion efficiency. An advantage of acetylene moiety over ethylene moiety is their faster electron transfer yield, which enhance the IPCE of acetylene-based dye compared to ethylene-based dye. So, acetylene moiety can improve the properties of dyes and their DSSC performance, but more work needs to be done on the molecular design of dyes with acetylene moiety as linker in organic dyes, because ethylene moiety generally possesses better characteristics.

Table 2. Performance of synthesised dyes in DSSC

Dye	J_{sc} (mA·cm^{-2})	V_{oc} (V)	ff	η (%)
TC101	6.35	623	0.742	2.94
TC102	7.72	694	0.803	4.30
TC103	9.60	671	0.776	5.00
TC104	8.84	610	0.742	4.00
TC	5.26	636	0.776	2.60
TC105	7.58	693	0.773	4.06
TPC1	10.39	702	0.785	5.73
D5	12.41	663	0.760	6.25
TH208	11.99	643	0.743	5.73

Azomethine/Schiff base

Lokhande et al. [83] have come up with four new organic Schiff bases employing N-hexyl/N-phenyl carbazole moiety as a donor, 1-chlorobuta-1,3-diene as a π-bridge and 4-amino salicylic acid as acceptor for application as photosensitisers in DSSC (Figure 11). Incorporation of chlorine group along with additional π-bond worked effectively to improve the overall performance of dyes. Introduction of two acceptor units in 3b resulted in the decrement of HOMO-LUMO band gap with a bathochromic shift in absorption wavelength and broadening of the absorption spectrum. Introduction of hexyl unit in dyes exhibited better DSSC performance than the dyes with phenyl unit due to reduced aggregation of dye molecules on the TiO_2 surface [78].

Figure 11. Four those dyes designed and synthesised by Lokhande et al. in 2019 acting as photosensitisers in DSSC

In recent years, incorporation of theoretical studies on the physico-chemical and performance of these motifs are actively being performed. Particularly on the theoretical studies on the inclusion of azomethine moiety as linker in dye molecules. They investigated 10 dyes, of which three have already been reported experimentally and theoretically and of which seven are new structures inspired by the former. The effect of the pi-bridge was evaluated by combining azomethine, thiophene, and benzene derivatives using two and three units. In all cases, the inclusion of azomethine improved the electronic properties such as UV-Vis absorption, charge transfer from the donator part to acceptor part and the electron injection according to HOMO and LUMO levels, and chemical reactivity [84]. The incorporation of triphenylamine-thiopene based dyes with azomethine moieties as π-bridge, and their results showed that the dye with azomethine moieties were

capable of absorbing significant portion of light in the visible spectrum, suggesting its suitability for potential photovoltaic applications with further modification to its overall structure [85].

Heterocyclic

Heterocyclic is any cyclic organic compounds that contain at least one carbon atom with at least one other element such as nitrogen, oxygen and sulfur. In recent years, these compounds have been investigated greatly as spacer or linker in dyes for DSSCs applications. One of the derivatives of this heterocyclic moieties which has great potential to be utilized is known as isoindigo (Figure 12). It has been attracting great interest as an ideal building block for the electroactive materials for optoelectronics interest particularly in DSSCs. This is due to the fact that, it can afford high yields and turnovers [86]. Like other typical building block for organic electronics applications, it can be further developed into numerous molecular and polymeric materials with extended photophysical properties.

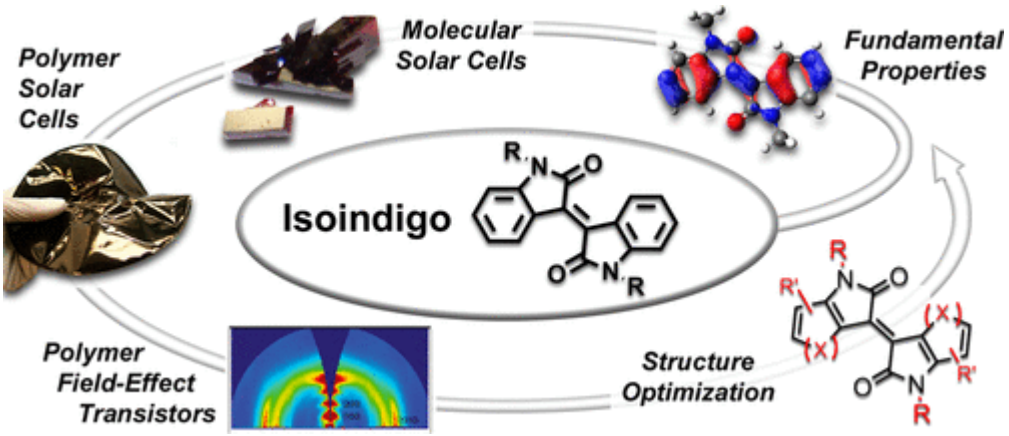

Figure 12. Numerous potential applications of isoindigo as building block in optoelectronics including in solar cells interests [86]

Isoindigo derivatives also have become a major focus recently in DSSCs acting as dyes. Synergistic studies involving computational approach of density functional theory (DFT) and the conventional experimental have become major interests among chemists and physicists in recent years. Hadsadee et al. [87] has utilized metal-free dyes based on isoindigo by performing DFT in order to improve efficiency in DSSCs. They have proposed triphenylamine as donor, thiophene as the π'-linker between the donor and auxiliary acceptor, and a phenyl or thiophene ring as the π-linker between the auxiliary acceptor and acceptor. The outcomes proven to exhibit good charge transfer properties and proven that the π-linker on photovoltaic would influence the performance in organic dyes.

By also incorporating DFT studies, a series of push−pull heterocyclic dyes of N, N diphenylhydrazones were prepared to study the effect of structural modifications with different π-spacers and electron withdrawing groups were studied further for their optical and non-linear properties. These derivatives were investigated for their potential as photosensitizers for nanocrystalline TiO_2-based DSSCs [88].

In designing and proposing well-performed DSSCs, the dyes should be highly efficient which the roles and influences of the donor (D) and acceptor (A) as well as ideal spacer or likers should be considered and chosen carefully. Due to its unique nature, heterocyclics containing sulfur and nitrogen like benzothiadiazole [89] were also explored and afforded great outcomes by altering the molecular backbones of the dyes. Similar computational method also can be utilised in other quite similar heterocyclic derivatives such as phenothiazine which in this study, the modification towards the bridging cores on their various properties such as structural, photovoltaic, electronic, and optical

properties were investigated further [90]. In 2020, a series of novel organic dyes containing bearing D-π-A system of phenothiazine were designed, synthesized and studied on their photophysical properties also pairing with DFT studies. It shows that, with the alteration on the substituents, the fundamental and thorough intramolecular charge transfers in these dyes can be understood further. [91]

Optical and redox properties of dyes are also essential features in photovoltaic studies. Incorporation of pyrrole and thiophenes in the molecular framework proven to that this sensitizer for DSSCs the best conversion efficiency up to 2.21%. This is mostly due to the contribution of the higher molar extinction coefficient, long π-conjugation of the heterocyclic system, higher oxidation potential and strong electron donating capacity of the ethoxyl group compared to the pirrolyl moiety [92].

With all the latest work and findings involving mixed moieties of D-πA system as dyes for DSSC and the greater impact these systems can contribute in solar cells studies, more exploration and in depth understanding on their fundamental features should be carried out. In recent years, typical experimental work paired with computational theoretical studies have shown that, a thorough details on the functionalities and performances of these developed DSSCs can be understood further. These two distinctive approaches are compatible to each other in supporting the development of an ideal usable DSSCs as an alternative green energy sources.

Conclusion and Future Outlook

There has been a thorough discussion on the fundamental aspects of DSSCs and other related elements featured in the build-up. The aim now is to explore various mixed moieties system that beneficial in term of extending the conjugation within the molecular framework of D-π-Acceptor system. The contribution of various substituents to the core of the molecules are also essential and may play a major role in giving the desired outcomes of the cells' efficiency and performances. In this contribution, a concise initial development of DSSC, its components and the overall working mechanism of the DSSC have been explored. Furthermore, the requirements for ideal organic dyes in DSSCs and the previous studies related to the application of acetylene and azomethine in dyes for DSSCs have been reviewed. Based on the reviewed works, dyes with acetylene, azomethine and heterocyclic mixed moieties have shown promising results for DSSC application and can be improved with further molecular tuning of the dyes. The ventures on the combination between these hybrid moieties as potential candidates as π-bridge in a dye molecule for DSSC should be taken into consideration Interestingly, focusing on the use of both acetylene and azomethine and taking highly elongated conjugation of these two can offer, there is no known research yet involving these moieties in individual molecular frameworks to date. Thus, the potentials are endless.

Abstract

The hydrolysis process of sunflower oil (SFO) was carried out to produce sunflower oil fatty acids (SFOFAs). The optimization of reaction parameters was performed using response surface methodology (RSM) via D-optimal design. The optimization parameters were varied from 1.0 to 2.5 M molarity of ethanolic KOH, 50 to 70°C of reaction temperature and 0.5 to 2.5 hours of reaction time. The highest percentage of SFOFAs yield was 96.68% with a free fatty acid (FFA) of 103.23%, which was achieved at optimal conditions: 2.3 M ethanolic KOH concentration, reaction temperature of 50.14°C and 0.97 hours of reaction time. The structure of SFO and SFOFAs were confirmed using Fourier Transform Infrared Spectroscopy (FTIR) and Nuclear Magnetic Resonance (NMR). SFOFAs was monitored by the absence of C=O (ester) at 1746.33 cm^{-1} and the existence of C=O (carboxylic acid) at 1710.23 cm^{-1} with OH stretching at 2400-3400 cm^{-1} in SFOFAs FTIR spectrum. Under the NMR spectrum of SFOFAs, the absence peak of ester (C=O) at 172.79 to 173.21 ppm (^{13}C NMR), the emergence peak of OH at 10.61 ppm (^{1}H NMR) and the peak of carbon for carboxylic acid (C=O) (^{13}C NMR) at 180.45 ppm showed that the fatty acid was successfully obtained.

Keywords: D-optimal design, hydrolysis, response surface methodology, saponification, sunflower oil

Abstrak

Proses hidrolisis minyak bunga matahari (SFO) telah dijalankan untuk menghasilkan asid lemak minyak bunga matahari (SFOFA). Pengoptimuman parameter tindak balas dilakukan menggunakan kaedah permukaan tindak balas (RSM) melalui reka bentuk D-optimal. Parameter pengoptimuman telah diubah daripada 1.0 hingga 2.5 M kemolaran etanol KOH, 50 hingga 70 °C suhu tindak balas dan 0.5 hingga 2.5 jam masa tindak balas. Peratusan tertinggi hasil SFOFAs ialah 96.68% dengan asid lemak bebas (FFA) sebanyak 103.23%, yang dicapai pada keadaan optimum: kepekatan KOH etanol 2.3 M, suhu tindak balas 50.14 °C dan 0.97 jam masa tindak balas. Struktur SFO dan SFOFAs telah disahkan menggunakan spektroskopi infra-merah transformasi Fourier (FTIR) dan resonans magnetik nuklear (NMR). SFOFAs dilihat dengan ketiadaan C=O (ester) pada 1746.33 cm^{-1} dan kewujudan C=O

(asid karboksilik) pada 1710.23 cm^{-1} dengan regangan OH pada 2400-3400 cm^{-1} dalam spektrum FTIR SFOFAs. Di bawah spektrum NMR SFOFAs, kehilangan puncak ester (C=O) pada 172.79 hingga 173.21 ppm (^{13}C NMR), kemunculan puncak OH pada 10.61 ppm (^{1}H NMR) dan puncak karbon untuk asid karboksilik (C=O) (^{13}C NMR) pada 180.45 ppm menunjukkan bahawa asid lemak berjaya diperolehi.

Introduction

Nowadays, the increase in the use of petrochemical products in daily life has caused various environmental problems [1]. The petrochemicals are used in many industries like plastics, soaps and detergents, solvents, drugs, fertilizer and pesticides [2]. The use of petrochemical products is an international issue because they contribute to environmental problem, global warming and climate change due to the disadvantages of petrochemical product such as low biodegradability (20-30%), toxic to the environment, cause an increase of the greenhouse gases that affect global warming and the material come from non-renewable sources [2-6]. The use of petrochemical products needs to be changed to other alternatives that do not have a negative impact on the environment. A suitable alternative is to replace petrochemical products with biobased products such as plant oil.

Fatty acid and glycerol are essential raw materials in the oleochemical industry [4]. It is widely used as a raw material in the food, cosmetic and pharmaceutical industries. Fatty acid can be obtained from the hydrolysis of plant oil and fats via saponification as shown in Figure 1 [7, 8]. Fatty acid can also be used as a starting material in the production of biolubricant (polyol ester) [9, 10]. There are several plant oils used in the production of fatty acids, including sunflower oil. There are various type of fatty acids in sunflower oil (SFO) such as palmitic (5.2%), stearic (2.7%), oleic (37.2%), linoleic (53.8%) and linolenic (1.0%) [11], which make the ingredients suitable for hydrolysis process. The hydrolysis reaction can be catalyzed using acid, base or enzyme (lipase) [4]. Nowadays, researchers focus more on potassium hydroxide catalyzed (base catalyze) hydrolysis in order to reduce energy consumption [12].

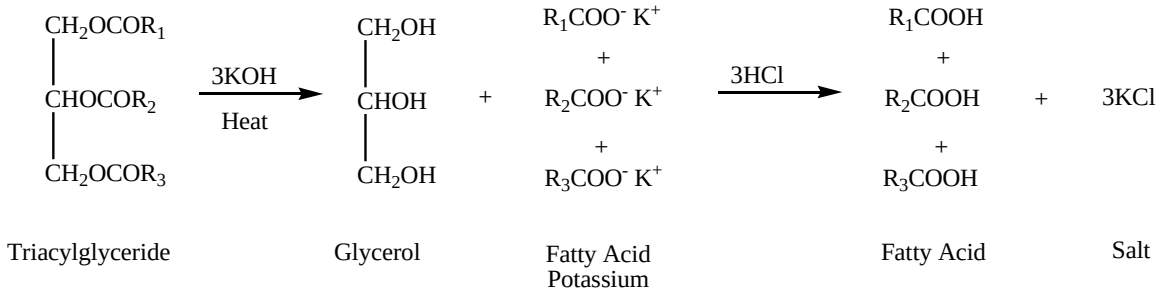

Figure 1. Hydrolysis process of triacylglycerol in plant oil

Based on the previous studies, there are several researchers who have carried out the hydrolysis process of plant oil in such as Bahadi et al. [4], who used different ethanolic KOH concentration, time and temperature for the optimization of the hydrolysis of crude palm kernel oil. The results of the study found that the free fatty acid (FFA) and yield obtained were 98% and 84.7% respectively with the optimum condition being 2.16 hours, 1.77 M ethanolic KOH at a temperature of 70 °C. Nor et al. [13] carried out hydrolysis of RBD palm oil using base catalyst. The conditions used were 1.5 M ethanolic KOH, 2.0 hours at a temperature of 60 °C and the yield produced was 95%. Ferreira et al. [14] also conducted the hydrolysis process of cottonseed, olive and palm kernel oil by using lipase enzyme from *Geotrichum candidum* (GCL-1) as catalyst. The result showed that GCL-1 gave the highest activity of hydrolysis only for plant oil that contained high amount of unsaturated fatty acids (cottonseed and olive oil) with optimum condition at 46.8% m/m oil, 6.6

U/g of reaction mixture at 40°C. In another study, Salimon et al. [8] carried out hydrolysis for preparing fatty acids from *Jatropha curcas* seed oil. The result of the study showed that the maximum recovery of FFA was 102.2% and the optimum condition were 1.75 M ethanolic KOH, 2.0 hours at a temperature of 65°C.

This research focus on using D-optimal design from response surface methodology for optimization process for hydrolysis of sunflower oil. Previous studies on the hydrolysis of sunflower oil focus more on using enzyme as catalyst [15, 16] and the used of base catalyze (potassium hydroxide) is limited. Most of the optimization process is done using conventional methods. There is no study done using the statistical method for hydrolysis of sunflower oil via D-optimal design.

Response Surface Methodology (RSM) is a practical method that uses mathematical and statistical analysis to fit empirical models to experimentally collect data [17]. The RSM can be used to optimize the reaction process since, in comparison to conventional method, it minimizes the overall number of experimental trials, operational costs, and time [10]. Typically, the prediction of responses in optimization process are specifically based on linear and quadratic models as shown in equation (1). As a result, an optimization study can be carried out to evaluate the experimental condition.

$$Y = \beta_0 + \Sigma\beta_i x_i + \Sigma\beta_{ii} x_i^2 + \Sigma\Sigma\beta_{ij} x_{ixj} \quad (1)$$

Where Y for response, β_0 for constant, β_i for linear, βii for square regression coefficient and β_{ij} for interaction regression coefficient and x_i and x_{ixj} are assigned as independent variables [18, 19]. D-optimal design is a useful tool to determine the factors that are significant to the experimental condition to achieve the best performance. The concept of D-optimal design exhibits remarkable flexibility and efficiency by accommodating a wide range of factors, both in terms of quantity and characteristics, as well as diverse levels of factor configurations and model specifications. It uniquely maximizes the determinant of the information matrix associated with the model, thereby systematically selecting the most informative experimental runs from a given set of candidates. This paper offers details on practical use for D-optimal design to optimize the hydrolysis of sunflower oil to obtain sunflower oil fatty acids (SFOFAs). D-optimal design was applied by using percentage yield and free fatty acids as responses to determine the optimal conditions for the hydrolysis.

Materials and Methods

Sunflower oil was obtained from IKO company, Negeri Sembilan, Malaysia. Potassium hydroxide (KOH), hydrochloric acid 37% (HCl), n-hexane 99%, ethanol 95% and anhydrous sodium sulphate (Na_2SO_4) were purchased from Systerm chemical Co, Malaysia. All chemicals utilized were analytical reagent grade and used without the need for additional purification steps.

Hydrolysis of sunflower oil

The hydrolysis of sunflower oil (SFO) involves two stages which are saponification and acidification. The hydrolysis was carried out using sunflower oil (SFO) with alkaline ethanol to produce sunflower oil fatty acids (SFOFAs). At saponification stage, 12.5 grams of SFO was mixed with 75 mL of alkaline ethanol into 250 mL two neck round bottom flask equipped with a reflux condenser, thermometer and mechanical stirrer. The mixture was heated and continuously stirred at 300 rpm using magnetic stirrer. After that, the mixture undergoes acidification process where 25 mL of hydrochloric acid was added to neutralize the alkaline solution. The washing continues by adding 50 mL of distilled water and 25 mL of n-hexane. After washing, anhydrous sodium sulphate was added to the product (SFOFAs) for overnight and the product was filtered using Whatman No 1 filter paper and the solvent was removed by using rotary evaporator [20]. At the next stage, the percentage free fatty acid (FFA) of SFOFAs was determined.

Optimization of hydrolysis

Software from Design Expert version 13 was employed for this optimization. There are three parameters used in the optimization of hydrolysis, namely the molarity of catalyst used (ethanolic KOH) (A), reaction temperature (B) and reaction time (C). The range used for the molarity of ethanolic KOH was 1.0 M to 2.5 M, the range for reaction temperature was 50 to 70 °C and the

range for reaction time was 0.5 to 2.5 h as shown in Table 1. The implementation of hydrolysis reaction based on D-optimal design in response surface methodology has generated 20 runs randomly for the hydrolysis of sunflower oil (SFO). Each experiment was carried out according to the parameter conditions set by the design model to obtain the responses, which were percentage yield and percentage FFA of SFOFAs. A regression coefficient R^2 was used to evaluate the model's adequacy and best fit [21].

Table 1. Parameter and level for D-optimal design of hydrolysis

Parameter	Unit	Symbol	Variable Level		
			-1	0	+1
Molarity ethanolic KOH	M	A	1.0	1.75	2.5
Temperature	°C	B	50	60	70
Time	h	C	0.5	1.5	2.5

Determination of percentage free fatty acids

Percentage of free fatty acids (FFA) were determined based on the study by Japir et al. [22]. 0.5 gram of oil sample was weighted, and 50 mL of neutralized isopropyl alcohol was added into the conical flask. The mixture was heated up to 40 °C until it fully dissolved. Then, 1 mL of indicator (phenolphthalein) was added to the mixture. Next, the mixture was titrated with 0.1N NaOH until light pink color appeared. The percentage FFAs as oleic acid was calculated using equation (2) below:

$$\%\ FFA\ as\ Oleic\ Acid = \frac{28.2\ x\ N\ x\ V}{W} \quad (2)$$

Where N is normality of NaOH (Eq/L); V is volume of NaOH solution used (mL); and W is weight of oil sample (g).

Verification of the model

The fitness of the constructed model was evaluated by comparing the actual values of the SFOFAs yield and SFOFAs FFA at optimum conditions with the predicted values. The model was validated using the value of Residual Standard Error (RSE), where the value cannot exceed more than 5% [17]. The percentage of RSE was calculated using equation (3).

$$\%\ RSE = \frac{(actual\ value - predicted\ value)}{predicted\ value}\ x\ 100 \quad (3)$$

Structure analysis of sunflower oil and sunflower oil fatty acids

Fourier Transform infrared spectroscopy (FTIR) and Nuclear Magnetic Resonance (NMR) were used to determine the functional groups and identify the structure of SFO and SFOFAs, respectively. Perkin Elmer Infrared spectrometer was used for FTIR in the range of 650 to 4000 cm^{-1}. NMR analysis was carried out using a JOEL-ECP 400 spectrometer at 400 MHz (^{1}H NMR) and 100.61 MHz (^{13}C NMR) and deuterated chloroform ($CDCl_3$) was used as a solvent.

Results and Discussion

Hydrolysis of sunflower oil

The hydrolysis of SFO with ethanolic KOH produced SFOFAs. The aim of this optimization is to produce a high percentage yield and high percentage FFA of SFOFAs. Table 2 shows the tabulated 20 experimental runs with results for both actual and predicted responses, namely the percentage yield of SFOFAs annotated as Y_1 and the percentage of FFA of SFOFAs annotated as Y_2 based on the conditions that have been generated from D-optimal design. The actual response values are almost equal to the predicted response values.

Table 2. Experimental runs, factors and responses of SFOFAs from D-optimal design

Run	Factors			Responses			
	Molarity Ethanolic KOH (M)	Reaction Temp. (°C)	Reaction Time (h)	Yield, Y_1 (%)		FFA, Y_2 (%)	
				Actual	Predicted	Actual	Predicted
1	1.7	50	1.60	95.81	95.08	100.03	100.28
2	1.0	57	2.50	82.70	82.36	88.93	88.58
3	2.4	60	0.59	89.91	91.07	96.16	98.01

Model selection is made based on the highest polynomial order in which all terms are significant, and the model is not an alias. Table 3 and Table 4 show sequential model sum of squares of percentage yield and percentage FFA. By examining the sum of squares of the model for both response variables indicates that the quadratic model stands out. This is evident from the highest F-values observed, which are 18.61 for Y_1 and 9.89 for Y_2, as well as the lowest p-values recorded, specifically 0.0002 for Y_1 and 0.0024 for Y_2. The model's F-value indicates the superior explanatory capability of the research model for both response variables.

Table 3. Sequential model sum of squares of percentage yield response

Model selection is also made based on the non-significant lack of fit value. Table 5 and Table 6 show lack of fit tests for percentage yield and percentage FFA. The value for lack of fit analysis is opposite to the value of the sequential analysis of the sum of squares where the lack of fit analysis gives the smallest F-value and the largest p-value or is not significant (>0.05) Based on the analysis of lack of fit, it shows that the quadratic model is the suitable model for the both responses based on the non-significant p-values.

Figure 2 shows the actual and predicted value of percentage yield (a) and percentage FFA (b) of SFOFAs. It shows that the plot is scattered along the straight regression line. The normal probability plot proves the accuracy of the individual experimental done.

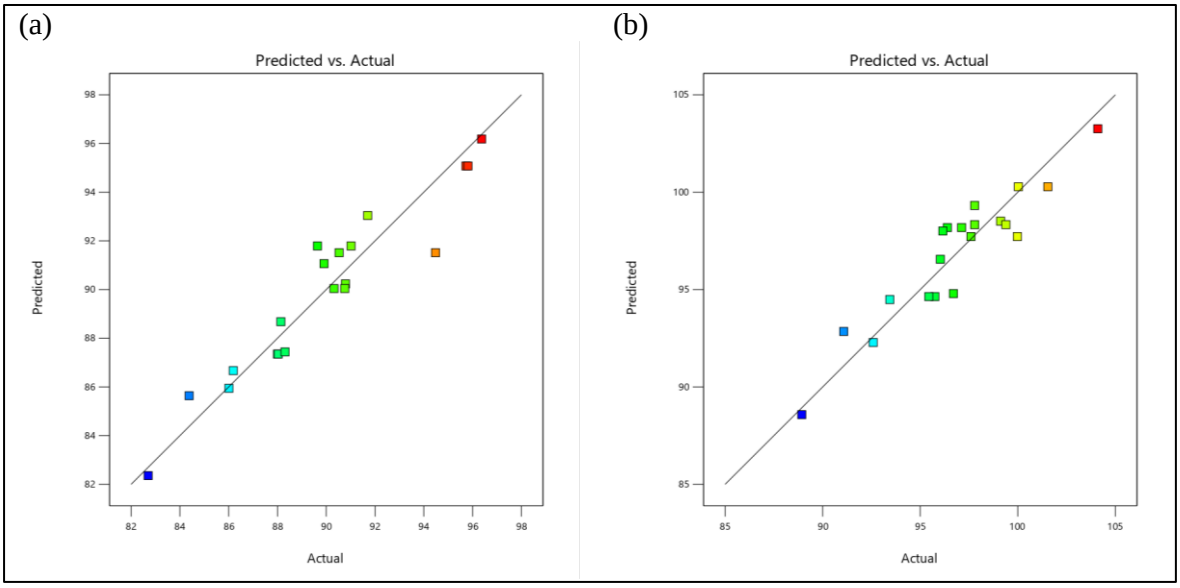

Figure 2. Actual and predicted value for a) SFOFAs yield and b) SFOFAs FFA

D-optimal design fitting

The ANOVA data analysis for percentage yield and percentage FFA of SFOFAs are shown in Table 7. The SFOFAs yield (Y_1) and SFOFAs FFA (Y_2) with p-values of 0.0004 (Y_1) and 0.0017 (Y_2), which are less than 0.05, indicate that the model for both responses are significant. The model F-values of 11.09 (Y_1) and 7.85 (Y_2) imply the model is also significant. Based on the F-values, there are only a 0.04% (Y_1) and 0.17% (Y_2) chances that an F-value this large could occur due to noise. The R^2 value for Y_1 is 0.91 and for Y_2 is 0.88. The model shows an adequate precision ratio of 12.6511 for Y_1 and 12.0673 for Y_2. Both adequate precision for Y_1 and Y_2 are desirable, which imply an adequate signal due to the value are greater than 4. Furthermore, the lack of fit for both Y_1 (0.2877) and Y_2 (0.0671) are not significant with p-value more than 0.05 which indicates that the model is satisfactorily fitting. The equation for regression line that are suggested by the model design for percentage yield of SFOFAs (Y_1) and percentage FFA of SFOFAs (Y_2) are shown in equation (4) and (5).

$$\text{Yield } (Y_1) = 93.35 + 1.52A - 1.28B - 1.96C - 2.90AB - 4.11A^2 - 3.58C^2 \quad (4)$$

$$\text{FFA } (Y_2) = 99.70 + 1.81A - 1.89C - 3.37AB - 2.56A^2 - 3.72C^2 \quad (5)$$

ANOVA analysis from the Table 7 shows for the Y_1, the linear relationship between three variable parameters which are the molarity ethanolic KOH (A) and the reaction temperature (B) are significant (p-value < 0.05) and the reaction time (C) is highly significant (p-value < 0.01). The interaction between the three parameters (AB, AC, BC) has been seen to be highly significant for AB (p-value < 0.01) but the interaction between AC and BC are not significant (p-value > 0.05). For Y_2, the linear relationship between parameters A, B and C shows that A and C are highly significant (p-value < 0.01) while B is not significant (p-value > 0.05). The interaction between AB, AC and BC shows that only AB is highly significant while AC and BC are not significant. For both Y_1 and Y_2, only the interaction between molarity ethanolic KOH (A) and reaction temperature (B) gives an effect in this optimization of hydrolysis.

Response surface analysis

The interaction effect between the reaction variables (A, B and C) on the percentage yield and percentage FFA of SFOFAs can be illustrated by using 3D response

surfaces and contour graphs. Figure 3 shows the interaction effect between ethanolic KOH molarity and reaction temperature (AB) on SFOFAs yield and SFOFAs FFA. Figure 3(a) shows that as the molarity of ethanolic KOH increases from 1 to 1.7 M, the percentage yield increases, but the percentage yield decreases as the molarity of ethanolic KOH increases from 1.7 to 2.5 M. As the temperature increases from 50 to 70°C, the percentage yield decreases. Increasing the molarity of ethanolic KOH and temperature cause the percentage yield to decrease. High temperatures can cause the breaking down of molecules (thermal degradation) and using high concentration of ethanolic KOH can lead to additional unwanted reactions, like excessive saponification. Figure 3(b) shows that the higher the molarity of ethanolic KOH and the reaction temperature, the lower the percentage of FFA. The 3-D surface contour has illustrated the maximum for both SFOFAs yield (Y_1) and SFOFAs FFA (Y_2) can be reached at a lower level of 50°C reaction temperature, and at the upper level of 2.3 M for molarity of ethanolic KOH.

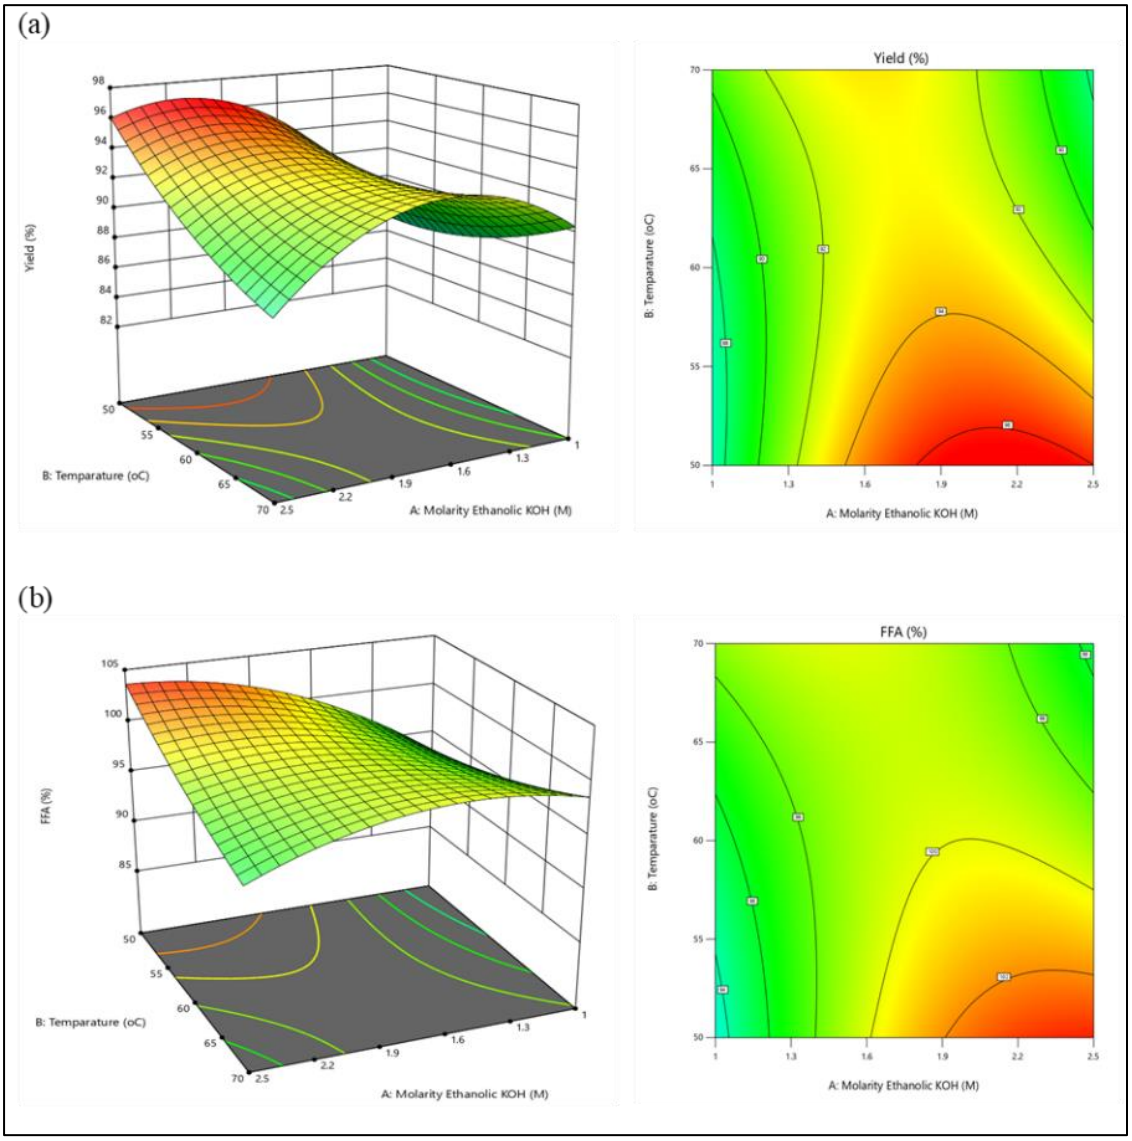

Figure 3. 3D surface and contour plot of molarity ethanolic KOH vs reaction time (AB) for a) percentage yield and b) percentage FFA

D-optimal design model verification

The numerical optimization was carried out to determine the optimum condition for hydrolysis of sunflower oil. The parameters A, B and C have been set in range to obtain the maximum percentage yield and percentage FFA of SFOFAs. The higher the desirability of the functions, the more accurate the model. Table 8 summarizes the limitation applied to obtain the optimum condition setting for higher percentage yield and higher percentage FFA of SFOFAs. The parameters A, B and C were set in a range while the responses were set at the maximum value. The desirability of the predicted model is equal to 1.00, which indicates that the model gives the ideal value. Figure 4 shows the estimated prediction from the numerical optimization model for hydrolysis of SFO.

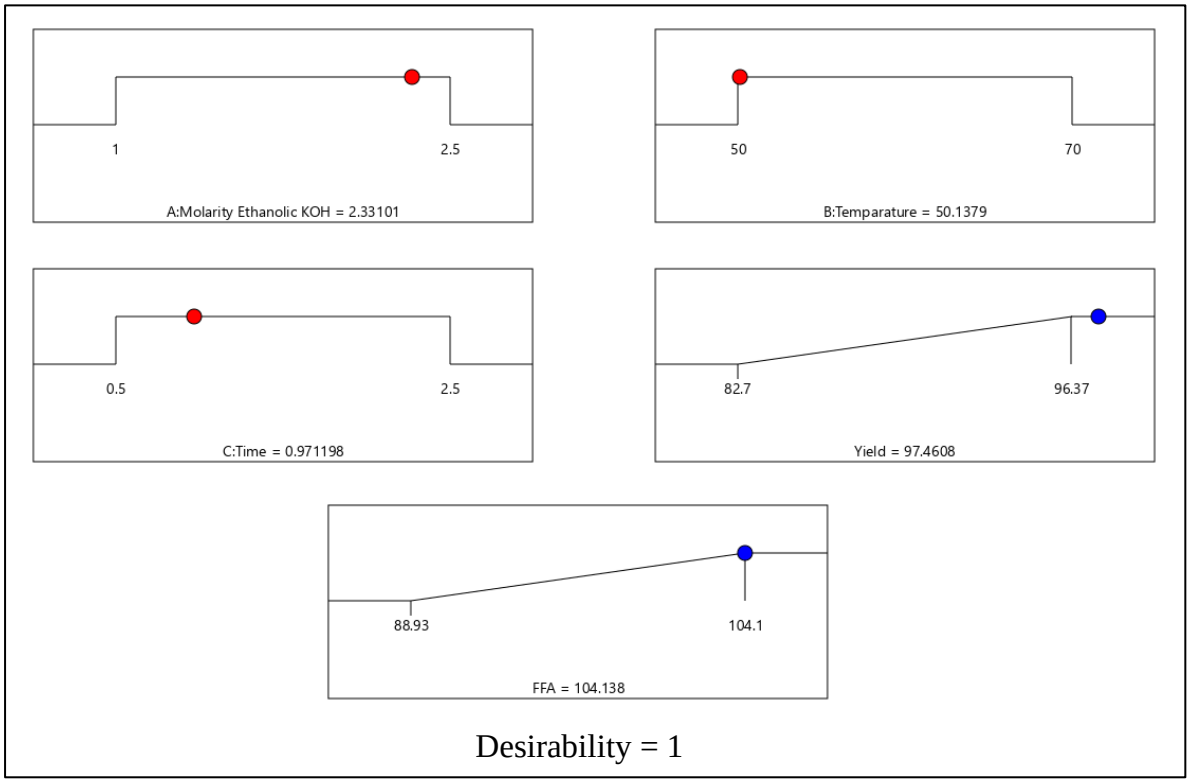

Figure 4. D-optimal predicted model at optimum condition for the hydrolysis of SFO

The suitability of the model generated from D-optimal design has been proven and verified by carrying out the hydrolysis process from three sets of reaction conditions that were chosen randomly. The actual and predicted value was compared by calculating the Residual Standard Error (RSE) value for each experiment and was only accepted if the value did not exceed 5%. The result from the Table 9 shows that all RSE values are less than 5%, indicating that this model is acceptable.

The predicted optimum condition from D-optimal design for hydrolysis of SFO was successfully acquired at 2.3 M of molarity ethanolic KOH, reaction temperature of 50.14 °C for 0.97 hour. Under this reaction condition, 96.68% SFOFAs yield with 103.23% of SFOFAs FFA were obtained. Table 10 shows the actual and predicted data for optimum condition. The validation of the optimum condition has been done with the RSE calculated, showing that the value was less than 5% where 0.80% for SFOFAs yield and 0.87% for SFOFAs FFA.

Table 7. ANOVA analysis data and regression model for hydrolysis of SFO

Comparison between current work and existing literature

Increasing temperature leads to a general acceleration of the hydrolysis rate due to heightened kinetic energy in molecules. Elevated temperatures facilitate more robust collisions between oil and hydroxide (OH) molecules, thereby promoting the cleavage of ester bonds within the oil [23]. Similarly, extending the reaction time also results in a higher yield of hydrolysis. The molarity of the catalyst plays a pivotal role in enhancing the hydrolysis yield. Elevating the catalyst's molarity increases the yield of hydrolysis by providing an alternative reaction pathway with lower activation energy. The outcomes of the experiment revealed a percentage yield of 96.68% for SFOFAs, accompanied by a 103.23% of free fatty acids (FFA) from SFOFAs, achieved under optimal conditions. These optimal conditions encompassed a molarity of 2.3 M for molarity of ethanolic KOH, a reaction temperature of 50.14°C, and a reaction duration of 0.97 hours. By comparison, the study contrasted with previous findings, **by** Bahadi et al. [4] wherein the yield of palm kernel oil was 84.7%, accompanied by a 98% percentage of free fatty acids, realized under optimal conditions of 2.16 hours, a temperature of 70°C, and a molarity of 1.77 M ethanolic KOH. Notably, the temperature and reaction duration in the present experiment were observed to be lower than those of the referenced study. This discrepancy can be attributed to the utilization of a higher molarity of ethanolic KOH in the current study compared to the study conducted by [4]. This distinction underscores the influence of elevated ethanolic KOH molarity in effecting a reduction in both reaction temperature and duration for the hydrolysis process.

FTIR analysis of SFO and SFOFAs

FTIR spectroscopy was used to determine the functional groups in SFO and SFOFAs before and after hydrolysis. Figure 5 shows the FTIR spectra of SFO and SFOFAs and Table 7 shows the functional group and wavenumber of SFO and SFOFAs FTIR spectra. Before hydrolysis (SFO), a sharp peak appeared at 1746.33 cm^{-1} indicating stretching vibration for C=O (ester carbonyl). After hydrolysis (SFOFAs), the peak for C=O (ester carbonyl) has disappeared, and a new sharp peak appeared at 1710.23 cm^{-1} indicating stretching vibration for C=O (carboxylic acid) and broad OH peak for COOH appeared at range 2400 to 3400 cm^{-1} which showed hydrolysis has successfully converted the ester to carboxylic acid.

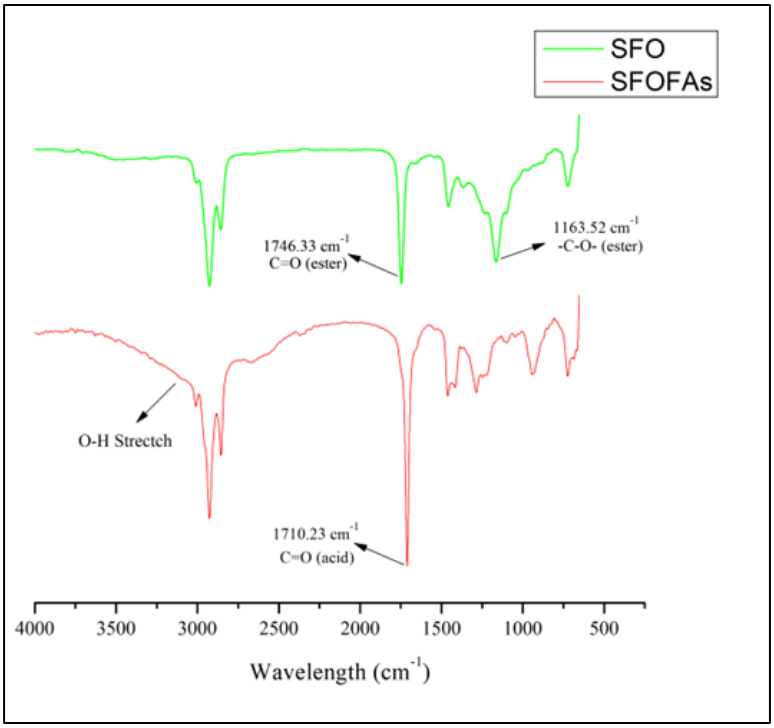

Figure 5. FTIR spectra of SFO and SFOFAs

Table 11. Functional group and wavenumber of FTIR spectra of SFO and SFOFAs

Functional Group	Wavenumber (cm^{-1})	
	SFO	SFOFAs
OH stretching (carboxylic acid)	-	2400-3400
C=C bending vibration (aliphatic)	3007.93	3007.93
C-H stretching vibration (aliphatic)	2926.56, 2857.78	2926.93, 2856.16
C=O stretching vibration (ester)	1746.33	-
C=O stretching vibration (carboxylic acid)	-	1710.23
-C-O stretching vibration (ester)	1232.81, 1163.52	-
-C-O stretching vibration (carboxylic acid)	-	1292.04, 1249.00

NMR analysis of SFO and SFOFAs

NMR has been used to elucidate the structure of SFO and SFOFAs. Figure 6 shows the ^{1}H NMR spectra of SFO and SFOFAs and ^{1}H NMR chemical shift of SFO and SFOFAs represented in Table 8. There are three peaks that have been focused on to determine whether the ester is successfully converted to fatty acid. From the ^{1}H NMR spectrum of SFO, two important peaks appeared at the range of 4.14-4.18 ppm and 4.29-4.33 ppm that signified the presence of -CH_2-COOR- and -CH-COOR- respectively. These two peaks represented proton from glycerol backbone in SFO and these two peaks diminished in ^{1}H NMR spectrum of SFOFAs indicating the hydrolysis process was successfully carried out. New peak appeared at downfield region around 10.61 ppm in ^{1}H NMR spectrum of SFOFAs, which confirmed the formation of fatty acid (-COOH) in SFOFAs. Since both SFO and SFOFAs dissolved in deuterated chloroform ($CDCl_3$), the solvent peak appeared at 7.28 ppm. Another type of proton has been tabulated in Table 8.

^{13}C NMR spectra and chemical shift of SFO and

SFOFAs were shown in Figure 7 and Table 9, respectively. There are several prominent peaks at 62.09 ppm (-CH_2-O), 68.90 ppm (-CH-O) and 172.79-173.21 ppm (O=C-OR) from SFO spectrum and peak at 180.45 (O=C-OH) from SFOFAs spectrum. Carbon for -CH_2-O- and -CH-O comes from the glycerol backbone in SFO. These two peaks disappeared at SFOFAs spectrum showing that the glycerol backbone had been removed. Peak at 172.79-173.21 ppm corresponding to O=C-OR ester had shifted to downfield region at peak 180.45 ppm corresponding to carboxylic acid in SFOFAs spectrum showing ester had been converted to fatty acid. Solvent peak ($CDCl_3$) was determined at 76.71-77.36 ppm. Table 7 shows another type of carbon present in SFO and SFOFAs. Chemical shift for peaks obtained for ^{1}H NMR and ^{13}C NMR are in a good agreement with the theoretical values.

*[24]

Conclusion

The hydrolysis process of sunflower oil with ethanolic KOH was successfully carried out to produce the sunflower oil fatty acids. The process responses of SFOFAs yield and SFOFA FFA were improved during the optimization process using D-optimal design from response surface methodology. The optimum condition for hydrolysis of SFO was successfully acquired at 2.3 M of molarity ethanolic KOH, reaction temperature of 50.14 °C for 0.97 hour and produced 96.68% yield with 103.23% of FFA. The RSE value of less than 5% indicates that the model design produced was suitable.

Abstract

Owing to the intricate nature of cancer treatment, traditional herbal medicines are being regarded as potential anticancer agents, primarily due to their reported low toxicity in normal cells. With this in mind, this study's primary objective was to identify the constituents present in the semi-purified 15% ethyl acetate fraction of *Morus rubra* bark (**M1**) and to investigate its antiproliferative property on immortalized cell lines (HT- 29, HepG2, BxPC-3, MCF-7, HeLa, and THP-1) by an *in vitro* cell viability assay with Zeocin and dimethylsulfoxide (DMSO) as the positive and negative controls. The chemical constituents present in **M1** were identified using gas chromatography-mass spectrometry (GC-EI-MS). The NIST library v 2.0 was used to putatively identify the thirteen (13) compounds observed in the GC-EI-MS chromatogram which were primarily tocopherols (27.58%) and phytosterols (44.06%). **M1** exhibited high cytotoxicity in HepG2 cell lines (IC_{50} = 7.09 µg/mL) and was followed by MCF-7 (IC_{50} = 7.12 µg/mL), HT-29 (IC_{50} = 7.98 µg/mL), HeLa (IC_{50} = 16.63 µg/mL), BxPC-3 (IC_{50} = 16.89 µg/mL) and THP-1(IC_{50} = 17.43 µg/mL). **M1** did not exhibit cytotoxicity on normal HDFn while Zeocin on normal cells were exceedingly disruptive. The data generated from this work suggests that **M1** could be an effective chemotherapeutic agent due to the presence of phytosterols and tocopherols.

Introduction

Mulberry, which is under the botanical order Rosales, family Moraceae, and genus *Morus*, is found in many areas of the world specifically in the sub-tropic regions of Asia such as Japan, India, China, and Korea as well as other regions, for instance North America and Africa [1]. The practice of mulberry cultivation using diverse morphological cultivars is estimated to have started around 400-500 years ago [2]. Several studies have documented the aqueous, methanolic, and ethanolic extracts of *Morus* species. The phytochemicals obtained were characterized to demonstrate several bioactivities

such as anti-oxidative, anti-diabetic, anti-stress, nephroprotective, antimicrobial, anti-mutagenic, anticancer, anxiolytic, hepatoprotective, anthelmintic, antimicrobial, immune-modulatory and cholesterol lowering effects [1].

Organic acids, sugars, flavonoids, alkaloids, steroids, some vitamins, and minerals such as Na, K, Fe, P, Mg, S were found in the extract of the *Morus* genus [2, 3]. It was also indicated that genetic, cultural, and ecological factors can influence the percentage composition of the compounds isolated from extracts of the Morus genus. Among the species under the genus, *M. nigra* (black mulberry), *M. rubra* (red mulberry), and *M. alba* (white mulberry) are the most recognized cultivated species of mulberry due to its availability and use in traditional medicines for diseases such as rheumatoid arthritis and the common cold [1].

The fruit of the mulberry species specifically *M. rubra* (purple), *M. nigra* (black) and *M. alba* (white), were found to contain higher vitamin C content for lighter colored species compared to the darkly colored species. The darkly colored berries demonstrated a higher total antioxidant capacity (TEAC) compared to the lighter colored berries due to the presence of anthocyanins. Previous reports have shown that anthocyanin pigments are medically beneficial due to their antioxidant capacity which can prevent or reduce free radical induced damage and inflammation [4-7]. Flavonoids such as rubraflavones A, B, C, and D were likewise isolated from *M. rubra*. These compounds are known to be antihyperglycemic phytochemicals which induce insulinogenic action [8, 9]. Further, the presence of phenolic acids in the fruit, such as cinnamic acid, were found to contribute to the antioxidant property of the plant and to neutralize carcinogenic substances such as nitrosamine. Among the three species, *M. nigra* exhibited the highest phenolic acid content [5, 7].

Glucopyranosides isolated from an ethanolic extract from the leaves of *M. alba* inhibited HL60 cell line proliferation and initiated an immune response which caused the differentiation in the expression of the CD66b and CD 14 antigens [7]. The rich quercetin content in the leaf of *M. alba* prevented P-glycoprotein (P-gp) production in the tumor's ATP-dependent pump which was construed to be responsible for exporting xenobiotic compounds out of the cell which may be the cause of multidrug resistance (MDR) of some aggressive malignant tumors [7].

M. rubra leaf extract's anticancer property was correlated with its ability to cause the accumulation of cells at the G1 phase via inhibitory action or through down-regulation of cyclins and kinases (CDKs)10. As a result, the said extract attenuated cell population at the S phase where DNA synthesis occurs. Additionally, *M. rubra* leaf extracts induced apoptosis by matrix metalloproteinase (MMP) depolarization in a dose-dependent manner as well as the inhibition of human telomerase reverse transcriptase (hTERT) expression, which caused the cessation of the proliferation of cancer cells [10]. *M. rubra* extract presented modest discriminating cytotoxicity on WiDr cells assessed along with foreskin fibroblast cells [11]. In fact, the aforementioned *M. rubra* extracts at 600 mg/mL dilution considerably amplified cell numbers at the G0/G1phase [11].

A study by Abbas et al. [12] reported a new stilbene, 2',3',4',5',5'-pentahydroxy-cis-stilbene isolated from the ethanol fraction which was obtained from the methanol extract of *M. nigra* stem bark. The new stilbene exhibited an effective antioxidant activity with an IC_{50} of 4.6 μM. The isolation of prenylated flavonoids from the stem bark of *M. nigra* extract from several distinct fractions (n-hexane, dichloromethane, and ethanol) was also reported. To the best of our knowledge, this is the first study aimed to provide the characterization and the investigation of the cytotoxicity on selected immortalized cell lines from a semi-purified extract prepared from the dried bark of the red mulberry species.

Materials and Methods

Plant material

M. rubra bark (Figure 1) was gathered from Abucay, Bataan, Philippines (14.7128° N, 120.4934° E) on well-cultivated arable land. The plant identity was established and validated by the Bureau of Plant Industry in Malate, Manila, Philippines.

Figure 1. Images of *Morus rubra* Linn

GC-EI-MS analysis

Dried *M. rubra* bark (3 g) was ground and extracted with methanol. The mixture was filtered using filter paper (Whatman 91) and then desolvated under nitrogen for one hour. The crude extract was reconstituted in 5% ethyl acetate in petroleum ether (PE). The resultant solution underwent separation using 5% increments of 5% ethyl acetate in PE as an eluent through column chromatography. The semi-purified fraction collected from 15% ethyl acetate in PE (2.9 mg) was then reconstituted and filtered through a syringe with a 0.45 μm nylon membrane and labeled as **M1**.

M1 was explored using an Agilent gas chromatograph-mass spectrometer (GC-MS) 7890B, by an HP-5ms (5% phenyl methyl siloxane) Ultra Inert column (30 m x 250 mm x 0.25 mm) and ultra-pure helium gas as the carrier gas to examine the vaporizable components. Helium gas constraints were stipulated using the following parameters: flow rate of helium gas was at 1 mL/min, the pressure kept at 8.2 psi, with an average velocity of 36.62 cm/sec and a holdup time of 1.37 min. The splitless inlet was conserved at 250 °C at 8.2 psi, with a total flow of 24 mL/min, and a septum purge flow speed of 3 mL/min. The injector temperature was maintained at 250 °C. The temperature gradient was initially at 70 °C with an automated linear ramp of 2 °C / min until 135 °C and was continued at this temperature for 10 minutes. Additional temperature changes were attained at 4 °C / min until 220 °C and were retained for 10 minutes. The temperature was then augmented to 270 °C at a 3.5 °C / min rate and was continuous for 37 minutes [13].

NIST library, v. 2.0 was used to identify the compounds, and the average percentage of the peak area was managed from the subsequent total ion chromatograms. The consequent data was established by assessing the analytes according to their elution succession on a non-polar stationary phase. A homologous series of *n*-alkanes was used to calculate the retention indices for each compound's entirety observed in the spectrum. The experiments were undertaken in three replicates.

Cell viability assay

The **M1** fraction obtained through the extraction technique previously described in the GCMS experiments was used for the PrestoBlue-based cytotoxicity assays on the preceding human cancer cell lines (ATCC, Manassas, Virginia, U.S.A.): colon adenocarcinoma (HT-29), hepatocarcinoma (HepG2), pancreatic adenocarcinoma (BxPC-3), breast adenocarcinoma (MCF-7), cervical adenocarcinoma (HeLa), and acute monocytic leukemia (THP-1). The primary culture of normal human dermal fibroblast neonatal (HDFn) (ThermoFisher Scientific, Gibco®, USA) was utilized as normal cell control. The cells were maintained and provided by the Cell and Tissue Culture Laboratory, Molecular Science Unit, Center for Natural Sciences and Environmental Research, De La Salle University. Cells were cultured in complete DMEM

(Dulbecco's Modified Eagle Medium with 10% fetal bovine serum and 1X antibiotic-antimycotic) (Thermo Fisher, Invitrogen, USA) and were incubated at 37°C with 5% CO_2 in a humidified chamber. The *in vitro* assays' constraints were described in our formerly published work [12] and stringently followed the protocols described therein. Zeocin (Thermo-Fisher, Invitrogen, USA), a cytotoxic intercalating agent, was used as positive control while DMSO was applied as negative vehicle control. All tests were performed in three replicates. Optical density ($O.D._{570\ nm}$) readings were utilized to determine cytotoxicity indexes, which were plotted against log concentrations from which the half-maximal inhibitory concentrations (IC_{50}) were derived. GraphPad Prism version 8.02 (GraphPad Software, Inc., USA) was applied to plot the non-linear regressions and was also employed for statistical analysis using ANOVA with Tukey's post-hoc assessment in an alpha of 0.05 level of significance.

Results and Discussion

GC-EI-MS characterization of M1 fraction

GC-EI-MS was used to identify the chemical constituents present in the 15% ethyl acetate in PE of **M1** fraction**.** As observed in the GC chromatogram, thirteen volatile components were identified and verified through the NIST library for spectral library matching and comparison of retention indices (RI) [14] (Figure 2). Identified compounds (Table 1) were listed according to their elution succession through a HP-5ms column. The **M1** fraction comprised the following constituents: tocopherols: [2R-[2R*(4R*,8R*)]]-2H-1-benzopyran-6-ol,3,4-dihydro-2,8-dimethyl-2-(4,8,12 trimethyl tetradecyl) or δ-tocopherol (3.36%), γ-tocopherol (7.40%), vitamin E (20.18%); diterpene: phytol (16.42%); diterpene acetate: phytol acetate (2.04%); and triterpenes: squalene (3.87%), γ-sitosterol (11.61%), β-amyrin (1.36%), lanosterol (3.87%), Lupeol (6.14%) and 3 β-D:B-friedo-B':A'-neogammacer-5-en-3-ol (6.81%); triterpene acetate:3β-lanosta- -8-24-dien- 3-ol acetate (9.50%) and 3 β -lup-20(29)-en-3-ol acetate (6.81%).

Major classes of compounds that were detected from the **M1** fraction included triterpenes and tocopherols, which are known to have several biochemical properties. The constituents identified from the extract are also known to exhibit cholesterol-lowering, anti-inflammatory, antibacterial, anti-ulcerative, and antiproliferative effects.

[a]Retention Index (HP-5ms column)

Cytotoxicity assessment of M1:

The examination of the antiproliferative capacity of **M1** on normal HDFn cells ensued no observable cytotoxicity, which afforded an IC_{50} value exceeding 100 µg/mL. Figures 3 and 4 show graphical representations of the percent cell viability as a function of the logarithm (log_{10}) of the concentrations. The characteristic inhibitory dose-response sigmoidal curve or distribution was exhibited in the majority of the plots. Charts reflecting the inhibitors' cytotoxic action on the specific cell lines' viability are displayed in Figure 4. The half-maximal inhibitory concentrations (IC_{50}) of the agents used are presented in Table 3.

One-way ANOVA on HT-29 trials showed that the paired treatments of **M1** versus Zeocin were similar ($p > 0.05$) and **M1** versus DMSO were dissimilar ($p < 0.05$). Statistical evidence also pointed out that there was similarity in the mean of **M1** (M = 7.98, SE = 1.15) and the mean of Zeocin (M = 11.60, SE = 1.08) but was different for DMSO trials (M > 100, SE = 37.93). The outcome revealed that the cytotoxicity of the inhibitors **M1** and Zeocin was analogous.

HepG2 tests presented that **M1** cytotoxic action was akin to Zeocin activity and found no significant differences ($p > 0.05$) as seen in post hoc data. Conclusions for the nonlinear fitting of the log (inhibitor) vs. normalized response using variable slope analyses illustrated that **M1** (M = 7.09, SE = 1.13) and the mean of Zeocin (M = 1.05, SE = 1.05) were similar in action but was markedly unlike DMSO trials (M > 100, SE = 5.85).

The cytotoxic action of **M1** on BxPC-3 experiments was typical of Zeocin activity ($p > 0.05$) as established in multiple comparisons. The means and standard error of the **M1** trials in BxPC-3 cells using the negative control DMSO (M > 100, SE = 2.33) were seen to be non-cytotoxic to these cells, whereas **M1** (M = 16.89, SE = 1.07) and the mean of Zeocin (M = 11.83, SE = 1.05) were comparable and were significantly distinct to DMSO tests.

Data generated using the inhibitor **M1** on MCF-7 cell lines indicated a half-maximal inhibitory concentration

of 7.09 µg/mL with a standard error of 1.07. Tukey's post hoc multiple comparison conveyed that there were considerable differences (p <0.05) in the means of the inhibitors **M1** and Zeocin (M = 8.85, SE = 1.06) to the negative control DMSO (M = >100, SE = 43.15). MCF-7 treated with **M1** and Zeocin were construed to be statistically alike (p >0.05).

One-way ANOVA analyses of the potential inhibitors on HeLa cells showed that the paired trials of **M1** vs. Zeocin were analogous (p > .05), and **M1** vs. DMSO were unrelated (p <0.05). Similarity the means of **M1** (M = 16.63, SE = 1.08) and Zeocin (M = 13.71, SE = 1.07) were noticeably different for DMSO trials (M > 100, SE = 1.96). The cytotoxic capacity of the inhibitors **M1** and Zeocin corresponded to each other. THP-1 presented the following IC_{50} data on the inhibitors: **M1** (M = 17.43, SE = 1.05); Zeocin (M = 8.15, SE = 1.05); and DMSO (M = >100, SE = 1.57). Multiple comparisons or Tukey's post hoc analyses expressed considerable differences (p <0.05) in M1 vs. DMSO and Zeocin vs. DMSO trials. The antiproliferative activity of **M1** and Zeocin on acute monocytic leukemia cells were found to be similar.

M1 was not cytotoxic to normal HDFn, with an IC_{50} value greater than 100 µg/mL. Post hoc comparisons of **M1** and human cell lines trials established that there were substantial variances, and that the null hypothesis (one curve for all data sets) was excluded (log IC_{50} the equivalent for all data sets). This was confirmed by the extra sum-of-squares F-test of the best-fit-parameter (IC_{50} concentration) between individual cell line experiments, F (6, 49) = 1.978, P = 0.0869, and to the observations in the dose-response curve fits F (12, 154) = 121.4, p <0.0001. Zeocin trials with each cancer cell line were observed to be similar (p >0.05). Zeocin a recognized cytotoxic proponent furnished IC_{50} values of 4.40, 11.60, 6.10, 11.83, 8.85, 13.71 and 8.15 µg/mL for HDFn, HT-29, HepG2, BxPC-3, MCF-7, HeLa, and THP-1, respectively and one-way ANOVA data disclosed similarity in the trials (p >0.05). Post hoc comparison of the half-maximal inhibitory concentration for the cancer cell line treatments also verified the results' congruency.

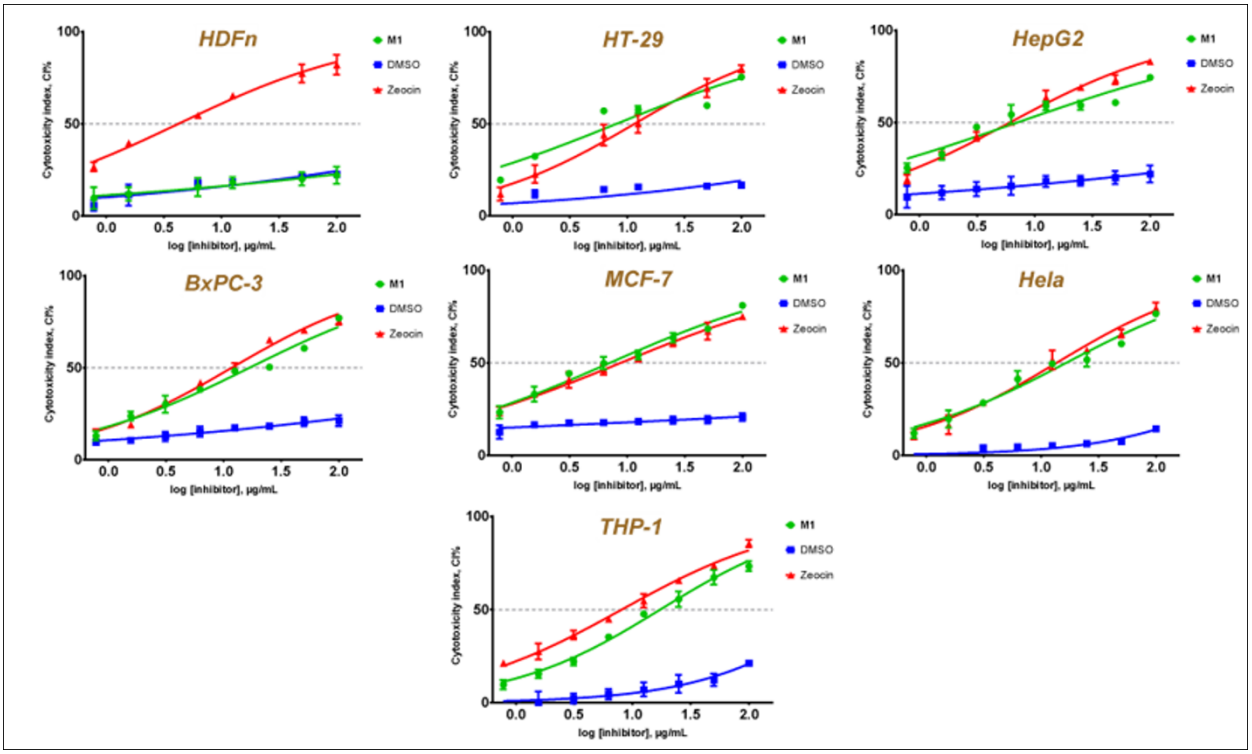
M1 presented the highest effectiveness towards HepG2 with a half-maximal inhibitory concentration of 7.09 µg/mL which was followed by MCF-7, HT-29, HeLa, and BxPC-3, which gave IC_{50} values of 7.12, 7.98, 16.63, 16.89 µg/mL, correspondingly. Substantial variances, as obtained in Tukey's post hoc multiple comparisons, were established in HT-29 vs. HDFn, HepG2 vs. HDFn, and MCF-7 vs. HDFn (p <0.05). The other paired treatments were deduced to be statistically similar (p>0.05). The figures of the subgroups of all the human cell lines and Zeocin demonstrated that the subcategories were comparable (p >0.05). It was found that HepG2, MCF-7, and HT-29 cancer cell lines were positively affected by **M1** and exhibited minimal half-maximal inhibitory concentrations (< 8 µg/mL), which were acquired for all of the trials. HeLa, BxPC-3, and THP-1 were moderately responsive to **M1**. Normal HDFn trials treated with **M1** were substantiated to be non-cytotoxic and presented half-maximal inhibitory concentrations of more than 100 µg/mL; while Zeocin on normal cells were exceedingly damaging as manifested in the IC_{50} = 4.40 µg/mL.

Results obtained from the cell viability assay of **M1** can be explained by the bioactivities reported from previous studies suggesting that phytosterols and tocopherols present in the extract can affect the signal transduction pathway in cancer cells. Targeted analyses have shown that phytosterols and tocopherols can prevent angiogenesis and induce apoptosis in tumor cells by an up-/down-regulating expression such as NF-κB [15] or by cell cycle arrest [16]. As observed in published studies, phytosterols are cytotoxic to common cancer cell lines such as breast (MCF-7) and colon (HT-29) which deemed phytosterols to be promising compounds against cancer. This is further confirmed by the ability of phytosterols to affect the following: inhibit angiogenesis; induce apoptosis (by controlling the cell proliferation process by cell cycle arrest); increase ceramide activities, protein phosphatase 2A (PP2A), and pro-apoptotic MAP kinase; and limiting the supply of nutrients to cancer cells [17, 18]. γ-Sitosterol was found to induce cell arrest in the G_2/M phase and cause apoptosis for MCF-7 and A549 cell lines by reducing the c-Myc expression [19]. The ability of phytosterols, such as those found in the isomers of sitosterol, to induce cell

arrest in the G_0/G_1 phase was believed to manifest the cytotoxic effect on the HT-29 cell line [20]. Another common phytosterol present in plants, lupeol, is known to have multiple-targeting capabilities that have the following properties: anti-inflammatory capability through different mechanisms; anti-diabetic effect by inhibiting the alpha-amylase; and anti-carcinogenic action as linked to the arrest of the cell cycle of cancer cells in G_2-M-phase. Lupeol was also established to induce apoptosis on different cancer cell lines through the following signal transduction pathways: Ras-induced protein kinase C-alpha/ornithine decarboxylase; p13K/AKt, MAPKs; and NF-κB signaling. Furthermore, lupeol activated an extrinsic apoptotic pathway by increasing the Fas receptor on prostate cancer. Lupeol has been heralded as a probable chemo preventive and anti-inflammatory agent by inhibiting hepatocellular carcinoma receptor 3 (DR 3) expression and reducing the production of IL-4 through T-helper type 2 cells, respectively [16].

The mechanisms linked to β-amyrin as an anti-inflammatory agent was found to be involved in the inhibition of NF-κB, activation of CREB, reduction of neutrophil filtration, curtailment of oxidative stress, and the depletion of the production of proinflammatory cytokine TNF-α for acute periodontal inflammation. Furthermore, β-amyrin induced a cytotoxic effect against human bladder cancer cells (NTUB1) when treated with cisplatin after 24 hrs. β-amyrin, which was isolated and purified from plants, hampered collagen-induced platelet aggregation with an IC_{50} value of 4.5ug/mL, which was comparable to the effects of aspirin (11 µg/mL) [21]. A polyunsaturated hydrocarbon triterpene, squalene, found to be present in the bark extract has been known to be an essential precursor for synthesizing phytosterols in plants specifically growth hormones, terpenoids, sterol, steroids, pigments, essential oils, and other defense compounds in the body. While the acyclic structure of squalene is responsible for connecting the lipid layers to the biological membrane's intermembrane, the structure of the molecule can scavenge free radicals by either donating or receiving electrons thereby preventing bio membrane damage [22, 23].

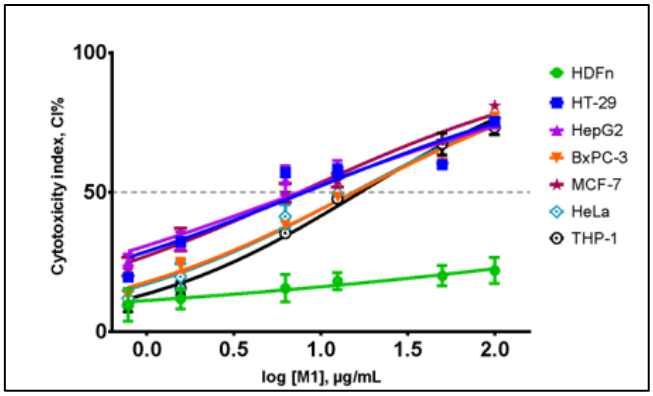
In addition to triterpenes, diterpenes have also been reported to exhibit antitumor effects. Phytol and its derivatives have often been reported as notable constituents of essential oils present in plants. Aside from being one of the components used in the formulation of fragrances, phytol is known to have multiple therapeutic functions such as anti-inflammatory, immune-modulating, antimicrobial, and cytotoxic as well as apoptosis-inducing effects in cancer cells. Since PPARs and NF-κB are known to be important regulators of inflammatory, immune response, and antiproliferative agents of cancer, phytol is perceived to be a modulator in the treatment of degenerative diseases [15].



Tocopherols have been communicated to affect human mastocytoma (HMC-1), MCF-7, U937 myeloid leukemia, and HT-29 cell lines. Vitamin E inhibits the proliferation of U937 by inhibiting the formation of oxLDL-induced macrophage foam cells by affecting the two expressions, NF-κB pathway and P-selection [24]. Among all tocopherols, delta-tocopherol induced apoptosis to HMC-1 cells at high concentrations. The proinflammatory response of reactive oxygen species (ROS) and stress-activated expressions, Nrf2 and NF-κB, are enhanced by delta-tocopherol. Delta-tocopherol also prevented lipid accumulation and antiangiogenic effects. Some studies imparted evidence that vitamin E could inhibit the proliferation of vascular smooth muscle cells by preventing PKC phosphorylation and stimulating platelet-derived growth factors. In contrast, vitamin E with tocopherol associated proteins (TAP) and albumin, have molecular functions such as modulating gene expression by acting as a transporter of ligands to enzymes and regulating enzymes ligand transfer. These functions are usually observed for antioxidants [24]. In a separate study, vitamin E was found to function as a free radical scavenger which prevents the reduction of DNA oxidative damage as verified by the decline of urinary excretion of 8-oxodeoxyguanosine (a product of DNA oxidation) [24,25] The accompaniment of chronic inflammation with oxidative stress was hypothesized to provide a suitable environment for cancer development. By addressing the reduction of biochemical markers affiliated to cancer development, the selection of M1 in its potential herbal and pharmaceutical effects proves

promising [2,26].

Table 2. Cytotoxic Activities (IC_{50}) of Inhibitors Against HDFN, HT-29, HEPG2, BXPC-3, MCF-7, HELA and THP-1



Cell Line	IC_{50}* (µg/mL)		
	M1	DMSO	Zeocin
HDFn	>100	>100	4.40
HT-29	7.98	>100	11.60
HepG2	7.09	>100	6.11
BxPC-3	16.89	>100	11.83
MCF-7	7.12	>100	8.85
HeLa	16.63	>100	13.71
THP-1	17.43	>100	8.15

*IC_{50} values were extrapolated from dose-response curves calculated from nonlinear regression analysis using GraphPad Prism 8.02. One-way ANOVA was the treatment employed for each cell line to evaluate the significant variances among the data groups. The statistical analyses are as follows: HDFn, F (2, 21) = 32.06, $P < 0.0001$; HT-29, F (2, 21) = 11.65, $P = 0.0004$; HepG2, F (2, 21) = 14.23, $P = 0.0001$; BxPC-3, F (2, 21) = 6.586 $P = 0.0060$; MCF-7, F (2, 21) = 13.28, $P = 0.0002$, HeLa, F (2, 21) = 11.17, $P = 0.0005$, THP-1, F (2, 21) = 11.20, $P = 0.0005$.

Data are shown as mean ± SEM. GraphPad Prism 8.02 was used to perform extra sum-of-squares F-test to (A) evaluate the significance of the best-fit-parameter (half-maximal inhibitory concentration) among different treatments, and to (B) determine the differences among the dose-response curve fits. HDFn F(Dfn, DFd) = (A) F (2, 21) = 9.964, $P = 0.0009$ and (B) F (4, 66) = 616.9, $p < 0.0001$; HT-29 (A) F (2, 21) = 3.436, $P = 0.0512$ and (B) F (4, 66) = 149.6, $p < 0.0001$; HepG2 (A) F (2, 21) = 5.731, $P = 0.0103$ and (B) F (4, 63) = 370.9, $p < 0.0001$; BxPC-3 (A) F (2, 21) = 6.638, $P = 0.0058$ and (B) F (4,66) = 480.9, $p < 0.0001$; MCF-7 (A) F (2, 21) = 6.602, $p = 0.0060$ and (B) F (4, 66) = 640.8, $p < 0.0001$; HeLa (A) F (2, 21) = 5.135, $P = 0.0153$ and (B) F (4, 66) = 468.8, $p < 0.0001$; THP-1 (A) F (2, 21) = 6.140, $P = 0.0080$ and (B) F (4, 66) = 699.3, $p < 0.0001$.

Figure 3. Dose-response curves showing the cytotoxic a of M1, DMSO, and Zeocin on the cell viability of HDFn, HT-29, HepG2, BxPC-3, MCF-7, HeLa, and THP-1. Each plot displays the effect of **M1** and controls against each cell line

Each plot displays the effect of **M1** against each cell line. Data are shown as mean ± SEM. GraphPad Prism version 8.02 was used to perform extra sum-of-squares F-test to (A) evaluate the significance of the best-fit-parameter (half maximal inhibitory concentration) among different treatments, and to (B) determine the differences among the dose-response curve fits. The results are: **M1**, (A) F (6, 49) = 1.978, P = 0.0869 (B) F (12, 154) = 121.4, p <0.0001.

Figure 4. Dose-response curves showed the cytotoxic activities of M1 on the cell viability of HDFn, HT-29, HepG2, BxPC-3, MCF-7, HeLa, and THP-1

Conclusion

M1 was found to be rich in phytosterols and tocopherols, which have been reported to be anticancer agents. This thereby presents *M. rubra* bark as a potential raw material for such applications. The most responsive cancer cells to M1 were HepG2, MCF-7, and HT-29. Hela, BxPC-3, and THP-1 were moderately responsive to **M1**. Normal HDFn trials treated with **M1** were not affected by the inhibitor, whereas Zeocin was highly cytotoxic to wild type HDFn cells. Due to the low toxicity of **M1** to normal human dermal fibroblasts, we the researchers recommend that further bioassays be performed to reveal the signaling pathways that could be modulated in aberrant cells and that *in vivo* assays also be done to substantiate *Morus rubra* as a possible anticancer agent.

Abstract

Ziziphus mauritiana (Z. mauritiana) tea is a medicinal herbal tea that is widely sold and consumed especially in Malaysia due to the belief of this herbal tea's beneficial health effects. However, there are limited comprehensive studies on the phytochemicals profiling of this herbal tea that have been published to date. Therefore, this study investigates the effects of different infusion times and volumes of water on the phytochemical's profiles of *Z. mauritiana* tea infusions. Phytochemical screening was conducted to identify the presence of saponin and flavonoid while the total phenolic content (TPC) of the herbal tea was quantified using the Folin-Ciocalteu assay method. The gallic acid standard calibration curve showed good correlation coefficient, R^2, at 0.9987. From the TPC study, it was indicated that 10 minutes of infusion time of Z. *mauritiana* infused tea with 200 mL water resulted in higher TPC (32.01 mg GAE/g) compared to other infusion times (15 and 20 minutes) and volume of water (50 and 150 mL). For chemical profiling of phytochemical compounds in tea infusion, the advanced chromatographic method of Liquid Chromatography Mass Spectrometry-ion-trap-time of flight (LCMS-IT-TOF) was applied to provide highly accurate analysis for phytochemical analysis and revealed the identification of 14–23 compounds, including phenolic, saponin, terpenoid, glycosides and alkaloid compounds in the *Z. mauritiana* infused tea sample.

Keywords: *Ziziphus mauritiana*, herbal tea, phytochemical, LCMS-IT-TOF, phenolic

Abstrak

Teh *Ziziphus mauritiana* (*Z. mauritiana*) ialah teh herba perubatan yang banyak dijual dan digunakan terutamanya di Malaysia kerana wujudnya kepercayaan bahawa teh herba ini mempunyai kesan kesihatan yang baik. Namun, sedikit sahaja kajian komprehensif yang telah diterbitkan setakat ini mengenai pemprofilan fitokimia teh herbanya. Oleh itu, kajian ini menyiasat kesan masa infusi dan isi padu air yang berbeza terhadap profil fitokimia infusi teh *Z. mauritiana*. Saringan fitokimia telah dijalankan untuk mengenal pasti kehadiran saponin dan flavonoid serta jumlah kandungan fenolik (TPC) teh herba yang dikuantifikasikan dengan menggunakan metode asai Folin-Ciocalteu. Keluk penentukuran piawai asid galik menunjukkan pekali korelasi yang baik, R^2, dengan nilai R^2 pada 0.9987. Daripada kajian TPC tersebut, ditunjukkan bahawa infusi selama 10 minit di dalam teh *Z.*

mauritiana dengan 200 mL air menghasilkan TPC yang lebih tinggi (32.01 mg GAE/g) berbanding dengan tempoh infusi (15 dan 20 minit) dan isi padu air (50 dan 150 mL) yang lain. Untuk pemprofilan kimia sebatian fitokimia di dalam infusi teh, kaedah kromatografi lanjutan iaitu Kromatografi Cecair Spektrometri Jisim-ion-perangkap-masa penerbangan (LCMS-IT-TOF) telah digunakan untuk menyediakan analisis yang sangat tepat untuk analisis fitokimia dan mendedahkan pengesanan 14 –23 sebatian termasuk sebatian fenolik, saponin, terpenoid, glikosida, dan alkaloid di dalam sampel teh *Z. mauritiana*.

Kata kunci: *Ziziphus mauritiana*, teh herba, fitokimia, LCMS-IT-TOF, fenolik

Introduction

The use of herbs or medicinal plants to develop products for medicines and supplements has increased rapidly over the past few decades due to the various medicinal benefits of those plants. Herb plants consist of unpurified plant extracts that consist of various constituents to cure certain types of diseases and enhance general health and well-being [1]. According to the World Health Organization (WHO), medicinal plants is a natural plant material that has been used in both developed and developing countries for many years because of their natural composition contained in the plant cause the least complications and more than 80% of the population in the world depend more on traditional drugs derived from traditional herb plants [2].

Ziziphus mauritiana plant is commonly referred to as Bidara by Malaysians and belongs to the Rhamnaceae family. This tree is native to Southeastern Asia's warm climate region [3]. It can withstand adverse conditions such as salinity, drought, and waterlogging, making it adaptable to a variety of soil types [3]. Bidara leaves, fruit, seed, and other plant parts have been used in traditional medicine and rituals to treat a variety of diseases. Malay people believed that cleansing a deceased body with Bidara leaves softens the body, strengthens the skin, and slows the decaying process [3].

In addition, fresh or dried flowers, fruits, leaves, seeds, and roots can all be used to make herbal teas by pouring boiling water over them and soaking it for a few minutes. After that, the herbal tea is strained, sweetened, and served. Many companies sell herbal teas due to their major source of dietary antioxidants, and scientists have been studying polyphenolic compounds, as well as vitamins and carotenoids, for decades [4]. However, the suitability and health effects of drinking this herbal tea still lacking to date and the bioactive compounds contained in this infused herbal tea remain unclear. The safety and quality of unregistered herbal tea for human health is a major concern. Contaminants from natural and anthropogenic sources frequently reduce the quality of medicinal herbs and herbal remedies, causing side effects and even fatal death. Indeed, many herbal products lack sufficient information on their acute and chronic toxicity, standardization, stability, and quality. Therefore, if the plant material is intended for human consumption, it is very crucial to ensure the chemical profile as well as metallic and nonmetallic elements in the herbal extract or herbal tea.

A study on the identification of phytochemical compounds in *Ziziphus* jujube leaf tea has been conducted previously by using HPLC-DAD-ESI-TOFMS. Based on the study, reported that the infusion tea does not contain caffeine and theophylline but is rich in flavonoids with possible sedative activity. It revealed that this infusion has good radical scavenging ability and can be a healthy beverage for the public [5]. Based on the study, the application of advanced mass spectrometry provides higher sensitivity and accuracy in the identification of both targeted and non-targeted compounds [6].

Therefore, this study aims to explore the effects of different infusion parameters towards the phytochemical content as well as to investigate the chemical profile of *Z. Mauritiana* tea infusion by identifying the primary phytochemical compounds qualitatively. A hybrid technology LC-IT-TOF/MS was implemented to explore the phytochemical compounds in infused tea which can offer high speed and high accuracy determination.

Materials and Methods

Reagents and materials

Methanol, gallic acid, Folin-Ciocalteu reagent, sodium carbonate anhydrous powder and 2N sodium hydroxide

were obtained from Sigma Aldrich (St. Louis, USA). All of the chemicals and solvents were of high analytical grade. Three brands of herbal tea samples were purchased from online local shops namely brands A, B and C, respectively.

Infusion method of herbal tea

1 g of tea samples was mixed with 50, 100, 150, and 200 mL of hot distilled water (95 °C) to make the tea infusion. After 5 minutes of infusion, the solution was cooled to around 50 °C. After that, the infused teas were filtered using a Whatman paper filter No. 1 before analysis. This study was adjusted by varying the volume of water (50, 100, 150 and 200 mL) and infusion time (10, 15 and 20 minutes). To find the ideal conditions for infusing *Z. mauritiana* tea at different volumes and times, the infusion process was optimized using a constant mass, which was 1 g of *Z. Mauritiana* tea. Each sample was prepared in triplicate.

Qualitative test for saponin and flavonoid

Qualitative phytochemical analysis of saponin and flavonoid compounds in tea samples was conducted using standard methods [7]. For the saponin test, 2 mL of *Z. Mauritiana* herbal tea was mixed with 6 mL of water in a graduated cylinder. The mixture was vigorously shaken, and the presence of saponins was determined by the formation of persistent 2 cm foam. As for the flavonoid test, 2 mL of *Z. Mauritiana* herbal tea was mixed with 1 mL 2N sodium hydroxide. The presence of flavonoids is indicated by the presence of yellow color.

Total phenolic content

The total phenolic content was determined using the Folin-Ciocalteu colorimetric method with gallic acid as a control. A gallic acid standard solution with concentration ranges of 0.05 to 0.4 mg/mL was prepared for the standard calibration curve. In this method, 1 mL *Z. Mauritiana* herbal tea and 2.5 mL Folin-Ciocalteu (0.2 N) reagent were mixed. Then, 2 mL of sodium carbonate (37.7 g/L) was added and thoroughly mixed. Then, 7.5 mL of distilled water was added to dilute it. The mixture was covered with parafilm foil and incubated in a dark place for 2 hours at 30°C. The absorbance was then measured in a UV-Vis spectrophotometer (Shimadzu) at 760 nm. The obtained result was calculated and expressed as mg of gallic acid equivalents (mg GAE)/mL of tea infusion as stated in Equation 1.

$$Total\ Phenolic\ Content = \frac{\mathrm{CV}}{m} \quad (1)$$

Where C is the concentration of *Z. Mauritiana* leaves herbal tea (mg/mL), V is the volume of *Z. Mauritiana* herbal tea (mL) and m is the weight of *Z. Mauritiana* herbal tea (g).

Analysis by LCMS-IT-TOF

For the phytochemical screening of *Z. Mauritiana* herbal tea sample, LC-MS analysis was performed using the Shimadzu Prominence Series LC coupled to the LCMS-IT-TOF (Shimadzu, Kyoto, Japan). Prominence Series components included two LC-20AD pumps, SIL-20A Autosampler, and a CBM-20A System Controller. The column used for reversed-phase LC analysis was a Shimadzu Shimpack VP-ODS packed with 4.6 µm particles (4.6 x 150 mm). The instrument was controlled through an LCMS solution, and data analysis was performed using the same software. The mobile phases consisted of eluent A (0.1% formic acid in water, v/v) and eluent B (0.1% formic acid in acetonitrile, v/v) with a flow rate of 0.5 mL/min. The injection volume was 10 µL with a gradient elution at the flow rate of 0.5 mL/min: 1% B (0 ~ 1 min), and was linearly increased to 35% (1 ~ 16 min), 35-100% (16 ~ 18 min) and 100% (18 ~ 20 min). Re-equilibration duration was five minutes between individual runs.

Data analysis

All data acquired were processed by Shimadzu LC-solution software (Kyoto, Japan), Version 3.0. The experimental results were performed in triplicate. The processed data was compiled in the Microsoft Excel software and further Mean, SD, relative standard deviation (%RSD), and Percentage Relative Error (%RE) values were calculated.

Results and Discussion

Effect of different parameters to the infused herbal tea

Observation of color was conducted to view the effect

of different water volumes on the color intensity of tea infusion. All brands of tea revealed that the intensity of the color decreased as water volume increased as can be seen in Figure 1. It can be seen that 50 mL has darker color compared to 100 mL, 150 mL and 200 mL. This is due to the increased volume of water used for infusion resulting in the dilution of the chemical compounds.

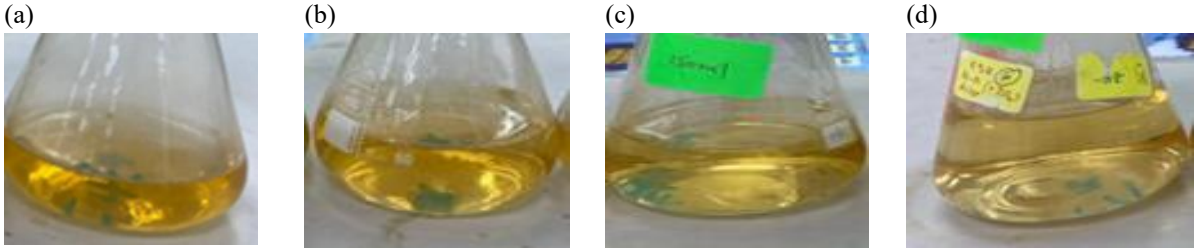

Figure 1. Color of infused *Z. mauritiana* tea at (a) 50 mL, (b) 100 mL, (c) 150 mL and (d) 200 mL

Furthermore, infusion tea with different infusion times (5, 10, 15 and 20 minutes) indicated that the intensity of the yellowish color of the infused tea decreased as infusion time increased. It revealed that 10 minutes of infusion time give darker color followed by 15 and 20 minutes of infusion time, respectively. According to previous studies, the flavor, color, and taste of tea beverages are said to be affected by a long infusion time. The infusion's turbidity increases as the infusion time increases due to the increase in protein and pectic structures, which are expressed at the same time [3]. Observing the turbidity through a UV spectrophotometer, the water-soluble compounds in the tea were found to pass quickly to the water, and the number of water-soluble compounds in the infusion increased slowly even as the infusion time increased [4]. Moreover, the brightness of the infusions decreased as infusion time increased. It can be stated that as the infusion time increases, undesirable compounds pass into the infusion, the emergence of some decomposed and degraded components, and increased turbidity cause a decrease in the brightness of the infusion. The number of compounds in the infusion increases with infusion time and these compounds affect the color of the tea, the change in color of the infusion is to be expected [5].

Qualitative test for saponin

A qualitative test of saponin was conducted to identify the presence of saponin in *Z. mauritiana* tea with infused parameter of 50 mL water and 10 mins. Saponins are amphipathic glycosides distinguished phenomenologically by the soap-like foam produced when shaken in aqueous solutions and structurally by the presence of one or more hydrophilic glycoside moieties combined with a lipophilic triterpene derivative. From this study, Brand A and C proved the presence of saponin after the mixture was shaken vigorously while Brand B does not record the presence as shown in Figure 2.

Based on previous studies on different tea plants, saponin content may vary but the processing of tea did not significantly affect them. Saponin can be found in many medicinal plants such as *alstonia scholaris, curcuma longa, jasmin sambac, phyllantus acidus* as well as *ziziphus mauritiana* [8]. This compound is beneficial as it has several pharmacological properties namely antimicrobial, antifungal, anti-inflammatory and antioxidant.

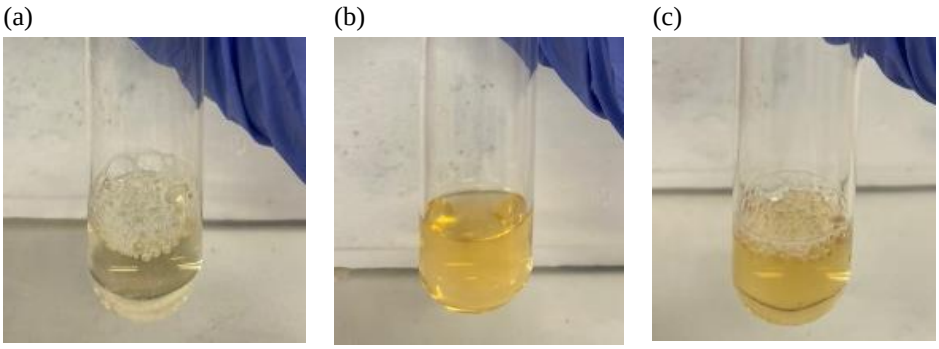

Figure 2. Saponin test in infused herbal tea at volume 50 mL and 10 min infusion time (a) Brand A (b) Brand B and (c) Brand C

Qualitative Test for Flavonoid

This test was conducted at infusion parameters; 50 mL water and 10 mins infusion time. The presence of flavonoids is indicated by the presence of an intense yellow color in the mixture as compared to blank infused tea [9]. Figure 3 shows that all brands contain flavonoids in herbal teas based on qualitative tests of flavonoids. Brand B shows the highest content of flavonoids due to the brownish-yellow color of the herbal tea of which is darker than Brand A, Brand C as well as the control (blank infused *Z. mauritiana* tea). Flavonoids and flavonols are typically yellow or ivory-colored pigments. Notably, the anthoxanthins content will impact the yellow colors [10]. Tea is particularly rich in three flavonoid classes: flavan-3-ols (or catechins), ooligomeric flavonoids (including thearubigins and theaflavins generated during fermentation), and flavonols (e.g. quercetin). These flavonoid oligomers in tea have very complex chemical structures that have yet to be fully characterized. The most common flavonol found in tea is quercetin [11, 12].

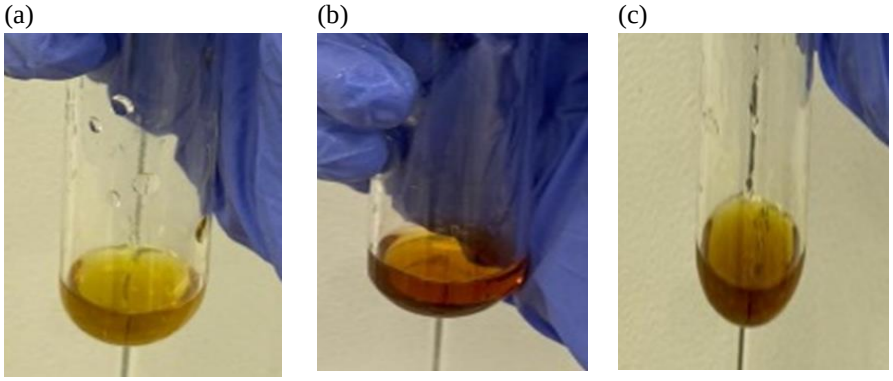

Figure 3. Flavonoid test in infused herbal tea at 10 mins infusion time and 50 mL of water volume (a) Brand A (b) Brand B and (c) Brand C

Effect of different water volumes on the TPC value of infused tea

Gallic acid was used as the standard calibration curve in TPC analysis and was measured using a UV-Vis Spectrophotometer at a wavelength of 765 nm. The correlation coefficient, R-value, obtained from the experiment showed a value of 0.9987 indicating excellent linearity of absorbance versus concentration.

Based on Figure 4, brand A had the most phenolic compounds, followed by brand B and brand C. Unlike the previous study, the amount of TPC increased by the increment of water volume for Brand A tea. More TPC values resulting from the increment of water volume in

Brand A might be due to better solvation of TPC in the sample as a result of interactions (hydrogen bonds) between the polar sites of the TPC molecule and the water [13]. Meanwhile, TPC for Brand B and C decreased as the volume increased to 200 mL. The phenolic compounds were expected to be reduced by the increment of water volume [6]. These results might be due to the other factors that potentially affect the phenolic content such as the drying process, topographical location of the planting and cultivation, season, climate and the storage conditions of the tea sample. This phenolic compound also contributes to antioxidant activity as well as contributes to the quality in terms of modifying color, taste, aroma and flavor [14].

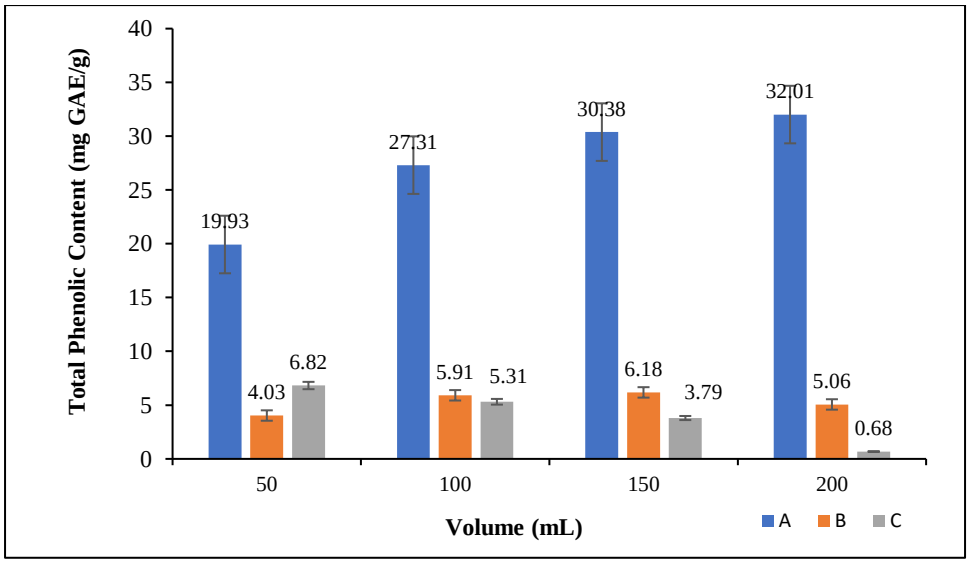

Figure 4. Total phenolic content for all types of brands with different volumes in mg GAE/g

Effect of different infusion time to TPC value of infused tea

Based on Figure 5, the amount of TPC in Brand A and B decreased by the increment of infusion time from 10 until 20 minutes. According to a previous study, increment of infusion time increases the chances of oxidation of phenolics due to their long exposure to unfavorable environmental factors such as temperature and oxygen [14]. However, TPC in Brand C increased at 15 minutes before being reduced at 20 minutes infusion time. As stated by a previous study, 10 minutes of infusion time for loosely packed teas is enough to infuse all the phenolic content into the water [15]. From this result, it concluded that *Z. mauritiana* Brand A significantly demonstrated the highest TPC values at different parameters as compared to Brands B and C. Brands B and C do not give much significant difference in the TPC value at different infusion times and water volumes.

LCMS-IT-TOF Analysis for *Z. Mauritiana* herbal teas

From the qualitative test and TPC test, it was shown that Brand A gave the highest amount of compounds compared to Brand B and C, thus, Brand A then continued for the analysis using advanced LCMS-IT-TOF. The identification and analysis of compounds detected were based on precursor ions and accurate mass measurement of either $[M+H]^+$, $[M+K]^+$, $[M+NH4]^+$ and $[M+Na]^+$. Table 1 indicated the identification of the active components in *Z. Mauritiana* herbal teas.

Based on Table 1, LCMS-IT-TOF analysis successfully detected 14 compounds based on their accurate mass categorized as amine, fatty acids, phenolic glycosides, phenolic and alkaloid. As can be seen in Figure 6, it revealed that *m/z* 304.2968 gave the highest intensity of the mass compared to others. Based on the accurate mass, it revealed that nitrosoxacin A was identified. This compound belongs to the class of organic compounds

known as trialkylamines. The other four main measured masses in Figure 6(a) were *m/z* 288.2696, 332.3311, 367.1376 and 381.1430 identified as amine, phenolic and indole compounds, respectively. Abietylamine is tricyclic abietane diterpenoids which mainly found in plants and exhibits pharmacological activity such as antimalaria properties [16].

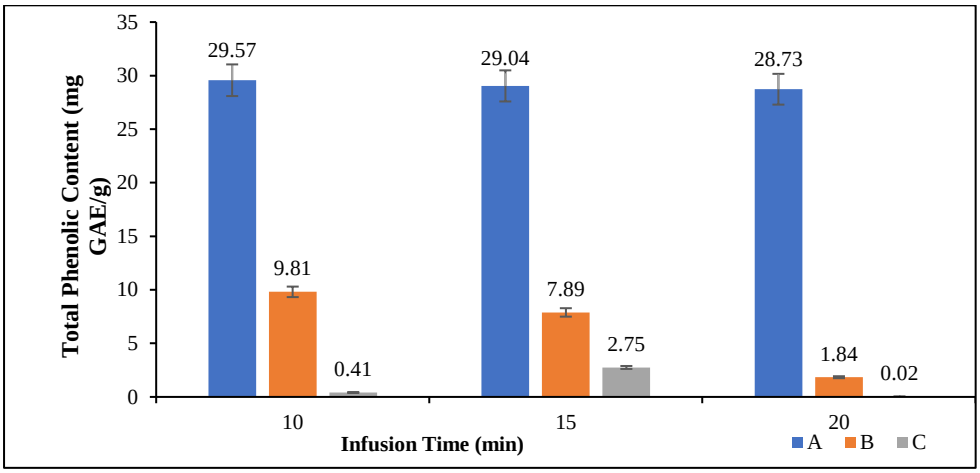

Figure 5. Total phenolic content for all types of brands with different infusion times in mg GAE/g

Meanwhile, dihydroconiferin belongs to the class of organic compounds known as phenolic glycosides, a plant metabolite that was quantitatively identified in a plant called *Lactuca orientalis* [17]. Varespladib (*m/z* 381.1430) is an anti-inflammatory agent which disrupts the first step of the arachidonic acid pathway of inflammation. All detected compounds in this sample were different compared to the previous study using the same herbal tea. There are three unknown compounds were identified to be further investigated for structure elucidation. The fragment ions can be used to study the elucidation of the proposed structures of the unknown compounds.

Based on Table 2, amount 23 compounds were identified using advanced LCMS-IT-TOF and categorized into four groups: saponin, terpenoids, glycosides, and phenols. As compared to Table 1, *Z. mauritiana* infused tea with different volumes of water affected the number of compounds detected. In 150 mL volume of water, it revealed that more compounds can infuse from the tea. Only nitrosoxacin A and camphor azine were detected in both infused samples at masses of *m/z* 304.2975 and *m/z* 318.2879. Camphor and its derivatives are considered among the most significant natural product, which has considerable pharmacological effects including antibacterial, antifungal, antiviral, anticancer and antidiabetic activity [18]. Based on previous studies, nitrosoxacin A and camphor azine were not detected in other infused herbal teas and no study has discovered these compounds in tea leaves. A further investigation on the potential and properties of nitrosoxacin A and camphor azine in *Z. mauritiana* tea can be conducted. Additionally, based on Figure 6, there are two possible molecular formulas detected at *m/z* 332 which showed a higher response, either $C_{23}H_{41}N$ and $C_{19}N_{41}NO_3$ at the volume of 200 mL (Figure 6a) and 150 mL (Figure 6b), respectively. Both molecular formulas indicated isomer compounds were identified and the possible compounds are amine and fatty acid.

In this study, it is noticed that changes in infusion parameters (volume and time) affected the number of compounds detected by LCMS-IT-TOF. Optimum infusion parameters play an important role in the infusion method to diffuse more compounds in the sample and thus be able to be detected by the chromatography method. From this, it can be concluded that the extractability of bioactive compounds from tea leaves depends on the infusion parameters.

Table 1. Number of compounds and its possible name detected in *Z. Mauritiana* herbal tea infused at the volume of 200 mL (10 minutes infusion time) by LCMS-IT-TOF.

No	Formula	Possible Detected Compounds	Ion	Measured *m/z*	Group of Compounds
1	$C_{20}H_{33}N$	Abietylamine	$[M+H]^+$	288.2696	Amine
2	$C_{16}H_{34}N_2O_2$	Nitrosoxacin A	$[M+NH_4]^+$	304.2968	Amine
3	$C_{20}H_{32}N_2$	Camphor Azine	$[M+NH_4]^+$	318.2893	Ketone
4	$C_{23}H_{41}N$	Benzylamine, N,N-dioctyl-	$[M+H]^+$	332.3311	Amine
5	$C_{17}H_{26}N_2O_4$	Bestatin Methyl Ester	$[M+Na]^+$	345.1777	Organic carbonic acids
6	$C_{19}H_{34}O_6$	Dodecanoic acid	$[M+H]^+$	359.2428	Fatty acids
7	$C_{16}H_{27}NO_8$	1-Aminoadamantane citrate monohydrate	$[M+H]^+$	362.1802	Amine
8	$C_{16}H_{24}O_8$	Dihydroconiferin	$[M+Na]^+$	367.1376	Phenolic glycosides
9	$C_{21}H_{20}N_2O_5$	Varespladib	$[M+H]^+$	381.1430	Indoles
10	$C_{30}H_{54}O_3$	2,3-Didodecoxyphenol	$[M+K]^+$	501.3701	Phenolic
11	$C_{26}H_{54}N_2O_7$	Glucoalkaloid	$[M+K]^+$	545.3584	Alkaloid
12	$C_{27}H_{57}NO_{10}$	Unknown	$[M+Na]^+$	578.3871	Unknown
13	$C_{29}H_{62}N_2O_7$	Unknown	$[M+K]^+$	589.4198	Unknown
14	$C_{30}H_{62}N_2O_{10}$	Unknown	$[M+Na]^+$	633.4245	Unknown

It also noted that even though TPC values showed the highest value in Brand A, the number of phenolic compounds detected by LC analysis is not much as expected. It can be due to the phenolic compounds being evaporated prior to LC analysis. Most phenolic compounds are volatile compounds which give the aroma to the herbal tea [19]. Sample preparation prior to LC analysis and the limited mass library could also be the reasons for only several phenolics being identified in this study. Hence, further studies are needed to comprehensively identify individual active compounds present in the infused *Z. mauritiana* tea prepared using different water volumes, infusion times as well as infusion temperatures, which might provide more details.

Conclusion

In this study, infusion parameters such as volume of water and infusion time were successfully demonstrated to give different visual appearances and affect the total phenolic content (TPC) of infused *Z. Mauritiana* tea. This infused herbal tea from Brand A, B and C were compared qualitatively and quantitatively. Based on phytochemical screening, it proved the presence of flavonoid and saponin in all samples however saponin was absent in brand B. In TPC analysis, infused tea from brand A at different volumes (50, 150, 200 mL) and different infusion times (10, 15, 20 min) showed the highest TPC value compared to others. In this study, an efficient LCMS-IT-TOF method was successfully performed to identify and compare the phytochemical compounds in infused *Z. mauritiana* tea by using 150 mL and 200 mL water, respectively. It proved that less amount of water used to infuse resulted in a higher number of phytochemical compounds. Results showed that most of the compounds detected were categorized as amine, fatty acids, phenolic glycosides, phenolic, alkaloid, saponin, terpenoids and glycosides. Moreover, only nitrosoxacin A and camphor azine were detected in both infused samples. It is concluded that the different infusion parameters gave a significant effect on TPC value as well as the phytochemical compounds in the infused tea which can be led to different biological activities. Hence, further studies could be planned to focus on the novel compounds extracted from *Z. mauritiana* tea that might benefit human health as compared to other herbal tea.

Abstract

Hexadecylpyridinium chloride monohydrate, a cationic surfactant, was employed to chemically modify coconut-grated residue to adsorb reactive orange 16 (RO16). The pH point of zero charge (pHPZC) and surface area were used to characterise the raw coconut grated residue (RGC) and the surfactant-modified grated coconut residue (SMGC). The pHPZC was 5.5, and the Brunauer-Emmett-Teller surface area was 1.86 m^2 g^{-1}. The dye solution pH and dose effects on RO16 adsorption were tested in a batch adsorption system. Maximum sorption was seen at an SGMC concentration of 10 g L^{-1}, while optimal adsorption was observed at a low pH. When dye-loaded SGMC was exposed to a basic solution, the desorption percentage increased to almost 70%, whereas low desorption was observed under acidic conditions. Furthermore, the isotherm study discovered that the Freundlich model explained RO16 adsorption of SMGC better than the Langmuir model. The Langmuir isotherm recorded a maximum adsorption capacity of 9.72 mg g^{-1}.

Keywords: cationic surfactant, coconut, reactive dye, adsorption

Abstract

Heksadekilpiridinium klorida monohidrat, sejenis surfaktan kationik, telah digunakan untuk memodifikasi kimia sisa parut kelapa untuk menjerap reaktif oren 16 (RO16). pH titik cas sifar (pHPZC) dan luas permukaan digunakan untuk pencirian sisa parut kelapa mentah (RGC) dan sisa parut kelapa yang dimodifikasi dengan surfaktan (SMGC). Nilai pHPZC adalah 5.5, dan luas permukaan Brunauer-Emmett-Teller adalah 1.86 m^2 g^{-1}. Kesan pH larutan pewarna dan dos terhadap penjerapan RO16 telah diuji dalam sistem penjerapan kelompok. Penjerapan maksimum dilihat pada kepekatan SGMC 10 g L^{-1}, manakala penjerapan optimum diperhatikan pada pH rendah. Apabila SGMC yang memuatkan pewarna terdedah kepada larutan alkali, peratus penjerapan semula meningkat hampir ke 70%, manakala penjerapan rendah diperhatikan dalam keadaan berasid. Selain itu, kajian isoterm menemui bahawa model Freundlich menjelaskan penjerapan RO16 pada SMGC dengan lebih baik daripada model Langmuir. Isoterma Langmuir mencatatkan kapasiti penjerapan maksimum sebanyak 9.72 mg g^{-1}.

Kata kunci: surfaktan kationik, kelapa, pewarna reaktif, penjerapan

Introduction

Many dye effluents are harmful to the environment and wildlife [1]. Global production of dye chemicals for commercial and industrial use totals approximately 700,000 tons annually, representing over 100,000 different colours [2]. Reactive dyes are among the popular choices for dyeing cotton and other cellulose fabrics due to their bright colour shades [3] and are readily water-soluble and easy to apply [4]. According to Allègre et al. [5], over 80,000 tons of reactive chemicals are produced annually, enabling pollution estimates given their extensive application, and after dyeing processes, treatment baths are discharged, including an initial dye bath with extremely high salt concentration and dark hue from substantial organic material resulting from additives used to facilitate dye uptake during fabric treatment. This causes environmental concerns as only 30% of reactive dye typically binds with fabric, meaning that the remaining unfixed dye gives colour to their effluent [6].

Dyes have been removed from effluent using various methods [7]. However, adsorption remains one of the best methods for removing various colour substances [8]. Due to some limitations associated with using activated carbon as an adsorbent, such as processes for regeneration and reactivation [9], alternative adsorbents sourced from plants have been actively explored. Many works have found the potential of plant-based adsorbents to remediate various water and wastewater pollutants [10].

Agricultural waste applied to treat wastewater has several advantages, including chemical stability, an abundant source, low cost, and environmental friendliness [11]. Many have reported that modifying raw agricultural waste improves sorption capacity [12]. Meanwhile, the successful modification of biomass with cationic surfactant in removing reactive dye has been extensively reviewed [13]. According to Kosaiyakanon and Kungsanant [14], cationic surfactants increased the adsorption affinity of negative dyes and introduced a positive charge to adsorbent surfaces. This enables the biosorbent surface and negatively charged anionic dye to attract electrostatically [15], as illustrated in Figure 1.

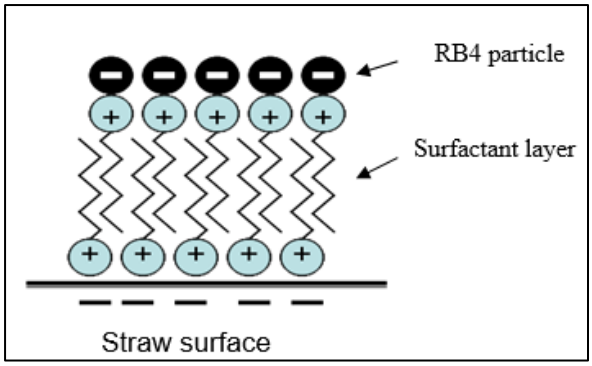

Figure 1. Schematic diagram showing reactive dye attracted to opposite charges on modified straw [15]

This study investigated the effectiveness of the cationic surfactant hexadecylpyridinium chloride monohydrate (CPC, $C_{21}H_{38}NCl$) in removing the anionic dye reactive orange 16 (RO16) from an aqueous solution. According to earlier studies, CPC cations on the adsorbent surface would modify surface characteristics and improve anionic contaminant adsorption [15,16]. Coconut flesh residue has been extensively studied to remove heavy metals like Cd (II) ion [17], Pb(II) ion [18], Ni(II) ion [19] and removal of dyes [20].

Materials and Methods

Materials

Reactive orange 16 (Figure 2) and CPC (98% purity) were purchased from Aldrich. Meanwhile, hexane was obtained from R&M Chemicals (UK). Distilled water was used throughout the adsorption experiments.

Preparation of surfactant-modified grated coconut residue

The preparation of surfactant-modified grated coconut residue (SMGC) has been reported before [21]. In summary, SMGC was prepared by shaking 1 L (2.50 mmol/L) CPC with a specific amount of dried, hexane-pretreated raw grated coconut residue (RGC). The treated grated coconut residue was separated from the liquid, washed with distilled water, and dried overnight in an oven at 60 °C. An anionic dye solution was made by dissolving the RO16 dye in distilled water.

Characterisation of surfactant-modified grated coconut residue

For characterisation, the pH point of zero charge (pHPZC) was measured using the salt addition method [22]. Briefly, NaCl solutions were prepared with volumes of 50 mL and a concentration of 0.01 M, covering pH values from 4 to 12. Each solution was supplemented with 0.15 g of SMGC and mixed for 48 hours at 150 rpm. The initial and final pH values were measured to determine the pHZPC, indicating the point of zero charge where ΔpH equals zero, signifying no surface charge.The surface area was measured using the Brunauer-Emmett-Teller (BET) method through N_2 adsorption, employing the Micromeritics 2010 instrument from Instrument Corporation, USA. Surface morphology testing was carried out using a field emission scanning electron microscope (FESEM-Zeiss Supra 40V) at 5000x magnification.

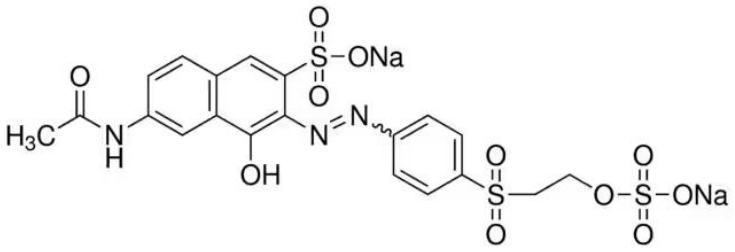

Figure 2. Chemical structure of RO16

Adsorption studies

The dynamic study involved agitating different concentrations of SMGC (10 and 20 g L^{-1}) with RO16 at a concentration of 100 mg L^{-1}. The solution was then sampled at specific time intervals for analysis. In the batch isotherm experiment, SMGC and RO16 were mixed and agitated for 60 minutes. While many parameters can influence the adsorption performance of the reactive dye on the biosorbent, this study focused on two important parameters: the pH of the dye and the dosage of the adsorbent. The SMGC dosage ranged from 5 to 50 g L^{-1} to examine the impact of different doses, while the pH of RO16 was adjusted from 3 to 9 to assess the pH effect. Throughout the study, samples were shaken using an Innova 2100 platform shaker. The pH of the solution was measured with a Mettler Toledo S20 pH meter, and the concentration of dye samples was determined using a HACH DR2800 portable spectrophotometer (UK) at a maximum absorbance wavelength of 493 nm. The initial pH of the dye solution was 5.5 at a concentration of 100 mg L^{-1}, and the agitation speed, adsorbent size, and dosage were set at 200 rpm, 0.12–0.25 mm, and 10 g L^{-1}, respectively, unless specified otherwise.

Desorption of dye-loaded adsorbent

RO16 desorption from dye-loaded SMGC was achieved by dispersing it at 10 g L^{-1} in deionised water at various pHs for 3 h. The mixtures were filtered and analysed at 493 nm using a HACH DR2800 portable spectrophotometer. Equation 1 calculates the desorption percentage:

$$\text{Percentage of desorption (\%)} = \frac{q_{e(des)}}{q_{e(ads)}} \text{ x } 100 \quad (1)$$

Where $q_{e(des)}$ is the desorption of RO16 (mg g^{-1}) and $q_{e(ads)}$ is the amount of RO16 adsorbed (mg g^{-1}).

Best fitting model estimation

The fit of the equation to the experimental data was established by regression correlation coefficients (R^2) and error estimation. The R^2 nearest to unity is assumed to fit best, whereas a lower Marquardt's percentage standard deviation (MPSD) (Equation 2) is better for error estimation:

$$\mathrm{MPSD} = 100\left(\sqrt{\frac{1}{p-n}\sum_{i=1}^{p}\left[\frac{(q_{e,meas}-q_{e,calc})}{q_{e,meas}}\right]_i^2}\right) \quad (2)$$

Where p represents the number of experimental data, and n is the model equation's parameters. The experimental data are $q_{e,meas}$ and the model equation data are $q_{e,calc,}$

Results and Discussion

Adsorbent characterisation

The pHPZC of the adsorbents was used to determine the ideal pH for anion adsorption and the nature of the interaction [23]. The calculated pHPZC of the SMGC was 5.50. When the pH is less than the pHPZC, the adsorbent positive surface charge favours anion adsorption [24]. The removal of Remazol Brilliant Blue in industrial waste sludge exhibited an identical behaviour, with a notable increase in removal as the pH decreased [23]. Given the above, physisorption would be expected as the adsorption mechanism due to the anionic dyes' electrostatic interaction with the active centres of the adsorbents, as suggested by Karaman et al. [16] in their research of cationic surfactant-modified carbon for removing Congo Red dye.

The textural analysis showed that the SMGC had a relatively low BET surface area of 1.86 $m^2\ g^{-1}$ and pore volume of 2.04×10^{-3} $cm^3\ g^{-1}$. These findings suggest that textural properties may not play a significant role in adsorption compared to other factors. For comparison, the reported BET surface area for acid-washed coconut grated in a separate study by Khalid and Hanafiah [20] was 23.673 $m^2\ g^{-1}$, significantly higher than SMGC as acid washing exposes more internal surface area by removing compounds and expanding pores. In contrast, Namasivayam and Sureshkumar [25] reported that surfactant modification coats and constricts pore networks of biomass, limiting accessible surface for nitrogen adsorption analysis.

The scanning electron microscopy (SEM) images (Figure 3), captured at 5,000x magnification, revealed that the SMGC exhibited a slightly more uniform surface than the untreated RGC. This coating effect resulted in a smoother morphology, as observed through the SEM analysis of SMGC. These findings are consistent with a study conducted by Chen et al. [26], in which they observed that untreated silkworm exuviae displayed a compact, uneven, and folded surface, while modified silkworm exuviae treated with hexadecyltrimethylammonium bromide, exhibited a porous and flexible surface.

In our previous work [21], we conducted an analysis to confirm the successful attachment of the cationic surfactant CPC to the surface of RGC. This was achieved through functional group analysis using Fourier transform infrared (FTIR) spectroscopy. The FTIR analysis revealed the presence of two distinct new peaks at wavenumbers 2921 and 2853 cm^{-1} in the spectrum of SMGC, which were attributed to the asymmetric and symmetric C-H stretching vibrations of the cationic surfactant CPC, respectively. The emergence of these characteristic peaks provided strong evidence in support of the effective binding of the cationic surfactant to the RGC surface, which was consistent with other reported surfactant-modified biomass studies [27].

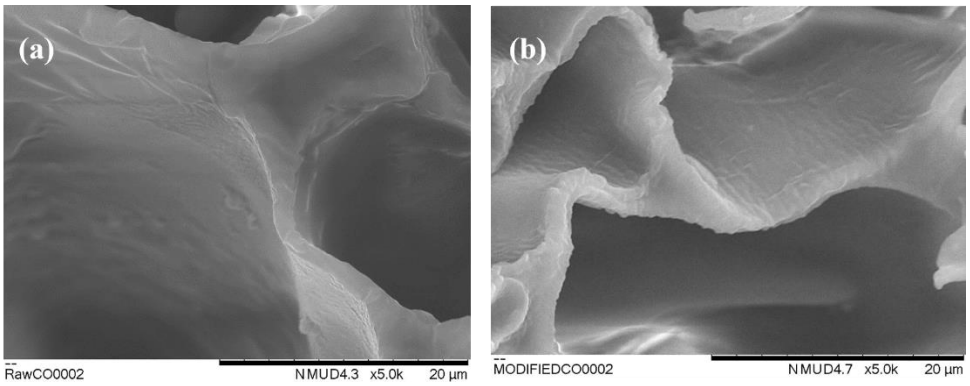

Figure 3. SEM micrographs of (a) RGC and (b) SMGC at 5000x magnification

Dynamic adsorption studies

A rapid initial phase and slow continuation are the characteristics of the adsorption reaction before it reaches equilibrium. For the SMGC dosage of 10 and 20 g L^{-1}, the equilibrium time was 30 min. Two widely used models, pseudo-first-order and pseudo-second-order, were used to investigate the dynamics of RO16 sorption onto SMGC, as given by Equations 3 and 4, respectively:

$$q_t = q_e\left(1 - e^{-k_1 t}\right) \quad (3)$$

$$q_t = \frac{q_e^2 k_2 t}{(1+q_e k_2 t)} \quad (4)$$

Adsorption capacities at time t and equilibrium are denoted by q_t and q_e, respectively, while the first-order and second-order rate constants are denoted by k_1 and k_2, respectively. Equations 3 and 4 are non-linear equations that were fitted using Polymath software. The results of the fitting are shown in Fig. 4 and Table 1. For both dosages (10 and 20 g L^{-1}), the R^2 for the pseudo-second-order model (>0.98) was slightly higher than that for the pseudo-first-order model (>0.94). The MPSD error value was also lower for the pseudo-second-order model (<6.64) than the pseudo-first-order model (<10.76). Furthermore, the pseudo-second-order model's calculated adsorption capacities ($q_{e,cal}$) and experimental adsorption capacities ($q_{e,exp}$) were nearly identical, indicating a better fit of this model to the experimental data. This finding is consistent with other surfactant-modified adsorbent for dye removal [28].

Table. 1. Pseudo-first-order and pseudo-second-order rate constants and error analysis.

		Kinetic Model Constants				Error Analysis			
Experimental		Pseudo First Order		Pseudo Second Order		Pseudo First Order		Pseudo Second Order	
Dosage ($g\ L^{-1}$)	Exp. q_e ($mg\ g^{-1}$)	k_1 (min^{-1})	q_e ($mg\ g^{-1}$)	k_2 (min^{-1})	q_e ($mg\ g^{-1}$)	R^2	MPSD	R^2	MPSD
10	5.75	0.22	5.54	0.05	6.09	0.94	10.76	0.98	6.64
20	4.41	0.45	4.35	0.27	4.50	0.98	3.23	0.99	1.42

Isotherm adsorption studies

Establishing the best equilibrium data correlations will help the adsorption system design [29]. Two well-known models are the Langmuir and Freundlich isotherms, which explain how adsorbate molecules are distributed in solid phases at adsorption equilibrium. Equation 5 is the Langmuir isotherm model [30] for monolayer adsorption on a physically homogeneous surface without molecule interaction:

$$q = \frac{Q_{max}}{1+bc_e} \quad (5)$$

Where Q_{max} is the maximum adsorption capacity, b is an adsorption energy constant, and C_e represents dye solution equilibrium.

The empirical Freundlich isotherm model (Equation 6) [31] describes interactions between adsorbed molecules on heterogeneous surfaces with multilayer adsorption:

$$q = K_F c_e^{\ 1/n} \quad (6)$$

Where K_F is the adsorption capacity and n is a heterogeneity-dependent empirical formula. Fig. 5 shows Polymath's trial-and-error fitting of Equations 5 and 6. With its higher regression coefficients and lower MPSD error value, the Freundlich isotherm more closely represents the experimental data (Table 2). The Langmuir model demonstrated the Q_{max} of 9.72 mg g^{-1}.

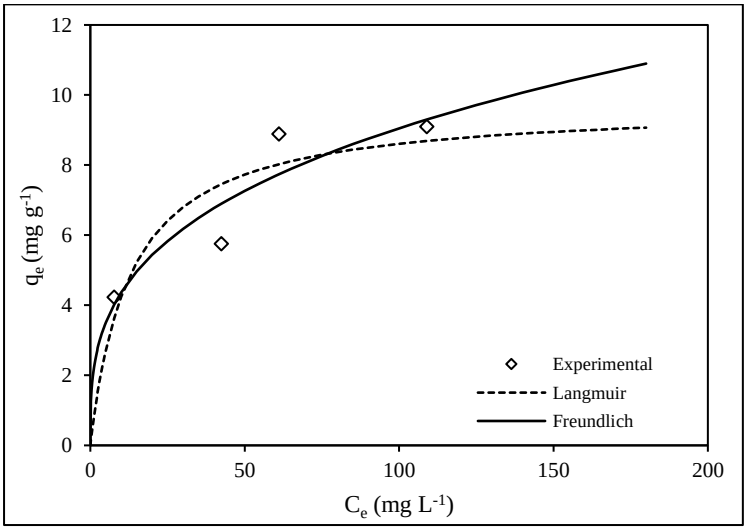

Figure 5. Adsorption isotherms by the nonlinear method for the adsorption of RO16 onto SMGC

Table 2. Freundlich and Langmuir isotherm constants and error analysis for RO16 adsorption

Isotherm Models Constant				Error Analysis			
Langmuir		Freundlich		Langmuir		Freundlich	
Q_{max} (mg.g^{-1})	b (L.mg^{-1})	K_F	n	R^2	MPSD	R^2	MPSD
9.72	0.08	2.11	3.16	0.92	24.40	0.95	17.25

Influence of pH

This study investigated the effect of pH on RO16 adsorption by varying the initial pH of the RO16 solution from 3 to 9. It was discovered that pH significantly impacts RO16 adsorption onto SGMC (Figure 6). The amount of RO16 removed decreased as the initial pH of the solution increased. At initial pH levels of 3, 5, 7, and 9, RO16 adsorption was 3.33, 3.25, 3.13, and 2.86 mg g^{-1}, equivalent to 100%, 97.63%, 93.84%, and 85.91% removal, respectively. Due to the negatively charged RO16 molecules' electrostatic repulsion with the adsorbent surface, RO16 removal was lower at pH 7 and 9. This was consistent with our data on pHPZC, which demonstrated that the SMGC became negatively charged when the pH of the dye solution exceeded 5.50, making it unfavourable for anionic contaminants such as RO16.

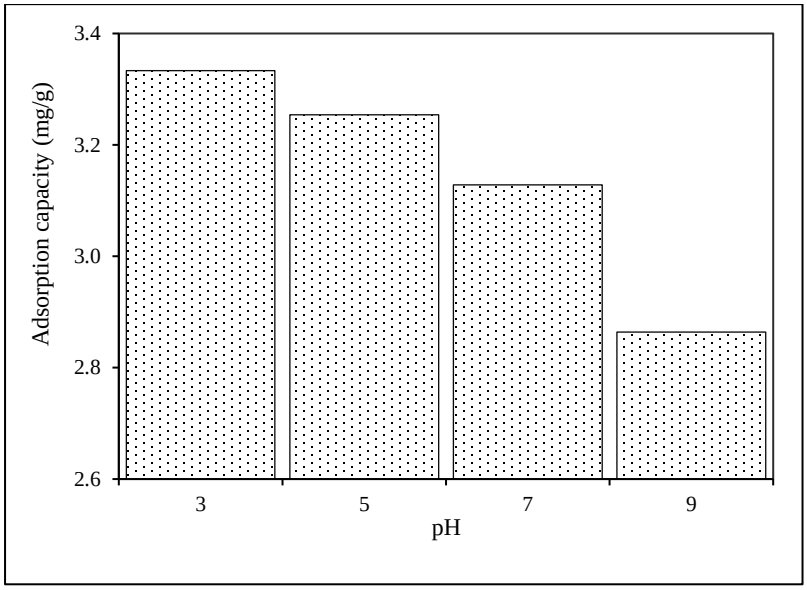

Figure 6. Effect of pH on the adsorption of RO16 onto SGMC

Influence of adsorbent dosage

As shown in Figure 7, as the amount of adsorbent used increased from 5 to 10.0 g L^{-1}, the RO16 dye adsorption capacity increased from 2.63 to 5.75 mg g^{-1}, equivalent to 13.17%-57.54% removal at equilibrium. The adsorption capacity for SGMC declined above 10.0 g L^{-1} to 1.99 mg g^{-1}, although at this point, the maximum removal of 100% was observed. The declining adsorption capacity at adsorbent dosages greater than 10 g L^{-1} is mainly due to the unsaturation of adsorption sites through adsorption. This is in line with the findings reported by Suhaimi et al. [32] in their study, which asserted that the overcrowding of the adsorbent sites was responsible for the decreasing removal capacity of methylene blue using bamboo-derived biochar.

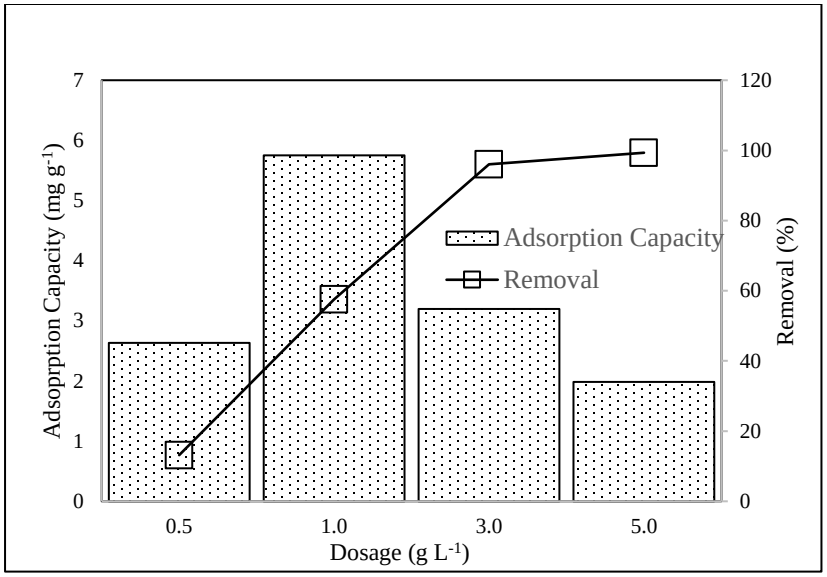

Figure 7. Effect of dosage on the adsorption of RO16 onto SGMC

Dye desorption

Figure 8 shows RO16 dye desorption from SMGC-loaded dye at different pH levels. As the pH increased, more dyes were desorbed. RO16 desorbed was 0%, 0.14%, 29.24%, and 68.38% at pH 3, 5, 8, and 11, respectively. As solution pH rises, the adsorbent surface net positive charge decreases. The electrostatic attraction of negatively charged dye particles to the more negatively charged SGMC surface indirectly aided desorption. This observation is consistent with research on reactive dye desorption using cationic polymer/bentonite by Li et al. [33].

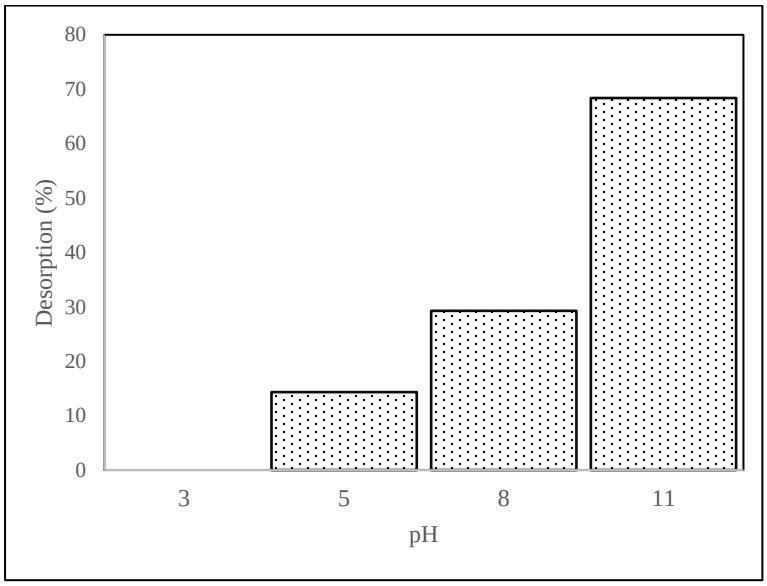

Figure 8. Desorption of RO16 from the dye-loaded SGMC

Conclusion

The results indicate that modifying the surface of grated coconut with a surfactant produced a promising reactive dye adsorbent for aqueous solutions. The pHPZC studies revealed that the SGMC had a net zero surface charge at a solution pH of 5.5, whereas the surface area

was relatively small at 1.86 m^2 g^{-1}. In the batch study, adsorption depended on the pH of the dye solution and the amount of adsorbent. The percentage of dye removed was greater in acidic conditions, with pH 3 showing the highest removal, whereas the adsorbent dosage of 10 g L^{-1} provided the highest adsorption capacity. With a maximum adsorption capacity of 9.72 mg g^{-1}, the Langmuir isotherm correlated best with the equilibrium adsorption data. The desorption of dye-loaded SMGC increased with increasing water pH and vice versa. Due to its abundance, ease of modification, and low cost, the application of SMGC proved to be an effective substitute treatment method for dye wastewater.

Acknowledgement

The authors would like to express their gratitude to the Faculty of Applied Sciences, Universiti Teknologi MARA, Shah Alam, for their generous support in providing the laboratory facilities necessary for conducting this research.

Abstract

Vaping is a common phenomenon in the world including in Malaysia, and one that involves all strata of society. Recently, vaping has become an unintended mode of delivery for various illicit drugs of abuse. The objective of this study is to detect and identify the presence of illicit substances including opiates, tetrahydrocannabinol (THC), amphetamine-type stimulants (ATS), benzodiazepines (BZD), barbiturates, phencyclidine, ketamine and mitragynine in three vape liquid samples provided by the National Anti-Drugs Agency (NADA), Kelantan, Malaysia. Some of these drugs have been linked to fainting episodes after vaping. The samples were analysed using enzyme multiplied immunoassay technique (EMIT), thin layer chromatography (TLC) and gas chromatography-mass spectrometry (GC-MS). One of the samples was found to contain ketamine (the band was seen on the TLC plate and the result was further confirmed using GC-MS, with 99% match) with an estimated concentration of at least 25000 ng/mL by linear extrapolation of the calibration curve. Two other samples were noted to contain nicotine (bands were seen on TLC plate and also confirmed by GC-MS). Ketamine abuse is not widely reported because the vast majority of drug-screening setups do not offer testing for ketamine. Ultimately, vape liquid samples in this study were found to contain illicit drugs such as ketamine and nicotine. This suggest that tighter regulation would help curb this health bane on society.

Keywords: vape, illicit drugs, enzyme multiplied immunoassay technique, thin layer chromatography, gas chromatography mass spectrometry

Abstrak

Vape atau rokok elektronik merupakan fenomena yang lazim di dunia termasuklah di Malaysia melibatkan semua lapisan masyarakat. Kebelakangan ini vape telah menjadi salah satu cara penggunaan dadah terlarang. Objektif kajian ini untuk mengesan

dan mengenalpasti dadah terlarang termasuk opiat, tetrahidrokanabinol (THC), amphetamine-type stimulant (ATS), benzodiazepin (BZD), barbiturat, phencyclidine, ketamin and mitragynine yang terdapat di dalam 3 sampel vape daripada pihak Agensi Anti Dadah Kebangsaan (AADK), Kelantan, Malaysia yang mana telah dikaitkan dengan keadaan tidak sedarkan diri pengguna vape tersebut. Sampel-sampel tersebut telah dianalisa dengan menggunakan kaedah imunoasai berganda enzim, kromatografi lapisan nipis dan kromatografi gas spektrometri jisim. Salah satu sampel didapati mengandungi ketamin (Jalur yg berkenaan kelihatan pada plat TLC dan disahkan oleh GC-MS dengan 99% kepastian) dengan kepekatan yang dianggarkan sekurang-kurangnya 25000 ng/mL daripada unjuran lengkung kalibrasi. Dua sampel yang lain didapati mengandungi nikotin (jalur yang berkenaan kelihatan pada plat TLC dan disahkan melalui GC-MS). Penyalahgunaan ketamin kurang dilaporkan kerana kebanyakan pusat saringan untuk pengesanan dadah tidak menawarkannya. Sebagai kesimpulan, sampel cecair vape dalam kajian ini didapati mengandungi dadah terlarang (ketamin) dan nikotin. Penguatkuasaan undang-undang yang lebih ketat mungkin diperlukan untuk membantu menangani kemudaratan kesihatan ini dalam masyarakat.

Kata kunci: vape, dadah terlarang, teknik imun berganda enzim, kromatografi lapisan nipis, kromatografi gas-spektrometer jisim

Introduction

Vape or electronic cigarettes (EC) are perceived by the smokers to be healthier alternatives to tobacco cigarettes [1]. These devices are used to deliver nicotine, flavourings and other chemicals via aerosolization [2, 3]. Vape liquids containing flavours, solvents and other unknown ingredients, are often heated in e-cigarettes and vape rigs, and creating an aerosol that users inhale.

Vaping is a common phenomenon globally. In Malaysia, the prevalence of EC uses increased from 0.8% in 2011 to 4.9% in 2019 [4]. Alarmingly, a cross-sectional study conducted in 2018 showed 73% of the students from a secondary school in Kuala Lumpur were EC users [5]. Unlike tobacco cigarette, ECs and vapes have been not regulated in Malaysia to date: there is no regulation; neither towards the group of users, the electronic device used (safety or design) nor the liquid contents. Therefore, the sale of these devices and related products to users including underage children or youth is possible which could lead to health risk problems and also criminal abuse of the vape liquid.

Daily vaping has been reported to increase the risk of developing myocardial infarction and E-cigarette or Vaping Use-Associated Lung Injury (EVALI). These problems may arise through various mechanisms, including oxidative stress and inflammation, DNA damage, altered haemodynamic and platelet activity [6-8]. Vape liquid's flavour has been reported to contain illegal psychoactive drugs which was adulterated in addition to the four primary components of vape liquids (propylene glycol, glycerol, various flavourings, nicotine). Previous literatures have reported the detection of amphetamine-type stimulants (ATS) [9], tetrahydrocannabinol (THC) [10, 11] and even various new psychoactive substances (NPS) [12] in vape liquids. These substances may cause significant health and development effects, especially among young users due to the are exposure to drugs of abuse via vaping itself and other side effects of vaping.

The presence of illicit drugs in vape liquids is factual. These have also been reported in other studies [13,14]. Analysis of drug of abuse in vape liquid was not implemented due to the absence of regulation and enforcement on vape liquid ingredients. To date, there is no standard procedure for the analysis of vape liquid, or suspected adulterated vape liquids when those samples are submitted for analysis to government laboratories. Therefore, this study reports on in-house exploratory screening and confirmatory analysis method of illicit substances in vape liquid. Three vape liquid samples were collected from National Anti-Drugs Agency (NADA), Kelantan, Malaysia and were tested for the presence of illicit drugs including opiates, THC, ATS, BZD, barbiturates, phencyclidine, ketamine and mitragynine. The samples were assessed following Pharmacology Laboratory, Hospital USM procedures and forensic narcotic screening protocols.

Materials and Methods

Chemicals and reagents

Methamphetamine (MA) hydrochloride, methyl enedioxymethamphetamine (MDMA) hydrochloride, nitrazepam, nimetazepam, diazepam, flunitrazepam and

mitragynine drug standards were purchased from Lipomed (via Labchem, Malaysia). Amphetamine sulphate, alprazolam, ketamine hydrochloride and nicotine were purchased from Sigma Aldrich, (USA). Morphine, codeine, oxazepam and midazolam were purchased from Cerilliant (Texas, USA).

Thin layer chromatography (TLC) reagents used in liquid-liquid extraction and as mobile phase components, ethyl acetate, methanol, ammonia 28%, chloroform, iso-propanol and petroleum benzine, were acquired from Merck, USA. The visualization reagents, ninhydrin, hexachloroplatinic acid, potassium iodide, sulphuric acid, naphthyl ethylenediamine, glacial acetic acid and bismuth nitrate were purchased from Merck, USA. Fast Black K, dimethylaminobenzaldehyde were acquired from Sigma Aldrich (USA). Sodium nitrite and ammonium sulphamate were bought from Acros Organic (New Jersey, USA).

Sample preparation: Drug standard

The drug standards methamphetamine (MA) hydrochloride, methylenedioxymethamphetamine (MDMA) hydrochloride, nitrazepam, nimetazepam, diazepam, flunitrazepam, mitragynine amphetamine sulphate, alprazolam, ketamine hydrochloride, nicotine, morphine, codeine, oxazepam and midazolam were prepared at 100 ng/mL concentration.

EMIT

For immunoassay analysis, vape liquid samples (sample 1, sample 2 and sample 3) were subjected to analysis without further sample preparation.

TLC

For TLC, the samples were subjected to liquid-liquid extraction (LLE). For benzodiazepine analysis, neutral extraction was performed by adding 0.6ml petroleum benzine to 0.3 ml of vape liquid sample and was centrifuged at 1000 rpm for 5 min. The top layer of the mixture that was the organic layer was removed. The sample was dried at 50 ^{o}C.

For ATS, mitragynine and for the analysis of other slightly alkaline substances such as ketamine and nicotine, the samples were first alkalinized to about pH 10 by adding dilute NaOH to 0.3 mL of vape liquid sample each. Basic extraction was then performed by adding 1ml of chloroform to the flask as the extraction solvent.

Extraction procedure

1 mL of vape liquid sample and 2 mL of chloroform were added to the tubes. The tubes were shaken on a rotator for 10 min. This was followed by centrifugation at 3000 rpm for 30 min. After centrifugation, the chloroform phase was transferred into V-tubes and evaporated to dryness under a stream of nitrogen at 45 °C. The dried extract was reconstituted with 70 µL of methanol, vortex-mixed and injected into the GC-MS system.

EMIT screening

The vape liquid samples were screened by a Viva-E drug analyser (Siemens, Germany) for the presence of opiates, tetrahydrocannabinol (THC), amphetamine-type stimulants (ATS), benzodiazepines (BZD), barbiturates and phencyclidine which uses Enzyme Multiplied Immunoassay Technique (EMIT).

Thin layer chromatography

Thin layer chromatography was performed for analytes that had significant readings on EMIT screening, as part of confirmation. 20µL of extracted vape liquid samples were spotted onto TLC silica plates, alongside drug standards to determine presence of substance of abuse using a TLC spotter.

For ATS TLC plate, the bottom of the spotted plate was placed in ethyl acetate/methanol/ammonia (8.5: 1.0: 0.5) for development and sprayed with visualization reagent (10% ninhydrin and Fast Black K). The spot retention factor (R_{fs}) values were compared against ATS standards including methamphetamine, amphetamine and 3,4-methylenedioxy-methamphetamine (MDMA). While this plate was specifically optimized for the ATS detection, it also can detect other amines, such as ketamine and mitragynine.

For BZD TLC plate, acetone/hexane mixtures (1:3) were used as developing solvent system. Both

unhydrolyzed and hydrolysed vape samples were spotted onto the TLC plates. The spot Rfs were compared against benzodiazepine standards including oxazepam, nitrazepam, nimetazepam, flunitrazepam, midazolam. Dragendorff's reagent and Bratton-Marshall's reagent were used as visualization reagents for unhydrolyzed and hydrolysed samples respectively.

For mitragynine plate, ethyl acetate/hexane (7:3) was used as a mobile phase. Spot R_{fs} were compared against mitragynine standard. Ehrlich's reagent (5% dimethylaminobenzaldehyde in 95% ethanol) was used as the visualization reagent.

Gas chromatography mass spectrometry

Drug standard mixtures and all the vape liquid samples (diluted and extracted) were analysed using GC-MS method to confirm the presence of the substances found during TLC. Narcotic scan program parameters were able to resolve all drug standards of interest. An Agilent 7890B Gas Chromatography System and 7683 Autosampler Agilent (USA) paired with Agilent 5977B Mass Spectrometry detector was used. Enhanced Chemstation software (Version F.01.03.2357) Agilent Technologies Inc. (USA) was used for instrument control and data acquisition. Spectral library comparisons for compound identification are referred to National Institute of Standards and Technology, NIST 14 Mass Spectral Library and Search Software (Version 2014).

Separation was carried out using HP5 MS capillary column (30 m x 250 m x 0.25 m) with helium carrier gas at a constant flow of 1.0 mL/min and injection in split mode ratio of 50 mL/min. The injector was heated to 27 °C and the transfer line is heated to 280 °C. Initial oven temperature is 80 °C then ramped at 20 °C/min to 150 °C and hold for 2 minutes. Second ramp is at 20 °C/min to 300 °C and hold for 14 minutes. The mass spectra were collected after 3 minutes solvent delay time. The ionisation voltage was 70 eV and the mass range were 40-500 m/z.

Results and Discussion

EMIT

EMIT screens were negative for opiates, THC, barbiturates and phencyclidine in all three examined vape liquid samples. Conversely, EMIT recorded readings for ATS in sample 1 and sample 2 whilst trace readings for BZD compounds were detected in all three samples.

TLC

None of the samples contains ATS. However, one band with higher Rf was noted on the ATS plate (Table 1).

ATS TLC plates revealed that none of the sample contains ATS compounds. In sample 1, the R_f values of the two bands were not comparable to the ATS standards. Interestingly, in vape liquid sample 2, bands for methamphetamine, amphetamines or MDMA were detected on ATS plate despite EMIT screening for ATS recorded detection of 6323.5 ng/mL. Nonetheless, a brownish band at R_f 0.75 and a large violet coloured band at R_f 0.93 were observed on the ATS plate. Although for the screening for MDMA revealed a violet band, the violet band in sample 2 may not be the same compound as MDMA since the R_f was different (R_f 0.93) compared to the Rf for MDMA was 0.57.

For BZD TLC plate there was a band that was compatible with flunitrazepam in sample 1, while there was one vague band compatible with diazepam is in sample 2 and 3. The presence of these unknown bands on both plates required further analytical evaluation to determine the compound. TLC for mitragynine was also performed to sample 1, however the results was negative. The amounts in sample 2 and 3 were insufficient for testing, thus was not performed.

Table 1. Summary of TLC analysis of ATS and BZD plate

Standards and Samples	ATS Plate			BZD Plate		
	Number of Band	Colour of Band	R_f Value	Number of Band	Colour of Band	R_f Value
Methamphetamine standard	1	Grey	0.56			
MDMA standard	1	Violet	0.57			
Amphetamine standard	1	Light Yellow	0.61			
Nimatezepam standard				1	Yellow	0.18
Nitrazepam standard				1	Yellow	0.12
Flunitrazepam standard				1	Yellow	0.15
Diazepam standard				1	Yellow	0.26
Sample 1	2	Pink Violet	0.44 0.75	1	Yellow	0.15
Sample 2	2	Brownish Violet	0.75 0.93	1	Pale yellow	0.26
Sample 3	0	Not available	Not available	1	Pale yellow	0.26

GC-MS

The chromatogram of the mixed drug standards showed that ATS standards eluted earlier than the BZD substances (Figure 1). All drugs were well separated and adequately resolved, despite there being similar chemical properties among the ATS group. Similarly, all four BZD standards separated adequately within analysis run time.

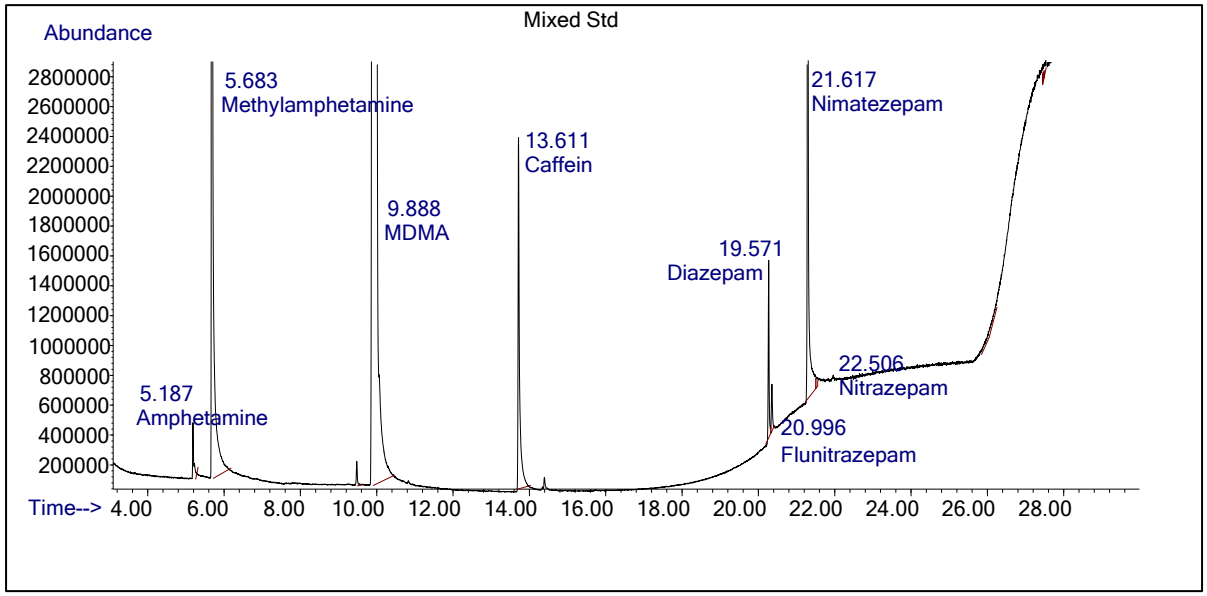

Figure 1. GC-MS total ion chromatogram (TIC) of mixed ATS and benzodiazepine (BZD) drug standards for cross reference with neat and extracted vape liquid samples

A large peak with retention time (R_t) ranging from R_t 3.553 to R_t 5.643 in mixtures of glycerine, L-arabinatol and ethyl acetate was noted in GC-MS total ion chromatogram (TIC) of diluted vape liquid samples (Figure 2). These compounds could be carriers for the vape liquid active compounds.

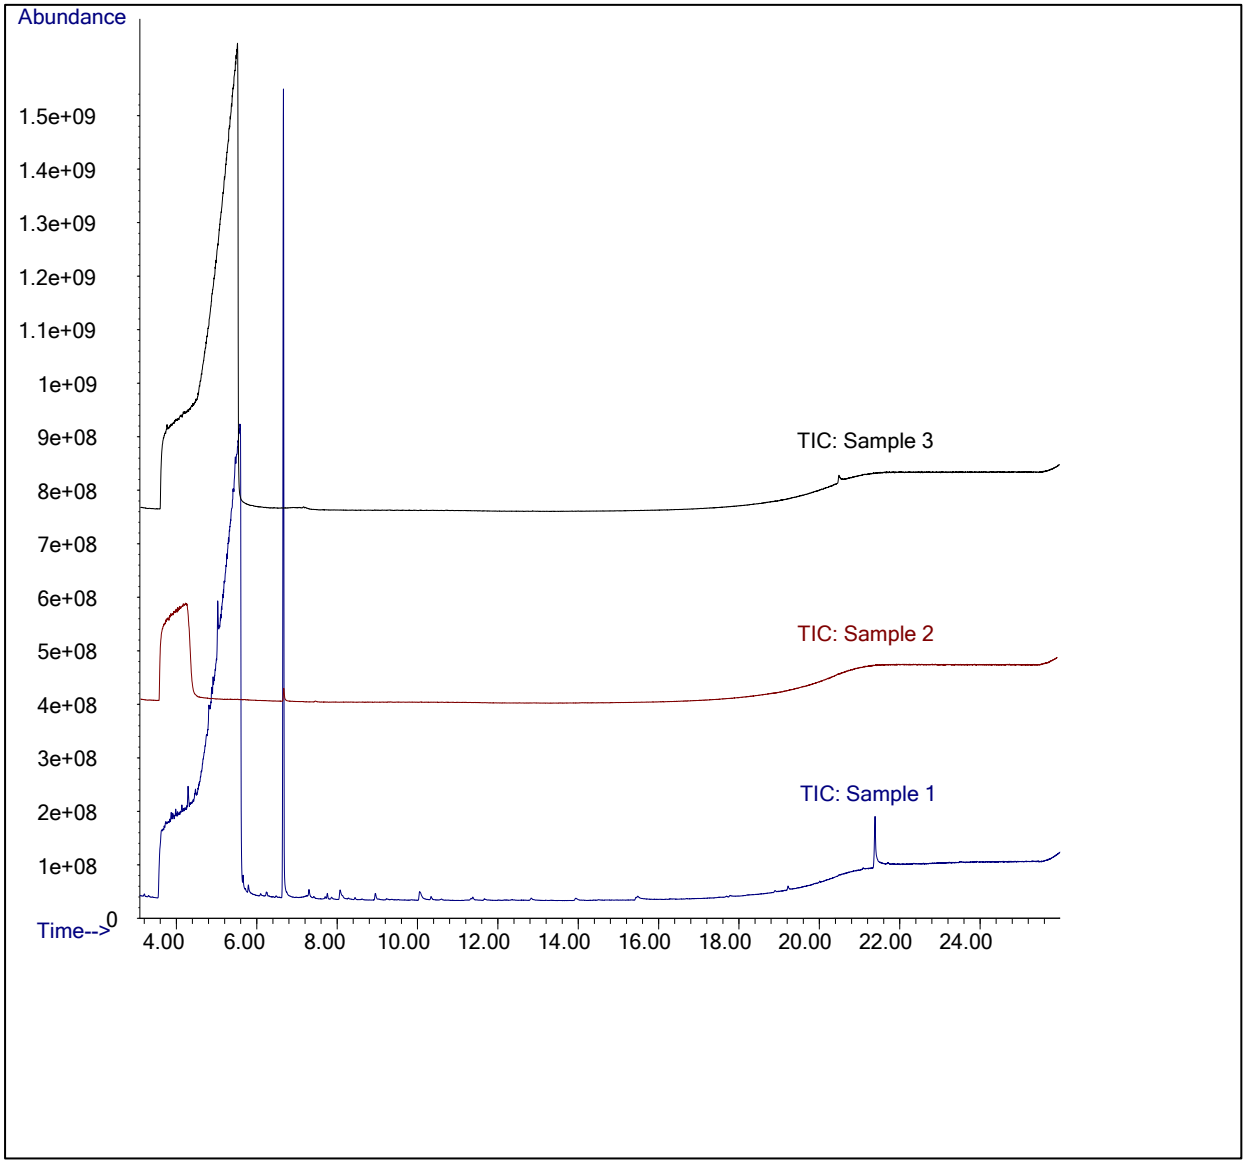

Figure 2. GC-MS total ion chromatogram (TIC) of neat vape liquid samples (2% vol/vol methanol).

Since amphetamine and methamphetamine compounds appeared at R_t 5.185 and R_t 5.679 respectively as shown in Figure 1, the presence of carrier peaks (shown in Figure 2) could have obscured the peaks of ATS compounds. Therefore, extraction was further performed on the samples in order to eliminate the effect of carrier. As a result, better TIC profiles were observed in the extracted vape liquid sample 1, 2 and 3.

Sample 1

GC-MS analysis was unable to detect the presence of the ATS compounds in sample 1. However, two prominent compounds were present at high levels peaks of R_t 6.674

and R_t 21.591 as shown in Figure 3. A mass spectral library search tentatively identified the peaks as 2-Heptenoic acid, heptadecyl ester (25% Qual) and 2,3-Diphenylbenzo-1,4-dioxin (27% Qual) respectively. Because the elution time of Sample 1 peak at R_t 21.591 is very close to the retention time of nimatezepam standard, there was a possibility of the GC chromatographic shift. The shift was checked out by comparing the mass spectrum of the compound and it was confirmed that neither nimatezepam nor lunitrazepam were present in sample 1 (Figure 4).

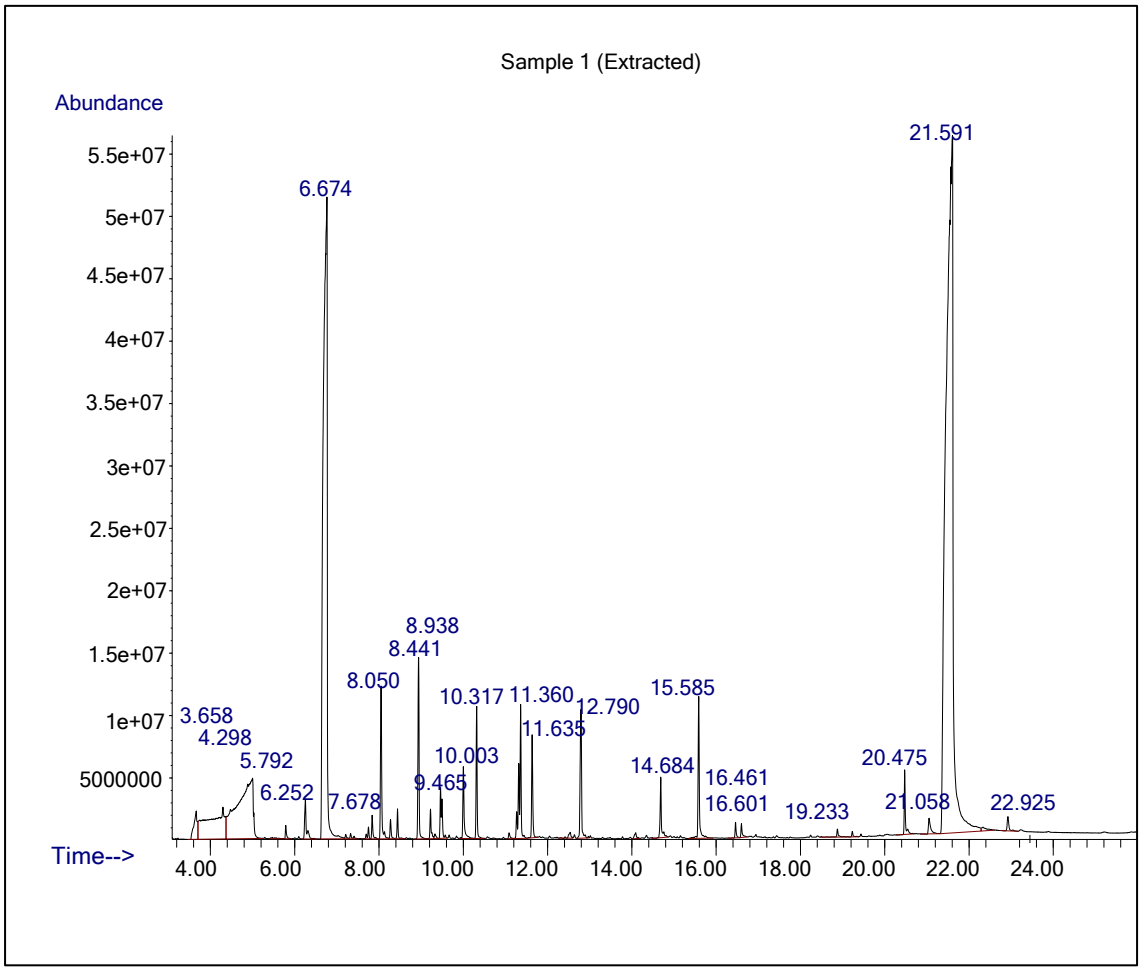

Figure 3. GC-MS total ion chromatogram (TIC) of extracted vape liquid sample 1

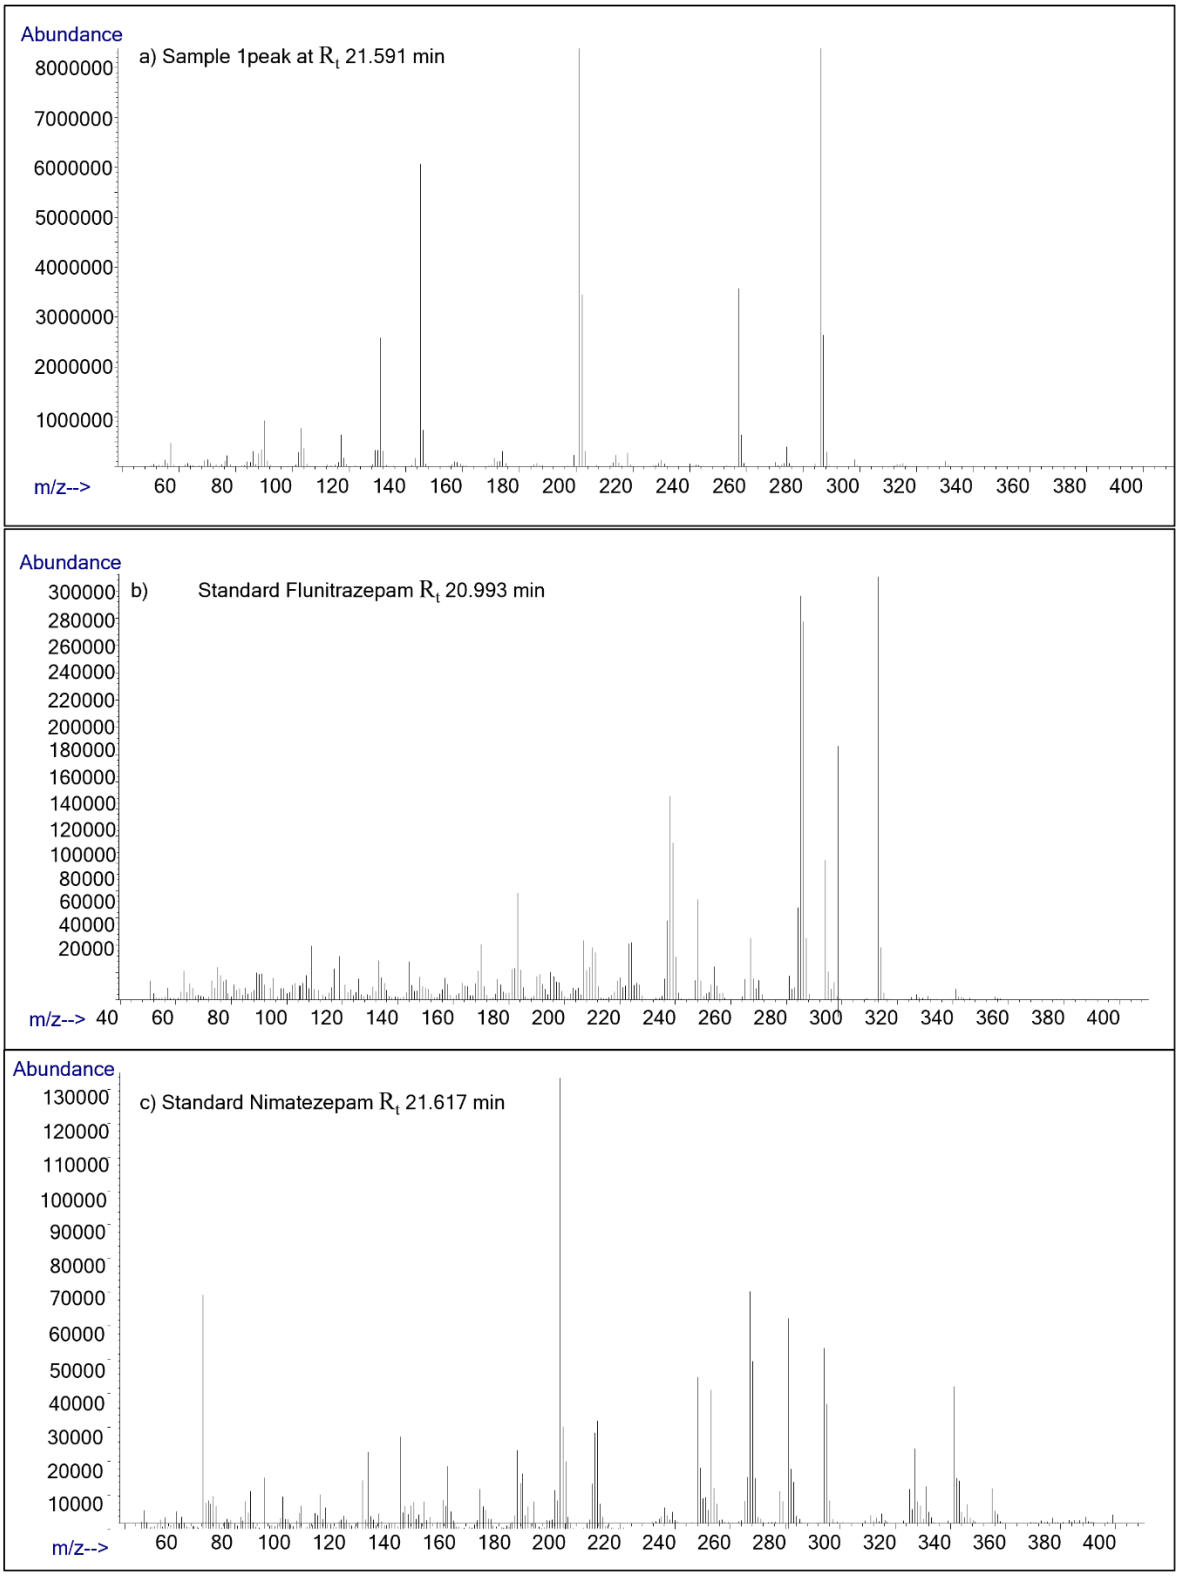

Figure 4. Mass spectrum of benzodiazepines in comparison to sample 1 peak R_t 21.591

Sample 2

The analysis of sample 2 using GC-MS identified peaks for nicotine and ketamine from the extracted sample (95-99% certainty according to NIST14 database), eluted at Rt 7.6 and Rt 13.9 respectively (Figure 5). Nicotine was identified with major fragments at 84 and 133 m/z as seen in Figure 6. The molecular ion, M+, appears at m/z = 162 and M-1 peak (m/z = 161,) was characteristic for cyclic amines [15]. Ketamine was identified at 179 and 220 m/z as shown in Figure 7.

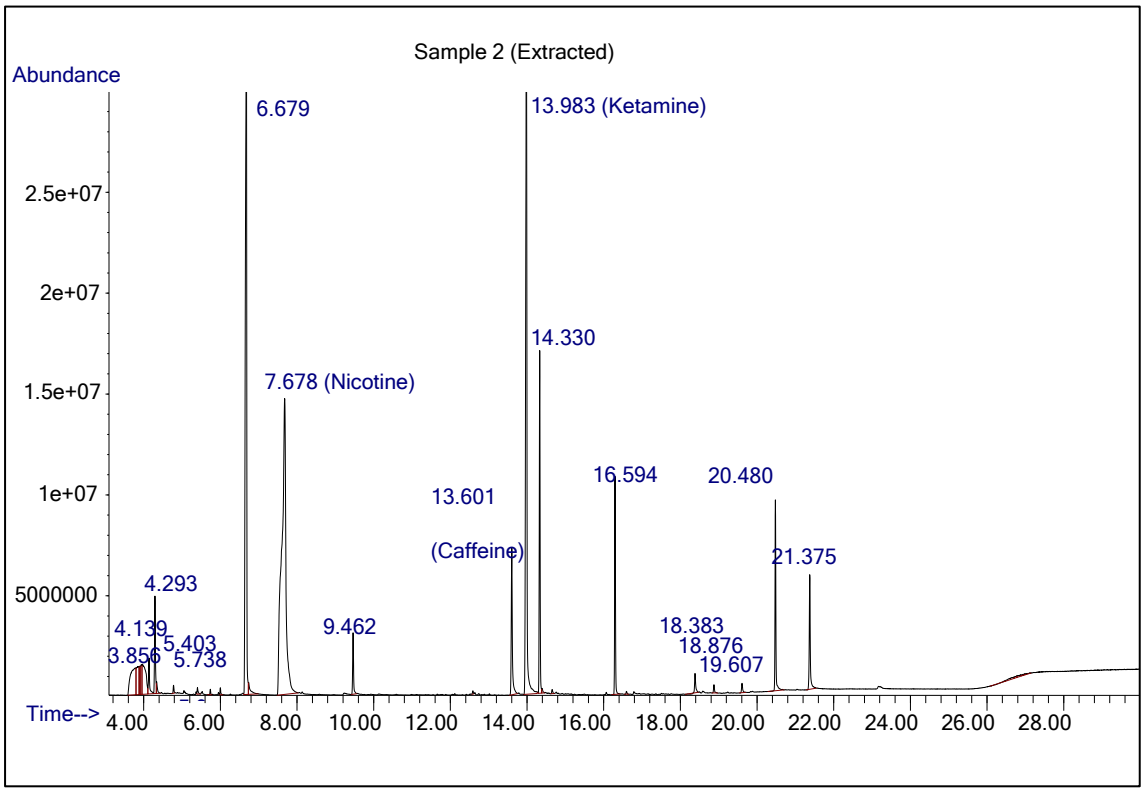

Figure 5. GC-MS total ion chromatogram (TIC) of extracted vape liquid sample 2

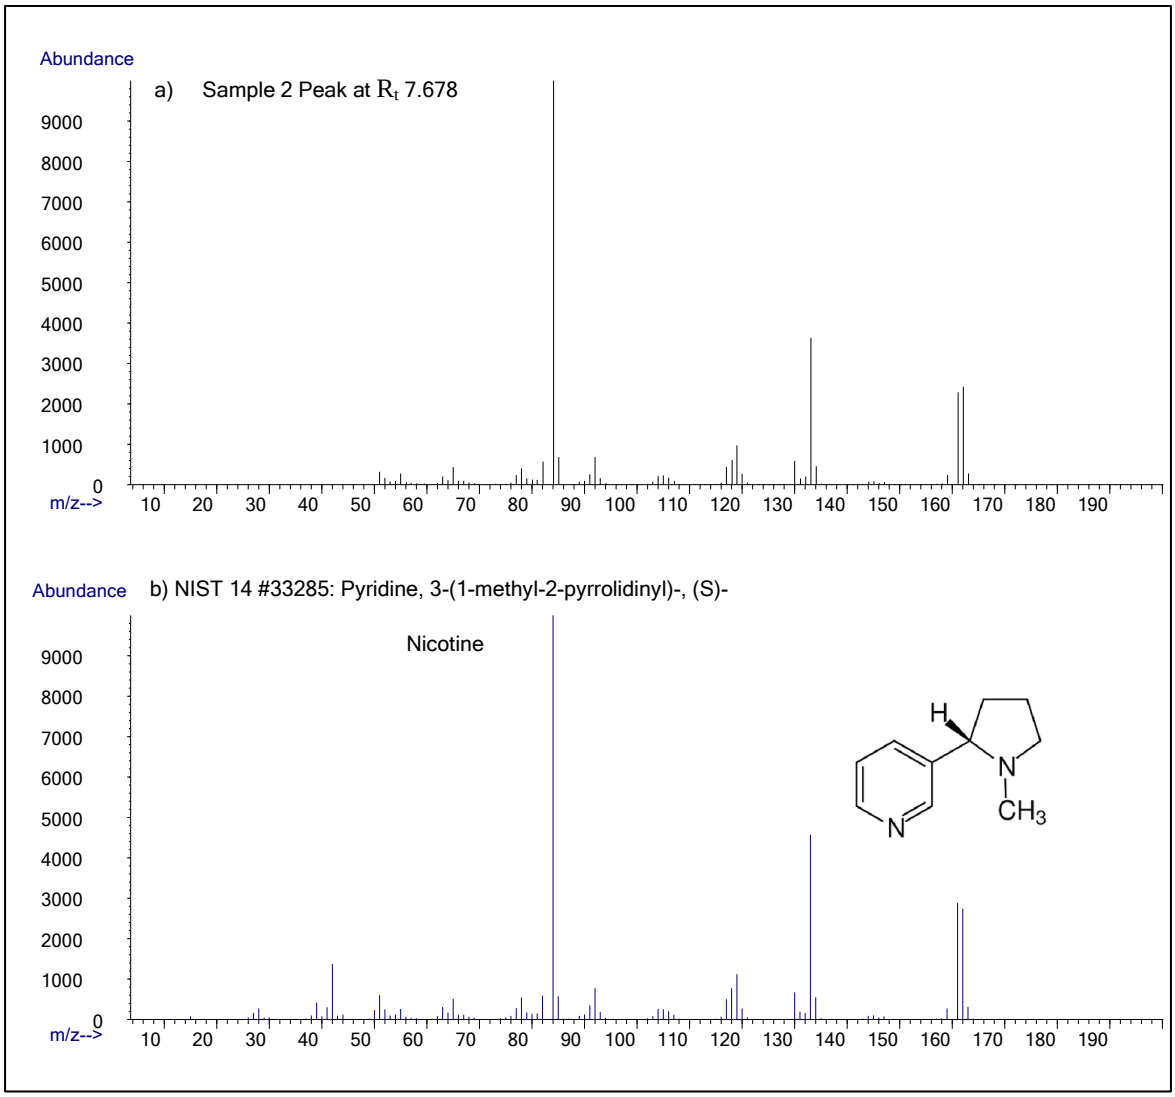

Figure 6. Mass spectrum of peak RT 7.675 identified as Pyridine, 3-(1-methyl-2-pyrrolidinyl)-, (S)-, generally known as nicotine.

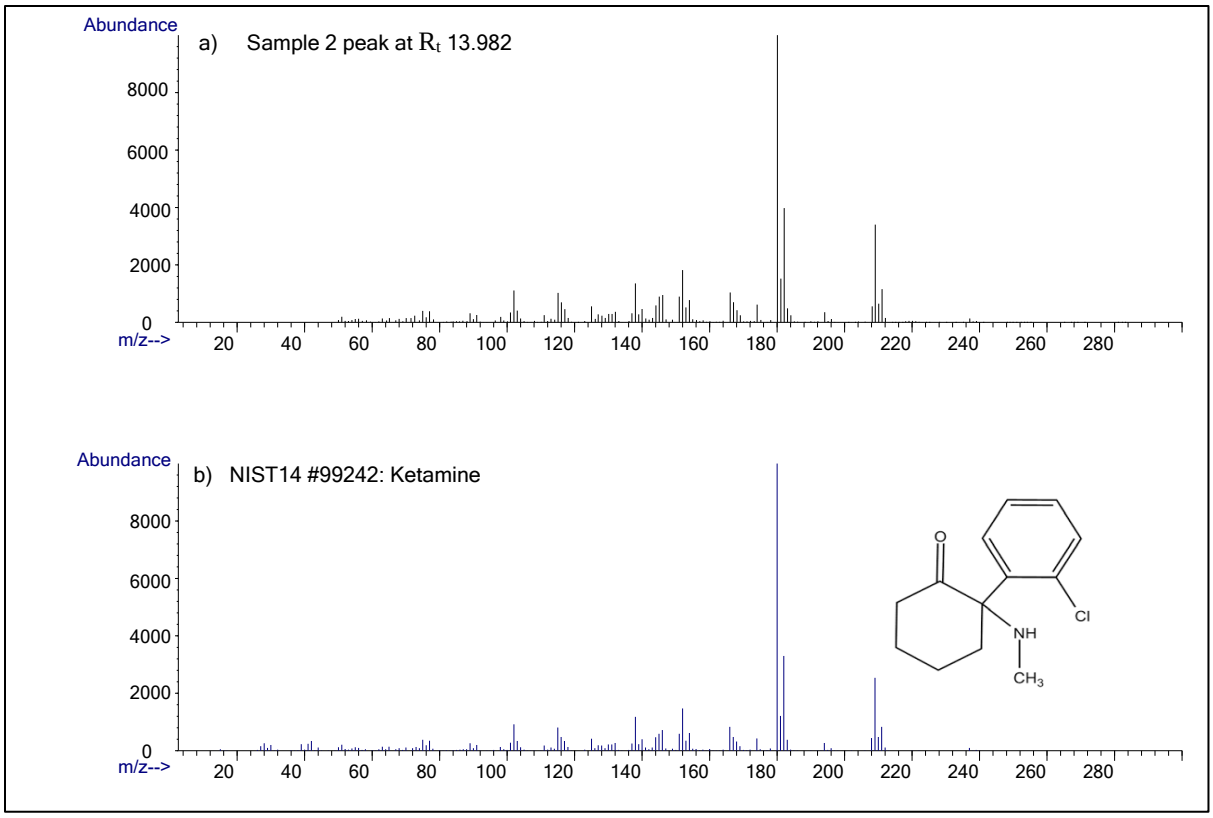

Figure 7. Mass spectrum of peak RT 13.983 identified as ketamine

Sample 3

TIC confirms the absence of ATS compounds in sample 3 in GC-MS analysis (Figure 8). In comparison to the other two samples, nicotine and ketamine were not detected. To confirm the BZD plate which obtained a band consistent to the diazepam standard, the mass spectrum of sample at RT 19.615 compared to diazepam peak RT 19.575 as presented in Figure 9.

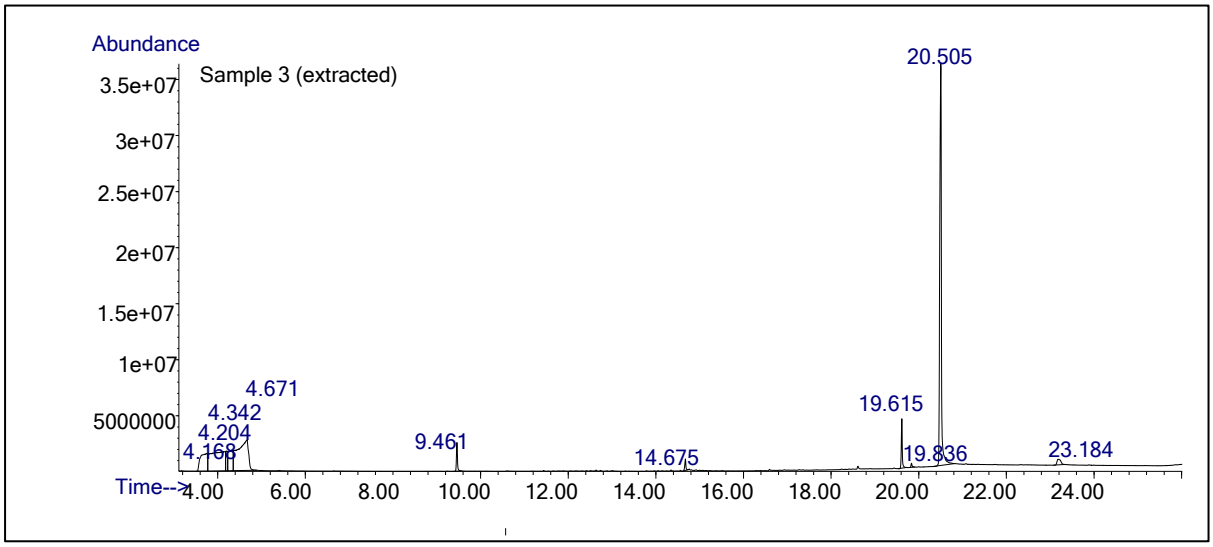

Figure 8. GC-MS total ion chromatogram (TIC) of extracted vape liquid samples sample 3

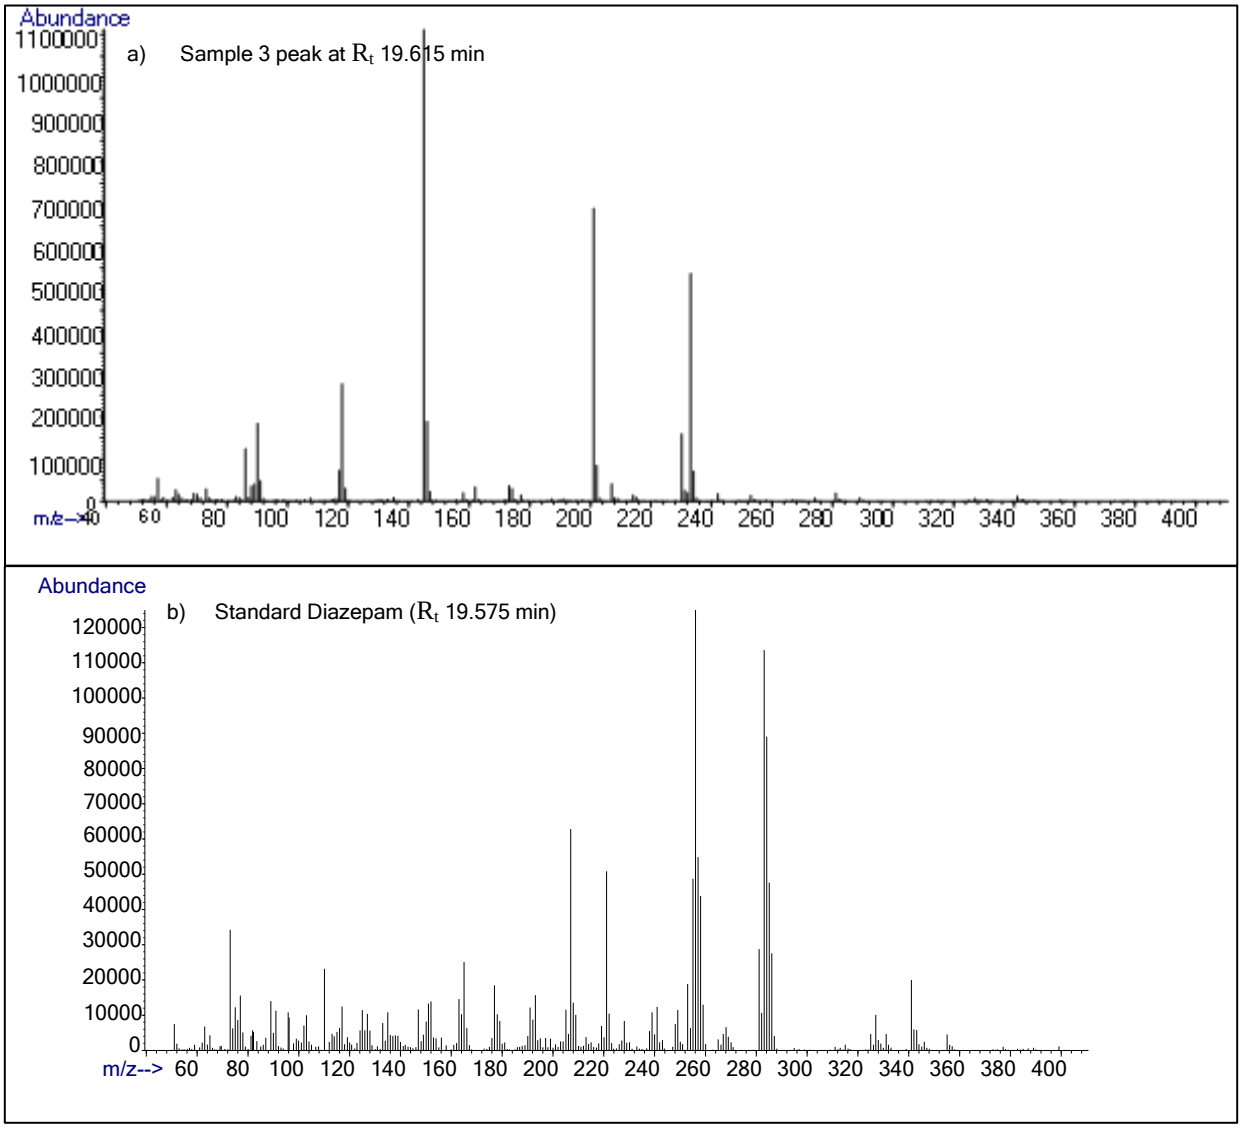

Figure 9. Mass spectrum of sample 3 peak R_t 19.615 in comparison to diazepam standard R_t 19.575

Vaping was originally intended to be a substitute to smoking, primarily serving as a nicotine delivery tool and reducing the number of harmful substances and carcinogens found in regular cigarettes. However, it has become an emerging system of illicit drug delivery [16] for various drugs of abuse, exacerbated by poor regulation from the authority. Ketamine has been discovered in recent raids in Malaysia [17] and also been reported in vape in previous surveys [12], but is relatively uncommon, most likely due to gross under detection since ketamine was not a drug that is routinely screened.

Abuse of methamphetamine dominates current cases in Kelantan [18], alongside benzodiazepines (nimetazepam, nitrazepam) and to a lesser extent opiates and THC. Ketamine on the other hand is infrequently reported, as it is not officially part of drug screening in district hospitals, or even in most tertiary referral centres in Kelantan. No exact history was available from subjects who used these vape samples. However, on further questioning, NADA did reveal general phenomena of light-headedness and fainting after using

this vape. The symptoms could be either due to ketamine or high levels of nicotine in the vape liquid.

Ketamine is a dissociative hallucinogen used clinically for the induction and maintenance of anaesthesia, acting via NMDA receptor blockade which explained the effects of light-headedness and fainting experienced by those using this vape liquid. Ketamine was not detected during screening since EMIT screening for ketamine was not available. The sample volume provided was also inadequate for a ketamine dipstick. While the ATS TLC plate revealed suspicious bands, we could not definitively confirm the presence of ketamine until GC-MS analysis was performed.

Even at lower doses, ketamine can cause changes in sensory perception, including visual or auditory hallucinations and a sensation of feeling detached from oneself and one's surroundings, hence its categorization as a dissociative. Other adverse effects include disorientation, confusion, or loss of motor coordination, dizziness, nausea, or vomiting. Increased blood pressure, heart rate, breathing, or body temperature are commonly seen. At high doses, ketamine induces loss of consciousness and unresponsiveness with respiratory depression (shallow or irregular breathing). The lethal dose for ketamine for a 70 kg adult is estimated to be about 4200 mg. LD_{50} in rats are established at 447 mg/kg. Typical doses used for anaesthesia range around 450-750mg and recreational use (via snorting) ranges around 75-125 mg.

Nicotine was detected in two of the vape samples. This result is alarming since nicotine use may result in dependence and abuse. With greater delivery, faster rate of absorption and higher nicotine concentration, the risk of dependence may be higher. Furthermore, the pharmacological effects of nicotine in the brain are influenced by the mode of administration and dose [19]. Since vaping has the potential of high and rapid nicotine delivery, vaping can cause or maintain nicotine dependence – this is why vaping as a method for smoking cessation is controversial [20]. It has been reported that a cigarette contains between 6.17-28.86 mg of nicotine, varying between cigarette brands [21]. Nicotine concentration in vape liquid varies considerably, ranging from 0-87.2 mg/mL [22]. The amount of nicotine delivered and the way in which it is delivered influence the addictiveness of a tobacco product [23]. As the vapers under the impression that vaping is safer than cigarette smoking, they may not control the amount of vape used. In addition, the heating process for vapes may lead to the generation of hazardous compounds [24]. Drugs may be abused freely in future through vaping since it is not obvious that the person took drugs using vape compared to "chasing the dragon", one of the current modes of administration using aluminium foils adopted by the drug users.

Conclusion

We detected ketamine in 1 of the 3 vape samples and nicotine in 2 samples collected from NADA. The presence of psychoactive substances in vape is a concerning issue as these products are sold to school going children. Here, we would like to ask for a reassessment of the risks and dangers of vaping and potentially the enactment of stricter laws and regulations to cover its use (essentially to ensure it does not contain dangerous psychoactive substances) and trade (limiting its availability to underaged children).

Acknowledgements

The authors would like to thank Muhamad C Ismail of AADK Kota Bharu for supplying the vape samples. The authors would also like to thank Mr Mohd Lukman Muhamad from Pharmacology Laboratory, Hospital Universiti Sains Malaysia for technical assistance in vape extraction and thin layer chromatography.

Abstract

Recent issues on the presence of glycidyl ester (GE), a potentially carcinogenic compound, in food have sparked consumer worry. Fatty acid esters of glycidol pose potential food safety concerns and have been classified by IARC as a "likely human carcinogen". They are generated during the high-temperature deodorization step. Vegetable oils consist primarily of five fatty acids, palmitic acid, linolenic acid, linoleic acid, oleic acid, and stearic acid. Palm kernel and coconut oil also contain significant quantities of lauric acid and myristic acid. These fatty acids of edible oil undergo various reactions, producing different GE. Researchers have developed a GE quantitation method called "indirect" methodology, but this method uses hydrolysis to release glycidol from GE instead of directly targeting the intact fatty acid esters. It also requires a derivatization step before gas chromatography-mass spectrometry (GC–MS) analysis. While the early methods developed to target these contaminants exclusively utilized the 'indirect' approach, they were critical in bringing attention to the presence of GE in oils. The factors that are highly related to GE formations include process temperature, process duration, and the presence of precursors. This paper reviews previous studies on various methods and instruments that focused on detecting GE in different matrices from 2015 to 2022.

Keywords: glycidyl ester, deodorization, hydrolysis

Abstrak

Isu terkini mengenai kehadiran ester glisidil (GE), sebatian berpotensi karsinogenik, di dalam makanan telah mencetuskan kebimbangan dalam kalangan pengguna. Ester asid lemak glisidol menimbulkan potensi keselamatan makanan dan telah

diklasifikasikan oleh IARC sebagai "kemungkinan karsinogen manusia". Ia dihasilkan semasa proses penyahbauan pada suhu tinggi. Minyak sayuran yang utama terdiri daripada lima asid lemak, asid palmitik, asid linolenat, asid linoleat, asid oleik, dan asid stearat. Biji kelapa sawit dan minyak kelapa juga mengandungi asid laurik dan asid miristik dalam jumlah yang banyak. Asid-asid lemak dalam minyak yang boleh dimakan tersebut melalui pelbagai tindak balas, menghasilkan GE yang berbeza. Para penyelidik telah membangunkan kaedah kuantitasi GE yang disebut metodologi "tidak langsung", tetapi kaedah ini menggunakan hidrolisis untuk membebaskan glisidol dari GE dan bukannya menyasarkan secara terus ester asid lemak yang utuh. Kaedah ini juga memerlukan langkah derivatisasi sebelum analisis kromatografi gas-spektrometri jisim (GC–MS). Meskipun kaedah-kaedah awal yang dibangunkan untuk mengesan bahan cemar ini menggunakan pendekatan tidak langsung secara eksklusif, kaedah-kaedah tersebut sangat penting dalam mengarah perhatian kepada kehadiran GE di dalam minyak. Antara factor-faktor yang berkait rapat dengan penghasilan GE termasuklah suhu proses, masa proses dan kehadiran pelopor. Makalah ini membentangkan resensi kajian-kajian terdahulu mengenai pelbagai kaedah dan instrumen yang tertumpu kepada pengesanan GE dalam pelbagai matriks dari tahun 2015 hingga 2022.

Kata kunci: glisidil ester, penyahbauan, hidrolisis

Introduction

Glycidyl fatty acid esters or glycidol (GE) are contaminants commonly found in most refined fats and oils, including edible oil such as palm oil and vegetable oil or any food made from these oils like margarine and fried products. Palm oil, corn oil, and coconut oil have been recorded with the highest presence of GE. The food industry uses palm oil because of its stability to high temperatures and long shelf life [1]. In some research, GE has been found in infant formula due to the use of vegetable oils [2]. It was also reported that the most abundant GE of fatty acids were esters of the palmitic and oleic acids [3]. Hence, the presence of GE has raised the concern of many people as GE is a carcinogenic compound. In general, a process called oil deodorization at a temperature within 230 ℃ to 270 ℃ could lead to the formation of GE as byproducts [4]. Specifically, this compound is formed from diacylglycerol (DAG) or monoacylglycerol (MAG) at high temperatures. The release of glycidol happens after GE is broken down during the digestion process. According to a report in European Food Safety Authority (EFSA) Journal in 2016, of all the available refined vegetable oils, palm-based fat and oils contain the highest amount of monochloropropanediol (MCPD) in the form of ester. Figure 1 and Figure 2 depict the general structure of GE and the chemical structures of several GE, respectively.

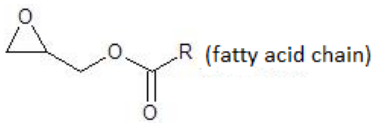

Figure 1. General structure of GE

Since gut lipases rapidly digest GE to free glycidol, GE intake should be considered a source of glycidol. Therefore, International Agency for Research on Cancer (IARC) suggested the application of the ALARA (As Low As Reasonably Achievable) principle on this genotoxic carcinogenic compound [3]. In 1990, the U.S. National Toxicology Program declared the multisite carcinogenicity of glycidol towards rodents. Later in 2010, an estimation of 1.3 mg/kg/day of glycidol was recorded for human cancer potency by the California Environmental Protection Agency [5].

As mentioned above, the presence of GE is due to the process of oil deodorization at high temperatures. The synergistic interaction between stripping stream rate and temperature is significant to the formation of GE. In the refining process of conventional edible oils, deodorization is the last procedure performed. The main purpose of this step is to remove undesirable substances. This is done to achieve the standard of oil production in taste, odor, color, and oxidative stability [6]. According to Stadler (2015), MCPD and GE's formation pathways in oil are different. Unlike MCPD, GE cannot be generated from triacylglycerols (TAG), but it is generated through intramolecular conversion and a free fatty acid chain loss. GE can also be generated via hydrolysis of MAG [4]. Arisseto et al. [8] proposed the formation of GE via either the internal nucleophilic attack of DAG or the nucleophilic attack of acyloxonium ion generated from the displacement of hydroxide group [7]. Even though GE could be formed

in all edible oil during the deodorization process, they tend to occur at the highest concentration in palm oil [8].

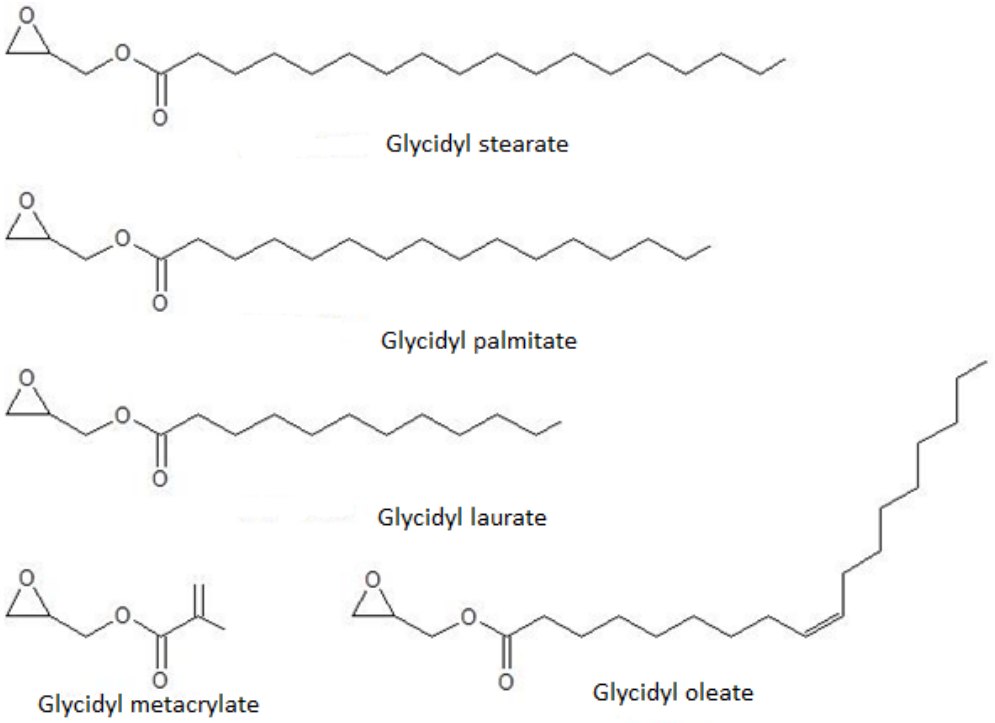

Figure 2. Chemical structures of several GE

Responding to such concern, much research is currently focusing on determining the presence of GE in edible oil. Edible oil such as palm oil was typically chosen as it provides the primary source of GE. Zelinkova et al. [10] studied the direct analysis of glycidyl ester laurate, myristate, palmitate, stearate, oleate, linoleate, and linolenate, and this method was successfully applied for the quantitation of GE in edible oils. Some research focused on determining the effect of frying temperature on GE formation since frying is one of the most convenient and common food preparation processes. According to Aniolowska et al. [3], by subjecting fat to high temperatures in the presence of the water and air during the deep-frying process, high number of new compounds that may be formed during the various hydrolytic, thermal, and oxidative reactions could be detected. In the frying process, the product of oil degradation, DAG, would react at high temperatures to form GE. GE also increased in concentration with increasing frying duration, frying temperature, and NaCl concentration [9]. Heating meat at high temperatures using an open fire charcoal grill can also generate a significant level of GE [10]. In 2017, the European Commission recommended compiling analytical data on the occurrence of GE in a broader range of food than only for oils, fats, and margarine [11]. At around the same time, the American Oil Chemists' Society (AOCS) publicized three methods suitable for analyzing GE, namely Cd 29a-13, Cd 29b-13, and Cd 29c-13 [4].

Due to the major advancement in analytical detection technologies, it is possible to analytically detect processing-derived food contaminants like GE at the level of parts per billion (ppb) [12] by using either direct or indirect approaches [7]. The direct methods allow the use of instruments like liquid chromatography-mass spectrometry (LC-MS) for quantitative and qualitative analysis of MCPD esters and GE, exactly as they are found in food. On the other hand, the indirect determination is based on the conversion of GE to glycidol. Glycidol will then be separated, derivatized, chromatographically isolated, and quantified. Several

analytical methods have been customized to accommodate the indirect method for measuring GE and MCPD ester in oils and fats [11]. Solid-phase extraction (SPE) or gel permeation chromatography clean-up is adequate to achieve acceptable separation of GE and MCPD from the oil matrix [11]. Wang et al. reported the involvement of cation-mediated and free radical-mediated intermediates in the formation mechanisms of GE [13]. Elimination of fatty acid radical or hydroxyl radical would form a free radical intermediate with five or six-membered cyclic acyloxionium structure. The presence and reactivity of chlorine compounds play vital roles in the formation of MCPD esters and, to a certain degree, GE.

In recent years, the amount of GE found in processed food and edible oils has significantly increased. Their presence is concerning to public health due to their ability to release potentially toxic glycidol via hydrolysis in the digestive tract [14]. The high level of chlorinated metabolites, the use of fertilizers that contain chloride salt, and the use of HCl-activated clays during the bleaching step of the refining process of palm oil contributed to its high GE concentration compared to other edible oils. Owing to the potential health risks and the levels of these contaminants in edible oils and foodstuff, the European regulatory has set limits of 1 mg/kg and 0.5 mg/kg of bound glycidol in processed food and infant formulas, respectively. One of the main strategies to contain the formation of GE is by removing the chlorinated precursor before deodorization [14], other than blending oils, refining methods improvement and acid and enzymatic degumming.

To produce refined oil of high quality in terms of organoleptic quality, stability, and nutritional quality, undesirable compounds are removed for safe human consumption [15]. The amount of GE contents in refined palm oil (RPO) range from 0.30 to 18.00 mg/kg, much higher than the level of GE in other oils like maize oil, olive oil, etc., which is in the range of 15 to 650 μg/kg. As shown in Figure 1 and Figure 2, GE contain an epoxide group and an ester group in addition to the long chain of fatty acid compositions. Both GE and its free form after hydrolysis in gastrointestinal tract, glycidol, are carcinogenic due to the presence of epoxide group that can react with DNA to form DNA adducts. Glycidol is known as genotoxic non-threshold carcinogen with evidences of toxicity in animal even at a very small dose [15], suggesting neurotoxicity, mutagenicity, and reproductive toxicity [16]. Detection of GE using indirect quantification based on gas chromatography-mass spectrometry (GC-MS) requires extensive sample preparation including transesterification, neutralization and derivatization steps and thus, more time-consuming. Albeit needing a high number of internal standards to detect a wide range of GE, direct methods based on LC-MS are much simpler and more commonly applied for the analysis of GE present in oily matrices due to their high sensitivity and specificity [17].

In this review, analytical method development including the sample preparation and detection of different types of GE are summarized in Table 1. The present article will address the development of sample preparation methods and analytical detection system of GE in various matrices, from the year 2015 to 2022.

Analytical Determination of GE

AOCS has published three indirect methods, namely Cd 29a-13, Cd 29b-13 and Cd 29c-13 to determine the amount of MCPD esters and glycidol in edible oils such as palm oil, canola oil and sunflower oil [4]. In these methods, the sum of MCPD esters and GE from various sources were expressed as free 3-MCPD and free glycidol. For instance, in the AOCS Official Method Cd 29c-13, the addition of dilute sodium hydroxide solution or sodium methoxide in methanol frees up glycidol and 3-MCPD via base catalysis, while the addition of excess acidic chloride-containing salt solution stops the reaction [18]. The free glycidol reacts with inorganic chloride to generate additional 3-MCPD and 2-MCPD. Then phenylboronic acid (PBA) is used for derivatization process, followed by the determination by GC-MS [4]. On the other hand, having the reaction stopped with an acidic chloride-free salt solution in excess does not generate additional 3-MCPD from free glycidol. As a result, this method allows for the indirect detection of GE (bound glycidol) under the assumption that no other compounds present are reactive towards inorganic chloride at ambient temperature to produce 3-MCPD [18].

In 2015, there were research developed to study the effect of the type of oil and degree of degradation on GE content during the frying process of French Fries. The study with the main purpose to determine the content of GE in oil that used for frying French fries were developed by Anilowska et al. By using LC-MS the presence of GE can be determined and the sample were analyzed for the acid and anisidine values, colors, refractive index (RI), composition of fatty acid and also content and composition of the polar fraction [19]. As in this study it was observed that the higher of time frying the content of GE were decreased. It is recorded with losses from 47% in the rapeseed oil and 78% in palm oil. This data was recorded after the frying process finished.

As the fat were extracted from the French fries, the GE analysis were conducted on the frying oil samples [19]. This lab work developed a double SPE procedure, chloroform and acetone were used as the medium for the oil to be dissolved. Spike extract was applied for the simultaneous determination of GE, it was used as the internal standard. The percent of recovery for each of 5 standard spiked GE which is 500 ng g^{-1},1000 ng g^{-1}, 2500 ng g^{-1} and 12, 500 ng g^{-1} were 99.5-103%, 98.5-1025%, 98.0-101.5% and 89-97.5% respectively. In the fresh oil that ranged from 0.80 to 25.34 kg^{-1} the total amount of GE can be detected. The GE content for all of the samples decreased during the frying process that was carried out. In within 24 hours (1 day), GE content in palm oil and palm olein recorded about 44% and 38% losses respectively. Within 40 hours after the frying process the losses for both of these oils, which is palm oil and olein were 78% and 67% respectively. From this observation it was stated that the main parameter of the losses of GE was dependent on the type of oil used. The time range was considered as the minor effect to the losses of GE in this oil. The GE degradation was stated to undergo fast degradation in the palm oil compared to the rapeseed oil.

The data obtained from the result showed that GE tend to undergo the stabilization while in the frying condition [19]. There was thing that can influence the content of GE in the ready product, it was the composition of the oil used for the pre-frying process. This phenomenon arises due to the fat exchange that occurs between the frying medium and the products being fried during the frying process [19]. The initial absorption of fat quality during the frying process can impact the subsequent increase in GE content within the fat. The duration of frying also plays a role in the reduction of GE levels within the extracted fat from fried French fries, potentially influencing the conversion and composition of GEs in this context. Moreover, the GE content can be significantly related to the aid and refractive index value. From this study, the GE content with the highest amount can be found in the fresh oil which is in palm olein (25 mg/kg) and the lowest content of GE was found in the rapeseed oil (0.8 mg/kg) [19].

Becalski et al. [5] published data on the presence of 2 and 3-MCPD ester and glycidol ester (MCPD and GE) in over 100 edible fats, oils, and products comprising fats and oils. In this study, GE and MCPD esters were determined using stable isotope dilution analysis with a glycidol-d5 labelled standard by LC-MS/MS in the mode atmospheric pressure chemical ionization (APCI), and GC-MS in the mode SIM after derivatization. All of the food samples were purchased in the local market in Ottawa, Canada. The sample was homogenized first before proceeding with the next step. LC-MS/MS was used for the determination of target glycidol fatty ester. The target of GE which was lauric and mystric revealed the recovery from the spiked cookies was 102% and 109% respectively. Meanwhile, the recovery of glycidyl laurate 103% and myristate 101% from the spiked of virgin olive oil. From the observation, the unprocessed oil does not contain any detectable levels of GE or MCPD ESTERS except for palm oil that recorded 100-550 ng/g for MCPD ESTERS. The GE and MCPD ESTERS concentration in processed oil or fats were found to be high, at 10.6 and 17.1 g/g, respectively.

Table 1. Extraction and determination of glycidyl esters (2015–2022)

Analytes	Extraction Techniques	Quantitation Instruments	Sample Matrices	Linearity (mg/kg)	LOD (mg/kg)	Precision, RSD%	Relative Recovery/ Recovery, %	Concentration Found (mg/kg)	References
2-MCPD 3-MCPD GE	SPE	LC-MS/MS	Edible oil	N/A	N/A		101 - 109	N/A	[5]

Wenzl et al. [20] in 2015, has reported that the EFSA and Joint Research Centre (JRC) were cooperate in order to obtain the data regarding the analysis of 3-monochloropropane-1,2-diol (3MCPD) and 2-monochloropropane-1,3-diol (2MCPD) and glycidyl ester (GE). They had developed a suitable method for analysis of these compounds. The tests were run under the different types of food such as meat products, potato based-snacks, cereal-based snack and margarines. In this study, the method developed will determine the ester-bound analytes, and the other analysis will determine the free 2-MCPD and 3-MCPD. The GE will be converted to the monobromopropandeiol ester and well known as MBPD. Both MCPD and MBPD will undergo the process transesterification before the derivatization process takes place. During the derivatization process the analytes will be treated with phenylboronic acid (PBA) in organic solvent. Gas chromatography mass spectrometry (GC-MS) was used to measure the PBA derivatives. The quantifications used the stable isotope labelled analogues. The sample extraction used was pressurized liquid extraction (PLE) with presence of tert-Butyl methyl ether 100% solvent and with temperature of 40 ℃. The fat from the food matrices were extracted and were determined by gravimetry. Both MCPD esters and GEs showed limits of quantification (LOQs) of 100 μg/kg or lower. In this study, the MCPD ester will be expressed as free MCPD meanwhile GEs will be expressed as glycidol. The estimated amount of LOD and LOQs for GEs were 17 μg/kg and 31 μg/kg respectively. For all of the targeted analyte, the gas chromatography mass spectrometry (GC-MS) with the presence of electron ionization with the selected ion monitoring mode.

In 2015, Dingel et al. [21] has reported the study on the non-formation of the 3-MCPD ESTERS and GE during the deep frying of the potatoes crisps in the large scale. In this study, high oleic-sunflower oils (HOSO) were used for deep frying. GC-MS was used to analyze the sample of potato crisps. There were 9 samples that were used for this analysis. All of the samples were collected directly from the German production line. The potato crisps sample weighed approximately 35 g. The sample preparation process began with the use of a typical laboratory mill for finely ground samples. The petroleum ether was then used to extract the compounds. The HOSO frying oils were utilized immediately for the analysis without any pre-treatment needed. The sample aliquots were dissolved in tert-butyl methyl ether before being spiked with the internal standard 3-MCPD-1, 2-bs-palmitoylester-d5. In this experiment, ester cleavage occurs, and it will halt once the acidified sodium chloride or sodium bromide solution is introduced to both aliquots. Each sample was extracted using a diethyl or ethyl acetate combination. Before the assays were evaporated, phenylboronic acid (PBA) was employed to mix the organic extracts of each experiment. As a result, GE's recovery was estimated to be between 98.7% and 100.2%. MCPD ESTERS and GE were both varied in terms of measurement uncertainty as a result of the experiment. Furthermore, it did not show any increases when compared to the oil utilized at the start of this investigation. The MCPD ESTERS and GE levels in this study were also low, ranging between 0.10 and 0.85mg/kg fat and 0.09 (LOQ) and 0.91 mg/kg, respectively. From the result obtained there were no significant changes in level of MCPD ESTERS and Ge while frying process occurred.

Research study regarding the monitoring of the glycidyl ester (GE) in the refined vegetables oils by using liquid chromatography-single-quadrapole mass spectrometry (LC-MS) was performed by Aniolowska et al. in 2015. Basically, refined vegetable oils from the retail outlet in Poland was used in order to analyze the GE [22]. For the analysis, 12 rapeseed oil samples, 4 sunflower oil samples, and 4 palm oil samples were employed. This study's analyses were carried out in duplicate. The high-performance liquid chromatography (HPLC) was used to extract GE-rich extracts from oils. Except for water, all of the solvents utilized in the LC-MS study were under HPLC grade. The extraction method used was double solid phase extraction (SPE). Methanol was used to condition the reverse phase of the SPE cartridge, whereas n-hexane or ethyl acetate was used to condition the normal phase of the SPE cartridge. In this study, the composition of the fatty acid can be determined by using gas chromatography (GC). From the result obtained, different analytes possess different concentrations, and the concentration of the analytes were range within 0.17 and 44.33 mg/kg. The LODs were determined within the

range 1.1 to 1.8 ng/mL while the LOQs were in range of 3.8 to 6 ng/mL. From the calibration curves the correlation was good with R^2 within 0.9981 and 0.9990. The percentage of recovery values were recorded from 89% to 103% and the standard deviation was less 5.4%. In 2016, Samaras et al. presented an indirect analytical method for simultaneous determination of 3-MCPD and GE in the various food stuff, including breads and roll, bakery wine, smoked fish products, fried and roasted meat, potato based snack, margarines and extra virgin olive oil blank sample, by using pressurized liquid extraction (PLE) and GC-MS [23]. The sample was immersed in liquid nitrogen, grinded, and then homogenized to produce a fine homogenous powder in order to increase the extraction efficiency. Based on the outcomes of literature and experimental studies, *tert*-butyl methyl ether (t-BME) was proposed as the best extractant for the determination of the MCPD esters and GE for this PLE technique. In order to overcome the overwhelming effect of fat content on the sample, for samples exceeding the 5% total fat contents (w/w), stable isotope-labelled internal standards would be added directly into 100 mg extract after PLE. After acid transesterification, the derivatization procedure was performed by using a low volume of derivatization reagent, phenylboronic acid (PBA), which provides lower background level and decreased limits of detection (LODs) compared to the AOCS methods [5]. Based on this study, the concentrations of 3-MCPD esters and GE were found to be the highest in margarines, followed by potato crisp snacks and bakery products. The targeted compounds were found only at trace levels in smoked fish, smoked meat and fried roasted meat. They were almost undetected in cereal-based products due to the products' low-fat content. This study suggested that food products prepared using palm oil are more likely to contain higher concentrations of MCPD esters and GE, implicating the threat of exposure of particularly European citizen toward these carcinogens [23].

Owing to the adverse health effects and widespread occurrence of bound MCPD and bound glycidol in foodstuff, Wohrlin et al. found it was necessary to study and monitor their concentrations in infant formula. In this study, accelerated solvent extraction (ASE) was performed to extract MCPD and GE from 14 samples of infant formula of Deutsche products [24]. After converting GE into monobromopropanediol (3-MBPD) esters, both MCPD esters and 3-MBPD esters were hydrolyzed and derivatized for detection by GC-MS. From the result, the recovery rates of the analytes can be determined by the fortification of the infant formula. It was stated that the recovery rates for 3-MCPD was between 93% to 103% while for 2-MCPD, it was between 91% to 96%. For GE it was determined that the rate of recovery values was between 92% to 109%. It was recorded that GE has the highest precision of the whole method, which is 12%. Meanwhile 3-MCP and 2-MCPD were 5% and 3% respectively [24].

Marc et al. [25] has reported the research study regarding the determination of MCPD ester and glycidyl ester (GE) by using microwave extraction in the different food stuffs in 2016. There were two types of sample preparation in this study which is sample preparation for oils and samples preparation for the infant formula. This research study used gas chromatography mass spectrometry (GC-MS) for the analysis of the sample. A new method of extraction for this study was developed which was using the microwave. Usually, the extraction method by using the microwave was used to extract the contaminants that come from non- food matrices such as soil or river water. However, this method was used by many laboratories before in order to determine the polycyclic aromatic hydrocarbons (PAH) in food matrices. In this study, the linearity of the method was studied starting from 0-10 mg/kg for the glycidol ester while the linearity for 2 and 3-MCPD ester were studied from 0-5 mg/kg. This method LOQs for both MCPD and glycidyl ester at 0.1 mg/kg, 0.02 mg/kg and 0.0025 mg/L respectively for oils, chips and crisps and infant formula. For LOD in oils was 0.03 mg/kg, 0.007 mg/kg for crisps and chips and 0.0008 mg/kg for infant formula for both MCPD and glycidyl ester.

In this study, the concern was focuses on the detection of 3-MCPD and glycidyl ester in infant formula [26].The quantitative analysis was using liquid chromatography-tandem mass spectrometry (LC-MS/MS). The method provided for extracting MCPD

and glycidyl esters from infant formula uses simple, liquid-liquid extraction processes that do not require complex instruments or expensive equipment. Ethyl acetate was used for extraction after the powdered infant formula was dissolved by using water. In this experiment all of the samples were purchased from the local market. The step of preparation of homemade infant formula for reference material were followed from the online recipe then followed by the preparation of the infant formula extracts. The infant formula extract solutions were prepared when the deuterated internal standard spiking solution of oil extract were pipetted for about 250μL of 5μg/mL into the glass centrifuge tube that contained oil extract. There were about 9 calibration curves that were used for the di-ester, monoester and glycidyl ester quantitation. The concentration prepared were 1, 2, 5, 10, 25, 50, 125, 250 and 400 ng/mL for each of the ester. The internal standard was 50 ng/mL. According to this study, infant formula was one of the food matrix components that presented a challenge due to their intricacy. It contained fats, carbs, proteins, vitamins, and minerals that had been properly homogenized and dried. During the development of this process, it was discovered that the quantity of fat extraction yields from various types of newborn formula available varied greatly from one type of infant formula to the next when the same set extraction was used. The percentage of recovery can be used to validate the method's performance. For the homemade powdered infant formula reference material, the ester recovery ranged from 84.9 percent to 109.0% on average. Meanwhile, the ester recovery rates for all concentrations and infant formulas ranged from 88.7 to 107.5 %.

The study in 2016 , Cheng et al. [27] has reported the concern to study and investigate the presence and the formation mechanism of glycidyl ester (GE) in the edible oils such as soybean oil, camellia oil and palm oil. This study focuses on the laboratory-scale preparation and refining during high temperature from 160 ℃ to 260 ℃ under nitrogen. Attenuated total reflection-Fourier transform infrared (ATR-FTIR) spectroscopy was used in this experiment in order to monitor the formation of the GE in chemical model 1,2-dipalmitin (DPG) and 1-monopalmitin (MPG). All of the sample of crude oil such as palm oil, soybean oil and camellia oil were purchased from the local market in Guangzhou China. The extraction method used in the preparation of crude oil was solvent extraction and hot pressing and cold pressing methods were also used in the preparation of crude oil. After the preparation of crude oil, the preparation of model oil was continued by using column chromatography with solvent mixture of petroleum ether and diethyl ether and about 80 g of silica gel were used. For the laboratory scale refining procedure, all of the crude oil was processed at the industry standard state. Nitrogen was used in this procedure. The main purpose of using nitrogen is to avoid oil oxidation.

The total polar components (TPC) were employed as the gravimetric method to determine the total amounts of the polar fraction after eliminating the nonpolar component using column chromatography separation. TPC was then tested for composition using thin-layer chromatography (TLC). Following that, the TPC composition was examined using high performance size exclusion chromatography (HPSEC). The GE analysis was carried out in accordance with the AOCS Official procedure. The GEs content was estimated using an indirect method based on the detection of 3-MCPD ESTERSs levels. It entailed the ester's release of 3-MCPD ESTERS and glycidol, PBA derivatization, and quantitation by gas chromatography-mass spectrometry (GC-MS). According to the main findings, no statistical differences in the GE content of the tested oils with varying refining degrees before deodorization were identified. The results also revealed that the GE level in crude oil extracted by the solvent was lower than the detection limit of 10 μg/kg. The low quantity of GE was reported in the pressing method of extracted crude oils, whereas hot-pressed oil reported the low amount of GE corresponds to cold-pressed oil. GE levels were reported to be highest in palm oil followed by camellia oil and soybean oil. The GE level was monitored by GC-MS and the linear correlation between the DPG and GE was found at R^2 =0.9607, which is relatively poor.

Rubio et al. [28] has reported the study in a novel single –step method for the simultaneous determination of 3-MCPD and GE in the sample of winterized and non-winterized fish oil by using gas chromatography

tandem-mass spectrometry (GC-MS/MS) in 2017. The process was based on the alkaline hydrolysis of ester at ambient temperature followed by a derivatization stage with phenylboronic acid (PBA) at 90 °C. The use of GC-MS/MS resulted in simpler sample treatment as well as improved limit quantification and precision of the analytical approach without the requirement for additional extract concentration. This approach verified both winterized and non-winterized fish oil by obtaining limits of quantification of 100 ng/g for 3-MCPD and 50 ng/g for glycidol. Furthermore, in order to validate the procedure, the laboratory results were compared to those obtained by an accredited reference laboratory (SGS Germany GmbH). The use of GC-MS/MS rather than GC-MS, which is often used to determine 3-MCPD and glycidyl derivatives, dramatically enhanced the signal-to-noise ratio while minimizing sample preparation and manipulation. The LOD and the LOQ for 3-MCPD were 0.05 mg/kg and 0.2 mg/kg respectively. While for glycidol, the LOD was 0.02 mg/kg and LOQ was 0.07 mg/kg. The recoveries obtained for both 3-MCPD and glycidol were almost near to 100 % which was 93.4% to 98.9% for 3-MCPD and glycidol respectively. Average value calculated were 99.8% for 3-MCPD and 99.0% for glycidol.

Previous studies on the analytical determination of the GE were fully validated only for oils, fats and margarine. This calls for a re-assessment of the critical steps in the AOCS Cd 29a-13 method, in 2017, for simultaneous determination of MCPD esters and GE in a broader range of different food, including meat, infant formula milk, fried fries, bakery product and cereal products [11]. Since overestimation of GE contents is more likely to occur with an indirect analysis of GE, the results can be confirmed by comparison of results achieved through an independent analytical method, such as the direct analysis of the GE by HPLC-MS/MS. In the direct method according to the AOCS standard method, internal standard is added to the pre-weighed fat and dissolved in cyclohexane: ethyl acetate (1:1, v/v) [11]. Before quantitative analysis, triacylglycerols (TAG) has to be removed from the extracted fats. The direct method proposed by Dubois et al. uses gel permeation chromatography (GPC) to separate the almost-similar analyte constituents. In this assay, six GE, namely glycidyl(G-) laurate, G-palmitate, G-stearate, G-oleate, G-linolate, and G-linolenate were determined, totaled up, and expressed in equimolar amounts of glycidol or glycidol equivalents for comparison of results with the indirect analysis method [11]. The results obtained from the two analysis methods were not significantly different. At 95% confidence level, only the results for three bakery products were significantly different. A linear correlation was found when plotting the difference of glycidol content measured by the direct and indirect method, against the content of MAG in the extracted fat sample. However, the results of the indirect method would be deduced as bias in the presence of higher than 1% MAG in the fat sample [11].

According to paper presented by Arisetto et al. [7], the analytical methods to determine these contaminant 3-MCPD and GE was using direct and indirect approaches. The indirect approaches were using gas chromatography coupled to mass spectrometry (GC-MS) for the analysis. This procedure necessitates the conversion of the compound into free form before the analysis can be carried out. The pros of using this approach were that it possesses a lowest number of analytical standards and was easier to comprehend the data. This method involves a few methods such as transesterification, neutralization, salting out and derivatization. Meanwhile, the direct method analysis was using high performance liquid chromatography-mass spectrometry (LC-MS/MS) for the identification and quantification of the different compounds. In direct method, a simple extraction procedure was required but it did not require transesterification and derivatization steps. In this study, samples such as fish oil, edible oil and several foodstuffs were used for the determination of 3-MCPD and GE. Generally, the LOD for both of these approaches was between 0.033 μg/kg to 50 μg/kg.

Kalkan et al. [9] evaluated the formation of 3-MCPD, 2-MCPD and GE in sunflower oil frying processes by using central composite design (CCD) methodology. Chemicals used were 3-MCPD, 3-chloro-1, 2 propanediol-d5 (3-MCPD-d5) and 2-MCPD, 2-chloro-1,3-propanediol-d5 (2-MCPD-d5), glycidyl stearate-d5 (Gly-Pd5) and glycidyl stearate (Gly-S-). Toluene,

tertbutyl methyl ether, methanol, sodium hydroxide, diethyl ether, ethyl acetate, isohexane, n-heptane, isooctane, sodium bromide, anhydrous sodium sulfate, sulfuric acid, and PBA. Sample used was frying oil that were capped into brown-stoppered flasks and stored it in refrigerator at -18 °C because to protect for deterioration until the analysis. For the determination of GE, free and bound 3-MCPD esters were converted into free 3-MCPD form by adding dilute methanolic sodium hydroxide solution. Then, free and bound 3-MCPD were analyzed in GC/MS by derivatization with PBA. The amount of GE was obtained by multiplying the difference of total 3-MCPD and free and bound 3-MCPD by conversion factor. The conversion factor was the standard addition method which GE internal standard was added into oil sample. It was calculated by using slope of calibration curve. An indicator of the acceptability of method was based on the sensitivity of an analytical method. The LOD, LOQ, recovery and relative standard deviation tests were performed. It was observed that temperature, duration and salinity were the factors that had significant effects. MCPD ester in frying was transformed into GE species with the increasing of temperature, duration and salinity. The highest 3-MCPD (0.30 mg/kg), 2-MCPD (0.09 mg/kg) and GE (0.72 mg/kg) formations were observed in the hardest conditions with 40 min., 180 °C and 300 mg NaCl/ 100 mL for oil [10].

Nguyen et al. [10] reported that a GC/MS-MS method was developed, validated and applied for the determination of MCPD ESTERSs and GEs to analyzed 60 infant formula and baby food products. Different commercial food products such as powder infant formula, liquid infant formula, cereal based and vegetables-based baby foods which include smoothies, puffs, and biscuits. All the samples were homogenized and stored at −18 °C for analysis. Fat extraction was needed to extract contaminants out of food matrices because MCPD ESTERSs and GEs was highly lipophilic. The sample was spiked with 50 µL of an internal standard mixture (5 ng/µL) and placed on high-speed vertical shaker and extracted at 1500rpm for 5min. 10g of sodium sulfate anhydrous was added to get better phase separation and salting out effect. Extracted fat were obtained by evaporation of combined upper layers to dryness under nitrogen steam at 40 °C. Food items have been reported to contain a significant amount of partial glycerides especially MAGs that can cause artifact formation of GEs during bromination of GEs. Hence, a cleanup step by aminopropyl SPE cartridge was employed to remove MAGs. The results showed low levels of MCPD ESTERSs, and GEs were observed in most vegetable oil containing products while samples with no added oil showed < LOQs levels. The degree of MCPD ESTERSs and GEs contamination was in the following order: cereal based puree liquid formula cereal-based puree powder baby puffs < powder formula < baby biscuits, with the exception for GEs where baby puffs showed the highest concentrations.

A new method was developed based on the headspace solid-phase microextraction gas chromatography–mass spectrometry (HS–SPME–GC–MS) method for the quantification of 3-MCPD ESTERSs, 2-MCPD ESTERSs and GEs in edible oils [29]. Hydrolysis method was used in this research with the addition of NaBr and NaCl to convert glycidols into 3-MBPD or 3-MCPD. The authors also stated that a critical factor for the alkaline analysis was reaction time to indicate the sensitivity. Hence, to keep higher recovery, acidic hydrolysis was employed. The method of solid phase microextraction (SPME) involved fibre coated with porous stationary phase. Since the analyte have variable partition coefficient with different fibre coatings, then type of fibres play an important role in extraction efficacy [29]. A HS–SPME–GC–MS labor-friendly method demonstrates greater precision, accuracy and adequate LOD/LOQ as compared with liquid injection of GC–MS.

The analysis traces of 3-MCPD and GE has been carried out by using ultra-high-performance liquid chromatography coupled to tandem mass spectrometry, using a triple quadrupole analyzer (UHPLC-MS/MS-QqQ) [17]. This method used a WX vortex from Velp Scientifica to homogenize the samples while a Reax 2 rotatory shaker from Heidolph extraction of the compounds. The MS conditions were optimized first then by applying full-scan MS, the characteristic ion of each compound was obtained. The target compounds were prepared at 10 mg/L in isopropanol to achieve a

proper optimization. To reduce the analysis time and obtain the best peak shapes, chromatographic parameters need to be optimized. To guarantee the reliability of the results, an internal quality control has been carried out during the analysis which consisted of blank sample, a matrix calibration line from 0.01 to 0.5 mg/L and two samples which has been already spiked and analyzed at 0.01 and 0.2 mg/kg. Each of these quality control are to check the absence of interferences, to evaluate the sensitivity and performs quantification of samples also to evaluate the efficiency of the extraction process [17]. The results showed that most detected esters in analyzed oil samples were from oleic, linoleic and linolenic acid because it was the major fatty acids that are present in oils. It is normal for extra virgin and virgin olive oil to not show high concentrations of esters since both are not submitted to any refinement process. This method has a simple and fast extraction method based on the use of solvents. By using UHPLC-MS/MS-QqQ, it takes less time to analyze the samples and by using this approach, the most significant identification and quantification of 3-MCPS and GE that are present in the samples are available.

Lastly, Goh et al. [30] had studied the detection of glycidyl ester in edible palm-based cooking oil and a total result was acquired from the market in a different oil sample. The amount of GE content from 1.338-18.362 mg/kg. The result was not surprising because all the palm oils refinery in Malaysia uses high temperature so that it has been proven for the main factor that cause formation of GE. Mixed glycerides and high portions of oleic, linoleic and linolenic acid were existing in palm-based cooking oil. In this research, GC-MS and ATR-FTIR were used for identification and quantification of GE. However, for the confirmation of the presence of GE was further by using 1H NMR spectroscopy and the results was it showed some signals that known as a characteristic of fatty acids, polyunsaturated fatty acids (PUFA) and TAG. TAG has the most abundant fatty acids that present in edible palm-based cooking oil sample [30]. NMR technique has been proven as a useful technique in order to get data verification and have a potential for alternative spectrum input in modelling process. The results showed that contamination of GE in palm-based cooking oil sample ranged from 1.338 to 18.362 mg/kg which showed a non-normal distribution.

Conclusion

The first proposed analytical method for the detection of glycidyl esters was an indirect approach which is by hydrolyzing variety of fatty acid esters, releasing free glycidol and the analysis was greatly simplified. However, this method was shown to provide inaccurate results. Hence, different methods have been developed such as by using ultra-high performance liquid chromatography tandem mass spectrometry with triple quadrupole analyzer (UHPLC- MS/MS-QqQ), GC-MS, LC-MS, GC-MS/MS and LC-MS/MS. The newly developed methods offer a superior advantage simplified clean-up procedure that only required several hours to complete that much faster than hydrolysis step and it employs several isotopically labelled internal standards that avoided the need for time consuming. Great progress has been made on the analysis of glycidyl esters in oils and other matrices over the past few years, with a number of methods producing comparable and accurate results, the analysis of complex foods is still developing. The challenges of extracting the wide variety of fat-containing foods combined with the lack of commercial reference materials slow the progress of development. However, there are a number of published methods which have recently been validated in complex foods. Moving forward, comparing their performance to one another and to standard reference materials is necessary to ensure accurate data is being produced for exposure and risk assessment purposes. In addition, further studies related to the GE formation during food processing should be extended to other thermal methods.

Abstract

Processing nutrient-dense breadfruit powder with the desired texture has gained lots of attention due to its characteristics heavily influencing its usage in food as an ingredient. This study was initiated to determine the breadfruit's characteristics in relation to its functional properties, thermal behavior, and physicochemical analysis. The native grounded breadfruit (BG) was assessed for its functional properties while its spray-dried powder (BFP and BFP+MD) was subjected to thermal behavior and physicochemical analysis. The physical properties of the breadfruit juice used for preparing BFP and BFP+MD were determined before the spray drying process. The water and oil absorption of BG were 9.08±0.20 g and 2.26±0.15 g, respectively, with the respective gelation properties observed at the concentrations of 13% and 20%. The analysis of breadfruit juice used for preparing BFP and BFP+MD revealed the following properties: pH of 6.39±0.20, TSS of 10.40% and 18.85%, and viscosity of 40 cP and 20 cP, respectively. The IC_{50} for antioxidant activity of breadfruit juice was 58.51±0.34 µg/mL, and its total phenolic content was 369.74±18.41 µg GAE/g. The analysis also revealed the following physicochemical properties of BFP and BFP+MD: moisture content (%) of 5.67±0.81 and 4.23±0.11, hygroscopicity (%) of 4.72±0.18 and 4.04±0.26, water solubility index (%) of 50.74±1.14 and 70.78±2.31, and bulk density (g/mL) of 0.55±0.02 and 0.48±0.01, respectively. BFP+MD demonstrated a lower melting point (28.29°C ± 0.20) than that of BFP (28.64°C ± 0.20). The nutritional value of BFP+MD were as follows: protein (1.7±0.10 %w/w), crude fiber (5.02±0.03 %w/w), fat (3.27±0.11 %w/w), ash (3.80±0.17 %w/w), and carbohydrate (86.84±0.18 %w/w). The evaluated characteristics enable the incorporation of breadfruit into a wide range of supplementary foods for a healthy diet.

Abstrak

Memproses serbuk sukun yang padat dengan nutrient serta tekstur yang diingini semakin mendapat perhatian kerana ciri-cirinya yang banyak mempengaruhi penggunaannya dalam makanan sebagai bahan ramuan. Kajian ini dilakukan untuk mengenal pasti ciri-ciri sukun dari segi sifat-sifat berfungsinya, tingkah laku terma dan analisis fizikokimia. Sifat-sifat berfungsi telah dikaji menggunakan buah sukun yang dikisar (BG), sementara tingkah laku terma dan analisis fizikokimia dijalankan ke atas sukun yang telah disembur kering (BFP dan BFP+MD). Sebelum disembur kering sifat-sifat fizikal jus sukun untuk kedua-dua BFP dan BFP+MD juga ditentukan. Keputusan BG untuk penyerapan air dan minyak masing-masing ialah 9.08±0.20 g dan 2.26±0.15, manakala sifat pembentukan gel diperhatikan pada kepekatan 13% dan 20%. Keputusan jus sukun untuk kedua-dua BFP dan BFP+MD masing-masing adalah seperti berikut: 6.39±0.20 untuk pH, 10.40% dan 18.85% untuk TSS dan 40 cP dan 20 cP untuk kelikatan,. Nilai IC_{50} aktiviti antioksidan ialah 58.51±0.34 μg/mL, dan jumlah kandungan fenolik ialah 369.74±18.41 μg GAE/g untuk jus sukun. Keputusan fizikokimia untuk BFP dan BFP+MD masing-masing ialah kandungan lembapan (%) (5.67±0.81, 4.23±0.11), higroskopisiti (%) (4.72±0.18, 4.04±0.26), indeks larut air (%) (50.74±1.14, 70.78±2.31) dan ketumpatan pukal (g/mL) (0.55±0.02, 0.48±0.01). BFP+MD menunjukkan takat lebur yang lebih rendah (28.29°C ± 0.20) daripada takat lebur BFP (28.64°C ± 0.20). Kandungan nutrisi BFP+MD yang ditentukan ialah protein (1.7±0.15 %w/w), serat kasar (5.02±0.03 %w/w), lemak (3.27±0.11 %w/w), abu (3.80±0.017 %w /w) dan karbohidrat (86.90 ±0.03 %w/w). Ciri-ciri yang diperhatikan membolehkan serbuk sukun menjadi ramuan dalam pelbagai makanan tambahan yang sihat.

Kata kunci: serbuk sukun, sifat-sifat berfungsi, tingkah laku terma, analisis fizikokimia

Introduction

As a result of the Covid-19 epidemic expanding into endemic, community well-being has taken precedence. It is critical to focus on acquiring health supplements for easy daily consumption to boost the immune system and reduce the problems associated with chronic diseases. A balanced diet should include an adequate amount of essential nutrients such as antioxidants, complex carbohydrates, low-glycemic index ingredients, and fibers that are readily accessible. Breadfruit (*Artocarpus altilis*) is one of the underutilized tropical plants recently studied for its potential health benefits to humans, either through oral consumption, e.g., food, or topical application, e.g. cosmetic ingredients. Because of its distinct qualities, such as its pale hue and bland sensory profile, it meets the requirements of the food sector, which prefers starch that is stable, white in color, and odorless [1].

Breadfruit (*A. altilis*), also known as *sukun* in Malay is a traditional crop and a reliable staple food that originates from South Pacific countries [2] Breadfruit trees are easy to grow and capable of bearing fruit in abundance. The fruits are highly nutritious and energy-rich and contain large amounts of phytochemicals which exhibit significant antioxidant properties [3, 4]. These compounds are beneficial for human health as they are associated with the prevention of cardiovascular diseases, urinary tract infections, and other chronic illnesses [5, 6]. In addition, antioxidant activity and total phenolic content are an important measure to improve food quality and prolong shelf life without imposing any undesirable effects from the addition of synthetic chemical preservatives [7, 8]. Breadfruit can also be a source of dietary fiber which aids in the regulation of blood sugar in diabetics, the reduction of unfavorable blood lipids (a risk factor for CVDs), and the management of weight. Besides providing essential minerals, breadfruit offers an alternative to gluten-free for those who are gluten intolerant, suffering from Type 2 Diabetes Mellitus, and health-conscious individuals [2-4, 6]. Breadfruit also contains highly resistant starch which has been empirically proven to offer numerous health benefits, including suppressing appetite and feeding the beneficial bacteria in the colon, boosting the number and diversity of bacteria [3]. The rheological behavior of breadfruit starch has been studied extensively in food applications. Based on rheological qualities, the stability of native and modified breadfruit starch has also been examined for its use in emulsion and baking [9]. Physical modification of starch involves the use of chemical or biological agents. Meanwhile, physical modification of starch is frequently favored in food products intended for diet [10]. By considering these properties of breadfruit, researchers can use them as intermediate ingredients or finished products to fulfill the demand of health-conscious consumers.

Apart from its potential use as an energy source, breadfruit offers a wide range of functionalities and diverse nutrients, making it great for functional food applications. Although breadfruit is healthy, it quickly deteriorates physiologically after harvesting. To reduce post-harvest losses and increase breadfruit utilization, the breadfruit can be processed into powder, which is more shelf stable. Conventional methods of oven-drying followed by grinding and spray drying in the making of breadfruit powder can help prolong its shelf life by reducing its moisture content and inhibiting microbial growth and enzymatic activity [11]. Spray drying is often used due to its rapidity and economic value. Maltodextrin is one of the drying aids that acts as a carrier or an encapsulating agent in the drying process. In addition, maltodextrin improves the properties of the powder by increasing its solubility and hygroscopicity and acting as anticaking. The production of breadfruit powder has enabled its application in a vast range of food industries. Some of the applications of breadfruit as a functional food ingredient include breadfruit flour, infant formulas, biscuits, fermented foods, extruded products, and stiff porridge [12]. Yet, the processing of breadfruit powder into a desired texture remains one of the areas that has gained a lot of attention and is under exploration.

There is a lack of research and established data supporting the eligibility of breadfruit powder for applications in food, which is largely influenced by its characteristics. Therefore, the current study focused on evaluating the functional properties, thermal behavior, and physicochemical properties of breadfruit powder. The physicochemical properties including solid and moisture content, bulk density, hygroscopicity, solubility, viscosity, antioxidant and phenolic compound, thermal behavior, and nutritional value were determined. Additionally, the functional properties such as water and oil absorption capacity, and gelation properties were used as complementary data for applications as processed food products. These findings will enhance the significance of our local sources and have a significant impact on product development for diverse age groups, which includes the application as an intermediate ingredient in health supplements for general consumption.

Materials and Methods

Material and chemicals

Matured breadfruits and corn oil were bought from a local market in Skudai, Johor, Malaysia. Maltodextrin was purchased from Agrin Chemical (M) Sdn. Bhd. Methanol, Gallic acid, Folin-Ciocalteu reagent, sodium carbonate, 1,1-diphenyl-2-picrylhydrazyl (DPPH), sodium chloride, and anticaking agent of analytical grade were purchased from SIGMA-Aldrich, US.

Preparation of breadfruit powder: Ground breadfruit powder

The matured breadfruits were washed thoroughly to remove dirt and were subsequently peeled. Next, the fruits were sliced with their core removed. Each of these samples was then dried in a hot air oven at 60 °C for six to eight hours. The dried samples were milled and ground into flour (BG) and were sieved through a 100-µm mesh to obtain fine-textured flour. Lastly, samples were packed into polyethylene bags and stored at room temperature for further use.

Spray-dried breadfruit powder

The matured breadfruits were washed thoroughly to remove dirt and were subsequently peeled. Next, the fruits were sliced with their core removed. Water was added to the sliced breadfruits at a ratio of 1:1 (breadfruit: water) and blended using a juice blender to obtain the breadfruit juice. The juice was filtered through a sieve (ASTM E11, 150-µm mesh) and transferred into a beaker. Next, 1 g of anticaking agent was added to the breadfruit juice, and the mixture was homogenized at 8000 rpm for 10 minutes. The spray dryer was set at a constant aspirator rate of 100 %, pump setting of 20%, nozzle speed of 5, and compressed air flow rate of 5 mL/min. Inlet temperatures were set at 180 °C with a constant maltodextrin concentration (30 % w/w) based on a method by Jafari et al. [13]. The process was repeated using the same parameter for breadfruit without maltodextrin. The samples prepared before the analysis were assigned as breadfruit without maltodextrin (BFP) and breadfruit powder with maltodextrin (BFP + MD).

Process yield

The weight of the dry material in the powder and juice was used to determine the spray drying yield. This factor was calculated from the following equation 1 [13]:

$$Yield\ (g) = \frac{P \times S_P}{L \times S_F} \quad (1)$$

where P is the rate of powder production (g/min), S_P is the percent of total solids of the powder, L is the feed flow rate (g/min), and S_F is the percent of total solids of the feed.

Functional properties of breadfruit samples: Water and oil absorption capacity

The water absorption capacity of the starch was studied based on the method by Pestorić et al. [14]. The methods were as follows; sample weighing 3g was dispersed in 25 mL of distilled water and placed in pre-weighed centrifuged tubes. The mixtures were stirred occasionally, held for 30 min, followed by centrifugation for 25 min at 3000 x g. The supernatant was decanted, excess moisture was removed by draining for 25 min at 50 °C, and the sample was reweighed [15]. For the determination of oil absorption, the samples weighed 0.5 g were mixed with 6 mL of corn oil in pre-weighed centrifuged tubes. The contents were stirred for 1 minute with a thin brass wire to disperse the sample in the oil. After a holding period of 30 min, the tubes were centrifuged for 25 min at 3000 x g. The separated oil was then removed with a pipette and the tubes were inverted for 25 min to drain the oil before weighing [16]. The water and oil absorption capacities were expressed as grams of water or oil bound per gram of the sample on a dry basis.

Gelation properties

Test tubes containing starch suspensions of 1%, 7%, 13%, and 20% (w/v) of material in 5 mL of distilled water were heated for 1 h in boiling water followed by rapid cooling under running water. The tubes were further cooled at 4 ℃ for 2 h. The least gelation concentration (LGC) is the concentration at which the sample does not fall or slip when the test tube is inverted [14].

Physical properties of breadfruit juice: pH

A digital pH meter was used to measure the pH of the samples. The digital pH meter was first calibrated using two buffer solutions of pH 7.0 and 4.0. The pH electrode was immersed into the beaker filled with 200 mL of samples and the readings were recorded [17].

Total soluble solids

A digital refractometer was used to measure the samples. The digital refractometer was calibrated by placing a drop of distilled water on its surface. The samples were placed on the surface of the digital refractor with a scale of 0–85 °Brix and the reading was recorded [17].

Viscosity

The viscosity of the samples was determined using a flow test at a shear rate ranging from 0.001 s^{-1} to 1000 s^{-1}, at a temperature of 25 ℃. The data obtained was generated by calculations with respect to the Herschel-Bulkley, Bingham dan Casson model [18].

Antioxidant activity of breadfruit samples

The antioxidant activity of fresh breadfruit and spray-dried breadfruit powder samples was measured by DPPH radical scavenging activity under minimal light conditions [19]. Samples of 0.4 g of breadfruit powder were weighed and dissolved in 40 mL of 80% (v/v) aqueous methanol to obtain a concentration of 10 mg/mL, followed by 20 minutes of sonication. Ascorbic acid was prepared as a standard reference at concentrations ranging from 1.25 to 200 µg/mL. Next, 0.1 mM DPPH solution was prepared by dissolving 2 mg of DPPH in 50 mL of 80% (v/v) methanol. Then, 0.5 mL of the ascorbic acid standards were added with 2 mL of DPPH solution in tubes and mixed well. After leaving the tubes in the dark for 30 minutes, the absorbance of the standards was measured using a UV-Vis spectrophotometer (DLAB SP-V1000) at 517 nm. These steps were repeated for the samples. The percentage of free radical scavenging activity at different concentrations was calculated using the formula (Eq.2):

$$DPPH\ scavenging\ activity\ (\%) = \frac{A_{517}\ control - A_{517}\ sample}{A_{517}\ control} \times 100 \quad (2)$$

A graph of free radical scavenging activity against the concentration of the standards and samples was plotted using a Microsoft Excel spreadsheet. From the graph, the linear regression ($y = ax + b$) obtained was used to determine the IC_{50} by using the formula (Eq.3):

$$IC_{50} = \frac{50-b}{a} \quad (3)$$

Total phenolic content of breadfruit samples

The total phenolic content (TPC) of fresh breadfruit and spray-dried breadfruit powder samples was measured using Folin-Ciocalteu colorimetric assay [18, 20]. Initially, 0.5g of dried breadfruit powder samples were extracted by mixing them in 10 mL of 80% (v/v) aqueous methanol solution, followed by 25 minutes of sonication. Next, 0.5 mL of the samples were introduced into the test tubes and added with 1.5 mL of Folin-Ciocalteu's reagent and 1.2 mL of 7.5% (w/v) sodium carbonate solution. The test tubes were vortexed, covered with parafilm, and allowed to settle for 90 minutes. The calibration curve was plotted by mixing 1 mL aliquots of 500, 250, 125, 62.5, and 31.25 µg/mL Gallic acid solutions with 1.5 mL of Folin-Ciocalteu's reagent and 1.2 mL of 7.5% (w/v) sodium carbonate solution. The absorbance was measured using a UV-Vis spectrophotometer at 765 nm. The absorbance was measured to determine the total phenolic content (TPC) in the samples using the formula (Eq.4):

$$TPC = C1 \times \left(\frac{V}{m}\right) \quad (4)$$

where C = total phenolic content in µg/g (in Gallic acid equivalent), $C1$ = concentration of Gallic acid established from the calibration curve (µg/ml), V = volume of extract (ml), and m = the weight of the plant extract (g).

Physicochemical properties of spray-dried breadfruit powder: Moisture content

The moisture content of the breadfruit powder samples was determined by a moisture analyzer (AND MX-50) at 80 ℃ until a constant weight was obtained [21].

Hygroscopicity

The hygroscopicity of the samples was determined by the method described by Cai and Corke (2000). Approximately 1 g of each breadfruit powder sample was weighed onto a crucible and placed in an airtight desiccator at a temperature of 25 ℃ with saturated NaCl solution (75% RH) for one week. The hygroscopicity (%) was calculated using the following formula (Eq.5):

$$Hygroscopicity\ (\%) = \frac{(W1\% + MC\%) \times 100}{(W1\% + 100)} \quad (5)$$

where,

$$W1\% = \frac{(Weight\ of\ sample\ after\ equilibrium - Weight\ of\ sample)}{Weight\ of\ sample} \times 100$$

$$MC\% = Moisture\ content\ of\ sample\ powder$$

Water solubility index

The solubility index (WSI) of the spray-dried breadfruit powder samples was determined using the method by [13, 22] with some modifications. Each powder sample weighed 2.5 g was dissolved in 30 mL of distilled water and stirred on a hotplate stirrer for 30 minutes. The mixture was centrifuged at 3000 × g for 10 minutes. The supernatant was placed in a preheated oven at 105 ℃ until a constant weight was obtained. The solubility of the breadfruit powder samples was calculated (Eq. 6) by:

$$WSI\ (\%) = \frac{Dried\ supernantant\ weight}{Initial\ sample\ weight} \times 100 \quad (6)$$

Bulk density

The bulk density of the samples was measured by pouring 2 g of each sample into a 10-mL graduated cylinder and vibrating using a vibrator. The occupied volume was observed [13, 21, 4] and the bulk density was calculated by the following equation (Eq.7):

$$Bulk\ density\ (g/mL) = \frac{m}{v} \quad (7)$$

where *m* is the mass of the breadfruit powder sample (g) and *v* is the volume (mL) occupied in the cylinder.

Differential scanning calorimeter analysis

The thermal behavior of the breadfruit powder samples was determined using the differential scanning calorimeter (DSC), (Mettler Toledo DSC1). Using standard indium and sapphire, the instrument was calibrated for heat flow and temperature. Fifteen milligrams of each sample were accurately weighed into the DSC aluminum sample and flowed using the pan and sealed with a lid while an empty pan with a lid was used as a reference. The process began by decreasing the temperature to -80 ℃ at a heating rate of 10 ℃/min, followed by a scanning from -80 ℃ to 80 ℃ at the same heating rate. Dry nitrogen gas was used as the purge gas at a flow rate of 50 mL/min [21, 23].

Nutritional value of breadfruit samples

The proximate analyses were performed to estimate the moisture, ash, fat, protein, and crude fiber contents of the breadfruit samples based on the AOAC Official Method [24]. Moisture content was determined using the oven drying method at 100 ℃ for at least five hours until a constant weight was obtained. Ash content was determined by the total mineral or inorganic residue remaining in food after either ignition or complete oxidation of organic matter following the application of the dry-ashing method. The protein content was determined based on the total nitrogen content using the Kjeldahl method. Fat content was assessed via the extraction using a non-polar solvent by the Soxhlet extraction method. The carbohydrate content in the sample was calculated by the energy difference. The calculation of the energy (kCal) of the sample was performed as follows:

$$Energy\ (in\ kCal) = 4 \times (Proteins\ and\ carbohydrates\ mass\ in\ grams) + 9 \times (mass\ of\ fat\ in\ gra \quad (8)$$

Results and Discussion

Functional properties of ground breadfruit

As depicted in Table 1, the water and oil absorption capacities of the BG sample were 9.08 ± 0.20 g/g and 2.26 ± 0.15 g/g, respectively. Oil absorption capacity is important for storage and stability especially in the development of rancidity during the storage period. In addition, a high absorption capacity allows for retaining flavor, improving mouthfeel, and increasing the soft texture in the mouth [25, 4].

Table 1. Water and oil absorption capacities of spray-dried breadfruit powder samples

Sample	Water Absorbed (g/g)	Oil Absorbed (g/g)	Gelation Capacity			
			Concentration (% w/v)			
			1	7	13	20
BG	9.08 ± 0.20	2.26 ± 0.15	-	-	+	+

Abbreviation: Grounded breadfruit (BG). Value is expressed as mean ± standard deviation (n=3). Symbol minus (-) as no gelation and (+) as has gelation capacity

Table 1 illustrates the gelation capacities of the spray-dried breadfruit powder samples. BG with 1% (-) and 7% (-) concentration showed no gelation capacity while BG with (+)13% and (+) 20% showed gelation capacity. In food industries, the gelling ability of spray-dried fruit powder is a desirable quality [25]. A higher least gelation capacity (LGC) indicates a lower ability to form a stable gel. Stable gelling formation is ideal in components with higher protein content due to the greater intermolecular contact, especially during cooking [4].

Process yields and physical properties of breadfruit juice

From the results shown in Table 2, the BFP+MD sample generated a higher yield (41.229 g) than the BFP sample (33.112 g). Noticeably, the addition of maltodextrin as a filler improved the process yield and increased the total solid content yet did not alter the pH value of the breadfruit juice. These results indicate that the addition of maltodextrin to spray-dried fruit powders does not alter their pH [17]. Moreover, the pH significantly improved the functional properties of the powder after spray drying. Thus, it is necessary to maintain a particular pH to obtain certain functionalities [26].

Table 2. Yield and physical properties of breadfruit juice

Samples	Yield (g)	pH	TSS (%)	Viscosity (cP)
BFP	33.112	6.19 ± 0.20	10.40	40
BFP+MD	41.339	6.39 ± 0.20	18.85	22

Abbreviation: Breadfruit juice without maltodextrin (BFP); Breadfruit juice with 30% maltodextrin (BFP+MD). Note that the parameters were measured for the breadfruit juice that will be spray-dried into powder.

The sample with 30% maltodextrin contained higher total solid content (18.85%) than the one without (10.40%). Solid content determines the percentage yield and quality of a product [27, 28]. Viscosity is also an important parameter to consider as it influences the emulsifying ability of powders [29]. BFP+MD exhibited a low viscosity (22 cP) compared to BFP (40 cP). This result is consistent with the findings by [30] who reported that the increase in maltodextrin concentration resulted in a reduced viscosity of spray-dried avocado powder.

Antioxidant activity and total phenolic content of breadfruit

In this study, DPPH free radical scavenging activity was used to determine the antioxidant activity and expressed in µg/mL of methanolic extract concentration required to inhibit 50% of the free radicals (IC_{50}). The capacity of the extract/sample to scavenge free radicals through hydrogen donation was assessed using the DPPH test. DPPH molecule is considered a stable free radical. DPPH appears purple/violet in a methanolic solution and will decolorize into shades of yellow in the presence of antioxidants [31]. The DPPH assay was used to measure the scavenging activity of breadfruit samples with ascorbic acid as a positive control. The free radical-scavenging antioxidants in the fruits donate hydrogen to the unpaired electron of the DPPH molecule, turning the purple-colored DPPH into its reduced form which is yellow.

Follin-Ciocalteu's colorimetric assay was performed to analyze TPC in the breadfruit samples. Follin-Ciocalteu reagent is a yellow phenol reagent containing phosphotungstate and phosphomolybdate. The reagent changes from yellow to blue when phenolic compounds are present in the sample. The changes are due to redox reactions, through which the samples turn the Follin-Ciocalteu reagent into its reduced form. Gallic acid, a type of phenolic acid was used as a standard. From the standard curve obtained, the absorbance values of the samples were used to determine the TPC which were expressed in terms of µg/mL GAE/g.

Table 3. TPC and antioxidant activity of fresh breadfruit and spray-dried breadfruit powder

Samples	TPC (µg GAE/g)	IC_{50} of DPPH (µg/mL)
BF_{fresh}	369.74 ± 18.41	58.51 ± 0.34
BFP+MD	745.26 ± 13.60	105.11 ± 3.61

Abbreviation: Freshly prepared breadfruit juice (BF_{Fresh}); Spray-dried breadfruit powder with 30% maltodextrin (BFP+MD). Value is expressed as mean ± standard deviation (n=3).

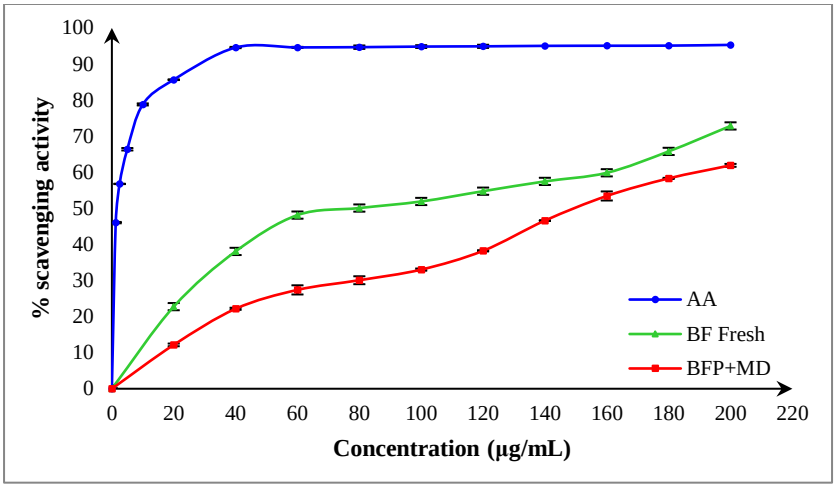

Figure 1. DPPH free radical scavenging activity of breadfruit samples. Abbreviation: Ascorbic acid (AA) as a standard, freshly prepared breadfruit juice (BF_{Fresh}) and spray-dried breadfruit powder with 30% maltodextrin (BFP+MD). Value is expressed as mean ± standard deviation (n=3)

Table 3 and Figure 1 illustrate the TPC and antioxidant activity of fresh breadfruit and spray-dried breadfruit powder with 30% maltodextrin added. Spray-dried breadfruit powder with 30% maltodextrin contained a higher total phenolic content (745.26 ± 13.60 µg GAE/g) than the fresh breadfruit (369.74 ± 18.41 µg GAE/g). Maltodextrin addition improved the phenolic contents in breadfruit during the spray drying process. In the DPPH assay, the lower the IC_{50} the better it can scavenge the radicals which are the propagators of the autoxidation of lipid molecules, and thereby break the radical-free reaction [32]. In addition, fresh juice was expected to contain higher antioxidant activity. Table 3 shows that the fresh breadfruit samples exhibited a lower IC_{50} (58.51 ± 0.34 µg/mL) than the spray-dried samples added with 30% maltodextrin (105.11 ± 3.61 µg/mL), suggesting a higher antioxidant activity in the fresh sample. Different phytochemicals with antioxidant activity have different levels of tolerance toward high temperatures and conformational changes which vary in different types of fruits [33].

Physicochemical properties of spray-dried breadfruit powder

The physicochemical properties are important in ensuring the suitability of spray-dried breadfruit powder to be utilized as food or food ingredients. Physicochemical properties such as moisture content, bulk density, hygroscopicity, and WSI are discussed in this section.

Table 4. Physicochemical properties of spray-dried breadfruit powder samples

Samples	Moisture Content (%)	Hygroscopicity (%)	WSI (%)	Bulk Density (g/mL)
BFP	10.80 ± 0.03	4.715 ± 0.18	50.74 ± 1.14	0.55 ± 0.02
BFP+MD	4.23 ± 0.11	4.035 ± 0.26	70.78 ± 2.31	0.48 ± 0.01

Abbreviation: Spray-dried breadfruit powder without maltodextrin (BFP); Spray-dried breadfruit powder with 30% maltodextrin (BFP+MD). Value is expressed as mean ± standard deviation (n=3). Water soluble index (WSI)

The spray-dried breadfruit powder samples were tested for their physicochemical and the results are summarized in Table 4. In general, the addition of 30% maltodextrin did affect the physicochemical properties of spray-dried breadfruit powder. The moisture content analysis revealed that the moisture content in spray dried-breadfruit powder with 30% maltodextrin was lower (4.23 ± 0.11%) than spray dried-breadfruit powder without 30% maltodextrin (10.80 ± 0.03%). These findings were similar to [34] which revealed that the increase in maltodextrin concentration resulted in a decrease in moisture content and water activity of spray-

dried "cempedak" powder. In industrial practice, only the powder with a moisture content below 10% is considered microbiologically safe [35] suggesting that the spray-dried breadfruit powder fulfilled this criterion. A low moisture content will also prolong the shelf life of food products by preventing microbial activity that induces food degradation [11, 36].

The sample added with 30% maltodextrin also showed lower hygroscopicity (4.035 ± 0.26%) than the one without (4.715 ± 0.18%). Hygroscopicity can be described as the tendency of a solid substance to absorb moisture from the surrounding atmosphere. Pure spray-dried fruit powders usually exhibit a high level of hygroscopic behavior. However, a spray-dried breadfruit powder with lower hygroscopicity is favored to prevent or minimize undesirable effects such as caking. Additionally, hygroscopicity determines the moisture content and behavior of adsorption isotherms at which high hygroscopic levels may lead to unwanted effects such as caking during food processing and manufacturing [37].

The addition of 30% maltodextrin increased the WSI of spray-dried breadfruit powder by 20.04 ± 0.08%. These results are consistent with [38] who reported that the addition of maltodextrin enhanced the solubility of fig powder. Producing spray-dried breadfruit powder with high WSI is desirable for producing functional food ingredients because WSI determines the powder's behavior and stability in aqueous phases [39].

The bulk density of the sample added with 30% maltodextrin exhibited a lower bulk density (0.48 ± 0.01 g/mL) than the pure sample (0.55 ± 0.02 g/mL). These findings are supported by Pui et al. [34] who described that the increase in maltodextrin resulted in a decrease in the bulk density of spray-dried "cempedak" powder. An increase in bulk density is necessary for packaging, as it enables the food product to be packed in greater quantity within a constant volume [40].

Differential scanning calorimeter analysis

DSC analysis was performed to evaluate the thermal behavior of spray-dried breadfruit powder samples. Table 5 and Figure 2 summarize the thermodynamic properties of the samples. Based on Table 5, the addition of maltodextrin in the breadfruit influences the melting temperature of both breadfruit powders, with BFP showing a higher melting temperature (28.64± 0.20 ℃) than BFP+MD (28.29± 0.20 °C) yet demonstrating a lower enthalpy (ΔH 1.99 J/g) than the BFP+MD (ΔH 2.37 J/g). This finding is similar to Nevin and Rajamohan [41] which revealed that the addition of maltodextrin with a low molecular weight requires a lower temperature but a higher enthalpy to achieve an optimum melting temperature. Furthermore, the presence of shorter glucose polymer chain lengths in maltodextrin may affect the level of stickiness and the melting temperature [23].

Table 5. The melting temperature, A1 and ΔH of spray-dried breadfruit powder samples

Samples	A1 (°C)	ΔH (J/g)
BFP	28.64 ± 0.20	1.99 ± 0.20
BFP+MD	28.29 ± 0.20	2.37 ± 0.20

Abbreviation: Spray-dried breadfruit powder without maltodextrin (BFP); Spray-dried breadfruit powder with 30% maltodextrin (BFP+MD). Value is expressed as mean ± standard deviation (n=3).

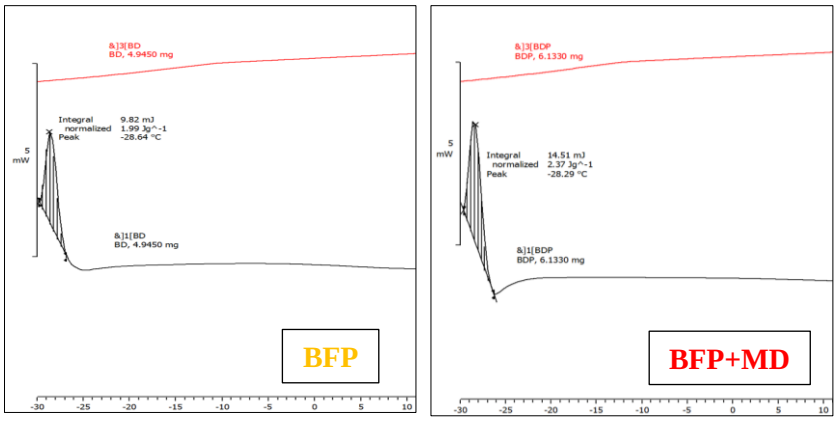

Figure 2. DSC thermogram of BFP and BFP+MD powder samples

Nutritional value of breadfruit samples

Proximate analysis is an important index to determine and classify nutritional values such as carbohydrates, protein, and fat content in a sample [42, 43]. Figure 3 and Table 6 depict the composition of nutritional values in the breadfruit samples obtained from the proximate analysis.

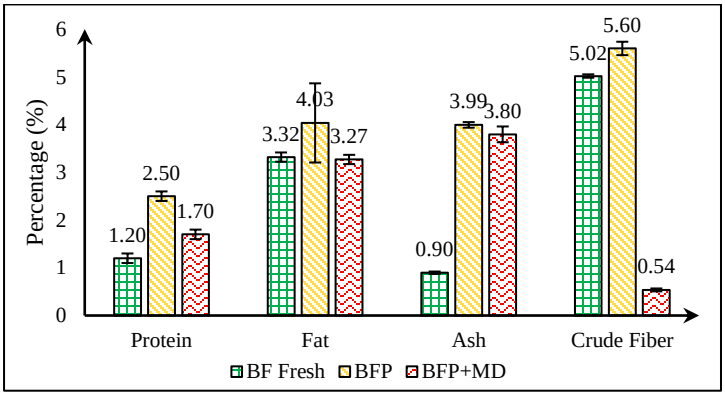

Figure 3. Nutritional value of the breadfruit samples

Table 6. Composition of carbohydrate and energy content of the breadfruit samples

Samples	Components	
	Carbohydrate (% w/w)	Energy (kCal)
BF_{Fresh}	10.42 ± 0.15	76.35 ± 0.78
BFP	73.08 ± 0.92	338.62 ± 3.79
BFP+MD	86.84 ± 0.18	383.80 ± 0.63

Abbreviation: Spray-dried breadfruit powder without maltodextrin (BFP); Spray-dried breadfruit powder with 30% maltodextrin (BFP+MD). Value is expressed as mean ± standard deviation (n=3).

Figure 3 shows that the spray-dried BFP samples generally contained the highest nutritional contents namely protein, fat, ash, and crude fiber (2.50 ± 0.10 % w/w, 4.03 ± 0.83 % w/w, 3.99 ± 0.06 % w/w, 5.60 ± 0.14 % w/w, respectively) compared to BFP + MD (1.70 ± 0.10 % w/w, 3.27 ± 0.11 % w/w, 3.80 ± 0.17 % w/w, respectively). The results demonstrate that both the BFP and BFP + MD samples of breadfruit retain their nutritional value despite the crude fiber content. Noticeably, the BFP + MD contained the lowest crude

fiber content (0.54 ± 0.03) compared to BF_{Fresh} (5.02 ± 0.04 % w/w) and BFP (5.60 0.14 % w/w). The low crude fiber content was probably due to the less soluble solid content in the breadfruit slurry before the spray dry process. Table 6 shows that BFP and BFP + MD contained high carbohydrate contents thus contributing to higher energy value.

Conclusion

Physicochemical, functional, and thermal properties determined in this research are important parameters for adding value to breadfruit processing and its utilization. These characteristics are principally responsible for the final product quality. Breadfruit as a whole is high in nutrients and a good source of energy and possesses extinguishing characteristics. Therefore, it can be potentially used in a variety of food products to offer health benefits. In addition, breadfruit powder with adequate antioxidant and total phenolic contents can be potentially incorporated into health supplementary products. Its favorable functional properties make it a suitable ingredient in the formulation of advanced food products without compromising the needs of health-conscious consumers.

Abstract

This study was conducted to incorporate tannin acid-chitosan (TAC) in solid phase method. The synthesized material was employed as an adsorbent to examine the effectiveness of solid phase extraction for preconcentration of Pb(II) in industrial wastewater. In addition, the parameters affecting extraction optimization were investigated and TAC was performed using a mass ratio of tannin acid and chitosan of 2:1 w/w. TAC absorbent was fully characterized using FTIR to detect functional groups and SEM-EDX to assess morphology and percentage of elements. The use of the optimal parameters for preconcentration on the performance of SPE method was obtained with adsorption, desorption, and enrichment factor at pH 5, a sample flow rate of 5 mL/min, Na_2EDTA eluent flow rate of 5 mL/min, a sample volume of 10 mL, Na_2EDTA eluent volume of 5 mL, sample concentration of 6 mg L^{-1} and Na_2EDTA concentration of 0.35 M. Furthermore, preconcentration application to Pb(II) wastewater at 0.05 mg L^{-1}, 0.06 mg L^{-1}, and 0.07 mg L^{-1} were concentrated 0.28 mg L^{-1}, 0.32 mg L^{-1}, and 0.38 mg L^{-1} with a factor of 5.6, 5.35, and 5.45 times. The result showed that the proposed method was effective for SPE with TAC adsorbent and Pb(II) preconcentration.

Keywords: solid phase extraction, preconcentration, Pb(II), tannin acid-chitosan

Abstrak

Penyelidikan ini menggabungkan asid tannin-kitosan (TAC) dalam kaedah fasa pepejal. Bahan tersintesis digunakan sebagai penjerap dan bertujuan untuk mengkaji keberkesanan pengekstrakan fasa pepejal untuk pra-pemekatan Pb(II) dalam air sisa industri. Di samping itu, parameter yang mempengaruhi pengoptimuman pengekstrakan telah disiasat. Asid tannin-kitosan (TAC) dilakukan menggunakan nisbah jisim asid tanin dan kitosan 2:1 b/b. Kemudian penyerap TAC dicirikan sepenuhnya menggunakan FTIR untuk mengesan kumpulan berfungsi dan SEM-EDX untuk menilai morfologi dan peratusan unsur yang terkandung di dalamnya. Menggunakan parameter optimum untuk pra-pemekatan pada prestasi kaedah pengekstrakan fasa pepejal diperolehi, dengan penjerapan, penyahjerapan, dan instrumen pengayaan pada pH 5 dengan kadar aliran sampel 5 mL/min, kadar alir eluen Na_2EDTA 5 mL/min, a isipadu sampel 10 mL, isipadu eluen Na_2EDTA 5 mL, kepekatan sampel 6 mg L^{-1} dan kepekatan Na_2EDTA 0.35 M. Penggunaan prapekatan pada air sisa Pb(II) pada kepekatan 0.05 mg L^{-1} boleh ditumpukan kepada 0.28 mg L^{-1} dengan faktor kepekatan 5.6 kali, pada kepekatan 0.06 mg L^{-1} boleh dipekatkan kepada 0.32 mg L^{-1} dengan faktor kepekatan 5.35 kali,

dan pada kepekatan 0.07 mg L^{-1} boleh ditumpukan kepada 0.38 mg L^{-1} dengan faktor kepekatan 5.45 kali. Nilai faktor kepekatan yang diperoleh sepadan dengan teori, 6 kali, masing-masing. Keputusan menunjukkan bahawa kaedah yang dicadangkan adalah berkesan untuk pengekstrakan fasa pepejal dengan penjerap TAC dan pra-pemekatan Pb(II).

Kata kunci: pengekstrakan fasa pepejal, pra-pemekatan, Pb(II), asid tannin-kitosan

Introduction

Wastewater generated from various industries, including garbage, metal plating, and leather industries, is known to pose a significant environmental risk by releasing harmful metal ions contaminating water [1]. Among these metal ions, lead (Pb) is particularly considered due to its toxicity, even at low concentrations, and can accumulate in living organisms, leading to long-term chronic exposure [2]. Typically, the concentrations in wastewater are measured by sampling at the site and then testing in the laboratory and the process often takes several days [3]. Determination of metal levels in water is commonly performed using techniques such as atomic absorption spectroscopy (AAS) instruments [4]. The accurate analysis becomes challenging when the metal ion concentration falls significantly below the detection limit of the instrument. Therefore, preconcentration step is necessary to enhance the detection capabilities of AAS instruments and solid phase extraction (SPE) has been widely recognized as an efficient method [5].

SPE is a technique used to separate compounds in a solution based on their chemical and physical properties [6]. The process in the SPE method begins with a conditioning step in which the column is filled with an adsorbent, serving as an analyte holder, followed by a loading step passed through the column/matrix/tube. In the third step, the column/matrix/tube is washed with Aquabides recovered by passing the eluent through the column/matrix/tube to analyse the results [6, 7].

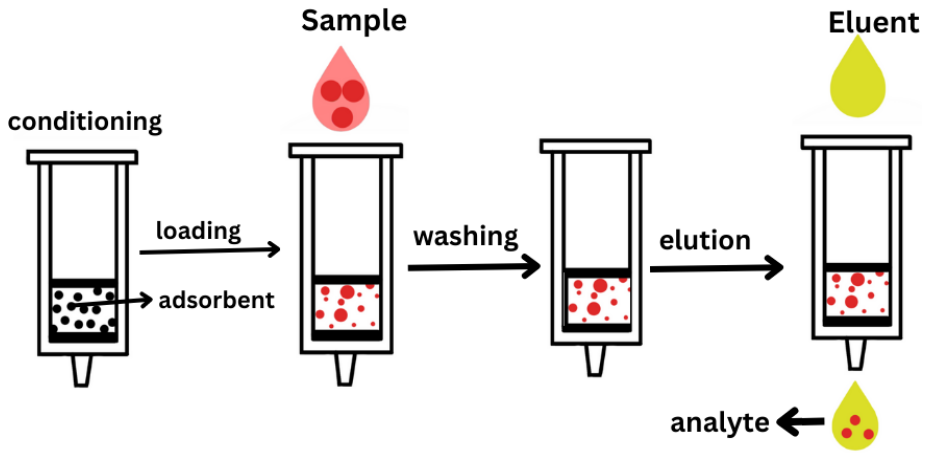

Figure 1. Main steps in solid phase extraction

Chitosan, a polymer found in crustaceans, fungal cell walls, and insect cuticles, is commonly employed as an adsorbent in SPE due to its hydroxyl and amino groups, acting as metal chelators and dye sorbents in solution [8]. Conversely, tannic acid possesses hydroxyl and carboxyl groups, making it suitable for adsorbing heavy metals. The high solubility in water necessitates immobilization with solid and porous materials, such as chitosan, to improve its applicability [9, 10]. Tannic acid and chitosan have been synthesized to obtain a new TAC adsorbent. It is more stable and effective for preconcentration/adsorption of metals riched in hydroxyl, carboxyl, and amino groups. A way to reduce metal analysis time is by combining the SPE method with TAC adsorbent.

The effectiveness of the SPE method can be evaluated based on the enrichment factor of the sample. The

enrichment factor, obtained from the performance of the SPE, reflects the increase in the absolute absorbance value, improving the validity of the concentration calculation beyond the detection limit on the linear curve [11]. In addition, optimization of parameters affecting SPE, such as solution pH, sample flow rate, eluent flow rate, sample concentration, and volume, can enhance the effectiveness of the method [12]. Previous studies also showed successful optimization of SPE parameters for preconcentrating Cd(II) and Pb(II), resulting in high concentration enrichment factors of 250 and recovery rates of 95% [13]. Similar efficiency and enrichment factor results have been achieved for Pb(II) using SPE in other studies [11, 14].

By combining the advantages of SPE with the use of TAC as an adsorbent, this study synthesizes and characterizes a novel adsorbent for preconcentration of Pb(II) from industrial wastewater. Additionally, the optimization of extraction parameters is explored to maximize the efficiency of preconcentration process. The results are expected to contribute to the development of sustainable and effective methods for preconcentration of heavy metal ions, specifically Pb(II), in industrial wastewater, facilitating the proper management and treatment of wastewater to mitigate the associated environmental and health risks.

Materials and Methods

Materials

The materials required are bi-distilled water and Merck's Pro-Analytical Quality (p.a.) chemicals, namely chitosan (%DD > 75%), tannic acid, $PbNO_3$, 25% glutaraldehyde, Na_2EDTA, filter paper, and universal pH paper.

Instrumentation

The equipment used includes laboratory glassware, stirrer, magnetic stirrer, analytical balance, oven, FTIR (Fourier Transform InfraRed, Thermo Nicolet Avatar 360), AAS (Atomic Absorption Spectrophotometer, Buck 205 Atomic Absorption Spectrophotometer), and SEM-EDX (Scanning Electron Microscope-Energy Dispersive X-ray).

Procedure: Synthesis of an adsorbent TAC

Tannic acid (up to 4g) was dissolved in 120 mL Aquabides by stirring until fully dissolved. Subsequently, 2g of chitosan was added to the solution and stirred for 6 hours using a stirrer. The stirring process was continued for 6 hours after adding 12 mL of 25% glutaraldehyde to crosslink the materials. The resulting precipitate was filtered and dried in an oven at 50 °C. The material was crushed using a mortar and pestle, followed by filtration to obtain the TAC adsorbent powder used in subsequent experiments [15].

Characterization of the TAC adsorbent

The TAC powder was subjected to characterization using an FTIR instrument (Thermo Nicolet Avatar 360) operating in the wave number range of 4000-400 cm^{-1}. This characterization aimed to identify the functional groups in the TAC powder analysed using an SEM-EDX instrument at a magnification of 1500-5000 times. The purpose of the analysis was to investigate the micro-scale properties of the material, including texture, morphology, composition, and surface characteristics.

Optimization of the SPE method

This study optimized SPE conditions by investigating different parameters. These parameters included the pH of the solution, the concentrations of the sample and eluent, the flow rates of the sample and eluent, the volumes of the sample and eluent, and the impact of eluent concentration on artificial wastewater.

Application of preconcentration to Pb(II)

The TAC adsorbent preconcentration process was applied to artificial wastewater samples containing Pb(II) ions. The experimental conditions included the pH, sample flow rate, eluent flow rate, sample volume, eluent volume, sample concentration, and optimal eluent concentration. The Pb(II) concentrations were set at 0.05, 0.06, and 0.07 mg L^{-1}, with a theoretical concentration factor of 6 times. Meanwhile, the resulting analyte concentrations were measured using an AAS instrument.

Results and Discussion

Characterization of the TAC adsorbent

The TAC adsorbent was subjected to characterization using FTIR to detect the functional groups present. The analysis results of the TAC adsorbent synthesis are presented in Figure 2, where peaks observed on the TAC adsorbent provide valuable information about the composition. Chitosan peak at 3442 cm^{-1} indicates the stretching vibrations of hydroxyl (O–H) and amino (N-H) groups. However, this peak shifts to 3434 cm^{-1} on the TAC adsorbent, suggesting the crosslinking of chitosan and glutaraldehyde [15]. Another peak shift is observed at 2932 cm^{-1} and 2955 cm^{-1}, which shifts to 2927 cm^{-1} on the TAC adsorbent, signifying the stretching vibrations of the (C–H) group [16]. Additionally, aldehyde stretching vibrations are indicated by a 2847 cm^{-1} peak on the TAC adsorbent [15]. The carboxyl group is confirmed by a peak at 1712 cm^{-1}, and the presence of the C–N group is indicated by 1341 cm^{-1} on the TAC adsorbent [16]. In chitosan, the carboxyl (C=O) stretching vibrations observed at 1642 cm^{-1} are shifted to 1627 cm^{-1}, suggesting the crosslinking of chitosan and tannic acid [15].

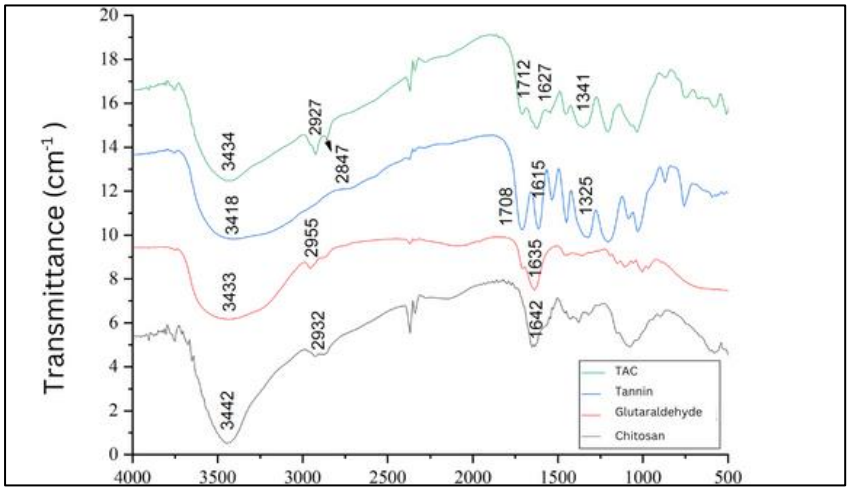

Figure 2. Spectra FTIR from tannin, acid, chitosan, glutaraldehyde, and TAC adsorbent

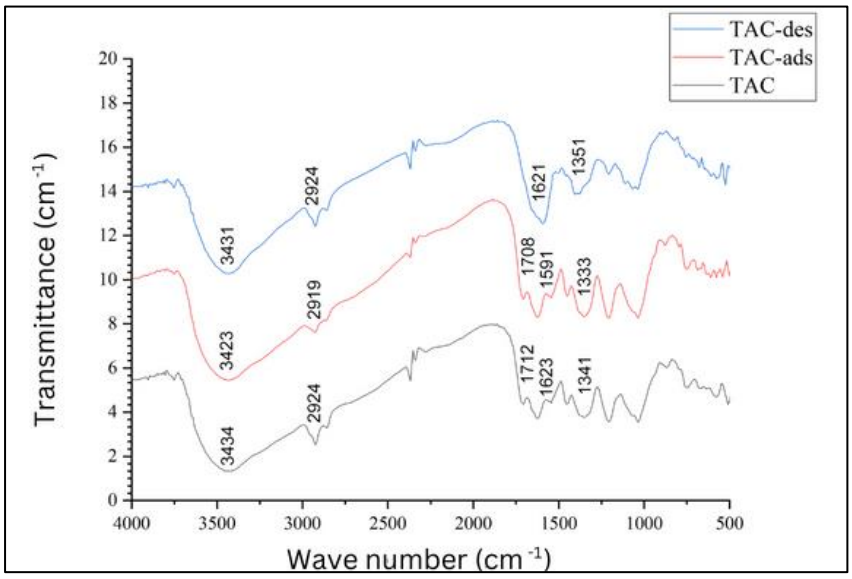

Figure 3. Spectra FTIR from TAC adsorbent, TAC-adsorption, and TAC-desorption

Characterization of the TAC adsorbent

The TAC adsorbent was analysed using Figure 3 to observe the peaks before and after adsorption and desorption. At the peak of 3434 cm^{-1}, there is a shift to 3423 cm^{-1}, indicating the narrowing of the stretching vibrations of the O–H and N–H groups. This shift suggests the interaction between the adsorbent and Pb(II) ions. In the desorbed TAC, the peak returns to 3431 cm^{-1}, indicating that Pb(II) absorbed in the adsorbent can be desorbed by the eluent. Another interaction can be observed at the 1623 cm–1 peak, which shifts to 1591 cm^{-1}, indicating C=O stretching vibration [15]. Moreover, the carboxyl and the C–N groups are visible at the peak of 1712 cm^{-1} and 1341 cm^{-1}, which shift to 1708 cm^{-1} and 1333 cm^{-1}, respectively. These shifts further confirm the interaction between the adsorbent and Pb(II) [17].

Based on the FTIR data described above, the interaction occurring in the TAC adsorbent with Pb can be estimated, as shown in Figure 4.

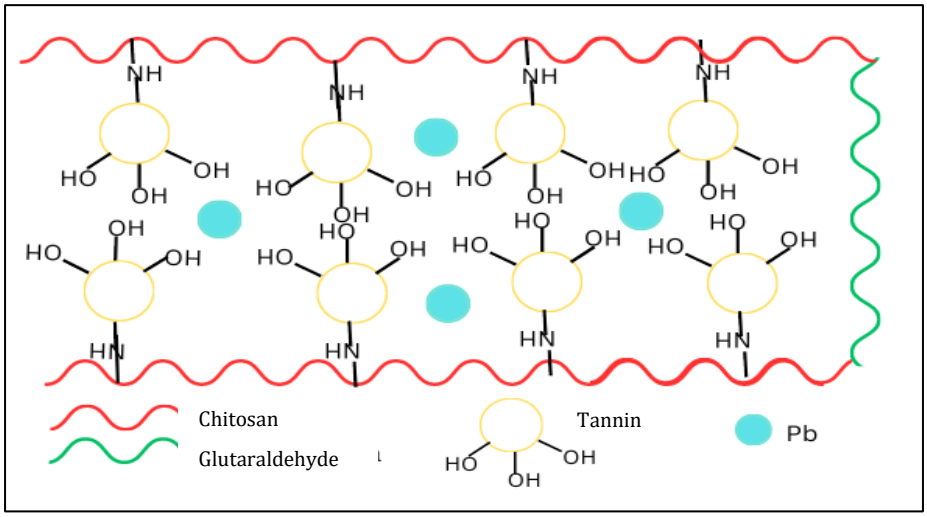

Figure 4. Estimation of the interaction between TAC adsorbent and Pb(II)

The morphology and percentage of elements present in the TAC adsorbent were assessed using SEM-EDX analysis. Figure 5 shows the morphology of the TAC adsorbent before and after adsorption and after desorption. Each sample was analysed at magnifications of 1000 and 5000 times to provide a detailed view of the surface morphology of TAC adsorbent during the different adsorption and desorption stages.

Figure 5 provides valuable insights into the structure and elemental composition of the TAC adsorbent. The adsorbent exhibits a complex and loose structure favorable for molecular diffusion and provides sufficient free space for Pb(II) molecules. In Figure 5b, the TAC adsorbent appears denser due to Pb(II) molecules filling the spaces. However, in Figure 5c, the TAC adsorbent returns to a looser structure, similar to the initial state, due to the desorption treatment. The analysis of the elements in the TAC adsorbent is presented in Table 1, displaying the mass percentage of elements in the TAC.

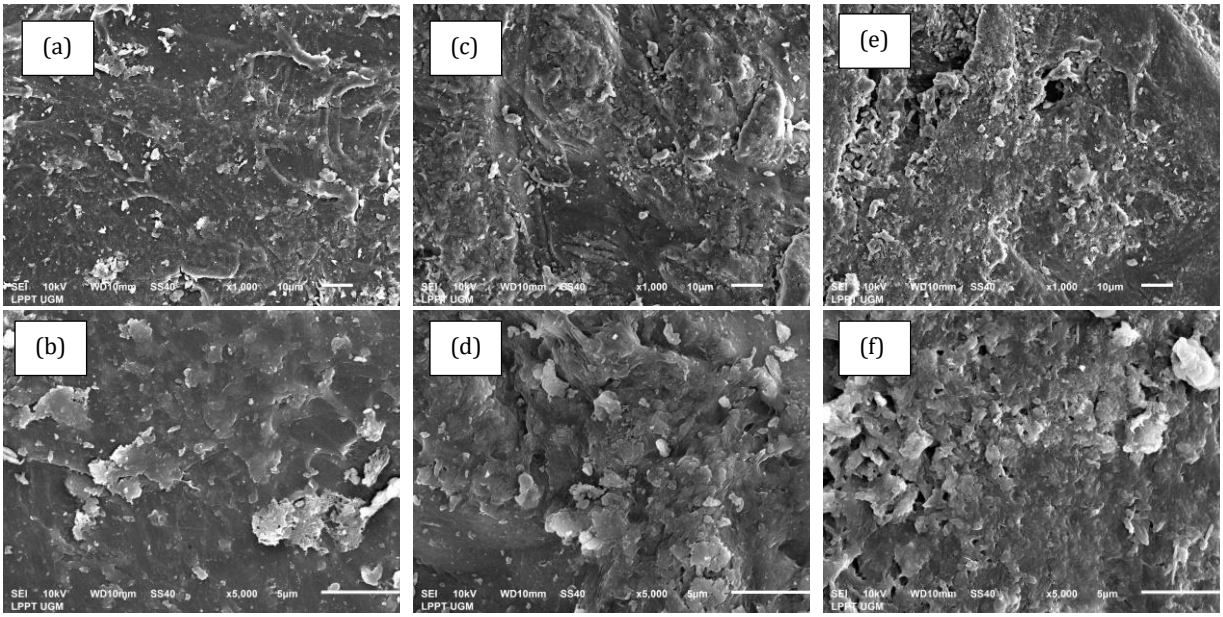

Figure 5. SEM images (a) TAC 1000x, (b) TAC 1500x, (c) TAC-adsorption 1000x, (d) TAC-adsorption 1500x, (e)TAC-desorption 1000x, and (f) TAC-desorption 1500x.

Table 1. Elemental composition in TAC before and after preconcentration

Sample	Elemental Composition (%)				
	C	N	O	Na	Pb
TAC	45.17	16.56	38.27	-	
TAC-adsorption	45.35	16.53	37.93	0.02	0.17
TAC-desorption	38.64	13.25	40.67	7.38	0.06

The TAC adsorbent contains 0.17% of the Pb element, decreasing to 0.06% after desorption. This significant decrease shows the successful desorption of Pb(II) using the Na_2EDTA eluent. The reduction in the Pb element can be attributed to the interaction between Pb(II) and the ligand of Na_2EDTA, confirming the effectiveness of the desorption process [18].

Optimization of SPE methods: pH optimization

The optimal pH of the solution plays a crucial role in the sorption of Pb(II) ions using the TAC adsorbent and the study tested pH 4, 5, 6, and 7. Figure 6(a) shows the varying percentage of Pb(II) sorption at different pH levels. The sorption capacity at low pH values (pH >4) is reduced due to the competition between hydrogen ions and Pb(II) ions for adsorption sites on the TAC adsorbent [19]. Additionally, the protonation of functional groups at lower pH values hampers the optimal adsorption of Pb(II) ions. At a higher pH (pH 5), the competition for protons decreases, leading to enhanced adsorption of Pb(II) ions on the TAC adsorbent [20]. However, at higher pH levels (pH 6-7), a decrease in adsorption is observed due to the precipitation of lead ions [19]. The optimal pH for the SPE process with Pb(II) samples is determined to be pH 5, aligning with previous results [20]. Furthermore, it is essential to consider the effect of solution pH on Pb(II) analysis and the changes in metal speciation for an effective SPE process [21].

Sample flow rate optimization

The flow rate of the sample is another influential factor in the SPE method. The study tested different sample flow rates, namely 5, 10, 15, and 20 mL/min to

determine the optimal flow rate, yielding high adsorption, desorption, and concentration factor. The results depicted in Figure 6(b) showed that the optimal sample flow rate was 5 mL/min. A low flow rate can positively affect adsorption due to selective interaction between the adsorbent and the lead metal [12]. However, at higher flow rates (10-20 mL/min), the limited contact time between the adsorbent and the metal decreases the percentage of adsorption [22]. This result aligns with previous studies, where higher flow rates result in insufficient absorption of lead metal by the adsorbent due to reduced contact time [23].

Eluent flow rate optimization

The flow rate of the eluent used for desorption significantly influences the desorption percentage and concentration factor of the SPE method. The study conducted tests with 5, 10, 15, and 20 mL/min variations for the eluent flow rate. The results in Figure 6(c), indicate that the optimal flow rate is 5 mL/min, since it provides a higher enrichment factor than other flow rates. Besides the higher enrichment factor, selecting an eluent flow rate of 5 mL/min helps avoid excessive duration [7]. This result was consistent with previous studies, where eluent flow rates in the 2-5 mL/min range were considered high for optimal SPE methods [24]. Conversely, higher flow rates (10-20 mL/min) resulted in decreased desorption and lower enrichment factors, possibly due to reduced contact between Na_2EDTA and the TAC adsorbent, which led to a decreased amount of desorbed Pb(II) analyte [25].

Sample volume optimization

The sample volume employed in the SPE method affects both the desorption percentage and the concentration factor. This study tested the optimal sample volume with 5, 10, 15, and 20 mL variations. The results in Figure 6 (d) show that the optimal sample volume is 10 mL and larger sample volumes increase the likelihood of a higher enrichment factor [26]. However, excessively large sample volumes can also reduce enrichment [12] and the obtained enrichment is low at lower volumes (5 mL) due to limited interaction between the analyte and the adsorbent [27]. In this study, the optimal results were obtained with a sample volume of 10 mL, and at higher volumes (15-20 mL), the active sites become saturated, leading to suboptimal absorption and decreased enrichment values [12]. These results are consistent with previous studies by Jiménez-Soto et al. [28] and Sanagi et al. [27], which found 10 mL to be the optimal sample volume for the SPE method.

Eluent volume optimization

The volume of eluent used for desorption affected the desorption percentage and the concentration factor in the SPE method. The study conducted tests of 5-, 10-, 15-, and 20-mL variations for the eluent volume, and the results in Figure 6(e), indicated that the optimal eluent volume was 5 mL. At higher volumes, there was a decrease in desorption due to excessive eluent volume, which had a limited effect after the analyte was sufficiently eluted. This result was consistent with the studies conducted by Sanagi et al. [27] and Maranata et al. [12], which determined the optimal eluent volume in the range of 3 to 6 mL for the SPE method.

Sample concentration optimization

The sample concentration influenced the desorption percentage and the concentration factor of the SPE method. This study tested the optimal sample concentration with 5, 6, 7, and 8 mg/L variations, and the results are shown in Figure 6(f), where the optimal result is 6 mg/L. Petrović et al. [20] stated that higher concentrations resulted in higher adsorption values as the availability of Pb(II) metal ions increased, leading to increased adsorption [29]. However, a significant decrease in adsorption occurred at higher concentrations (8 mg/L), impacting the enrichment value. This decrease was due to the saturation of active sites on the adsorbent caused by a more significant number, rendering the adsorbent suboptimal for adsorbing Pb(II) metal ions [30].

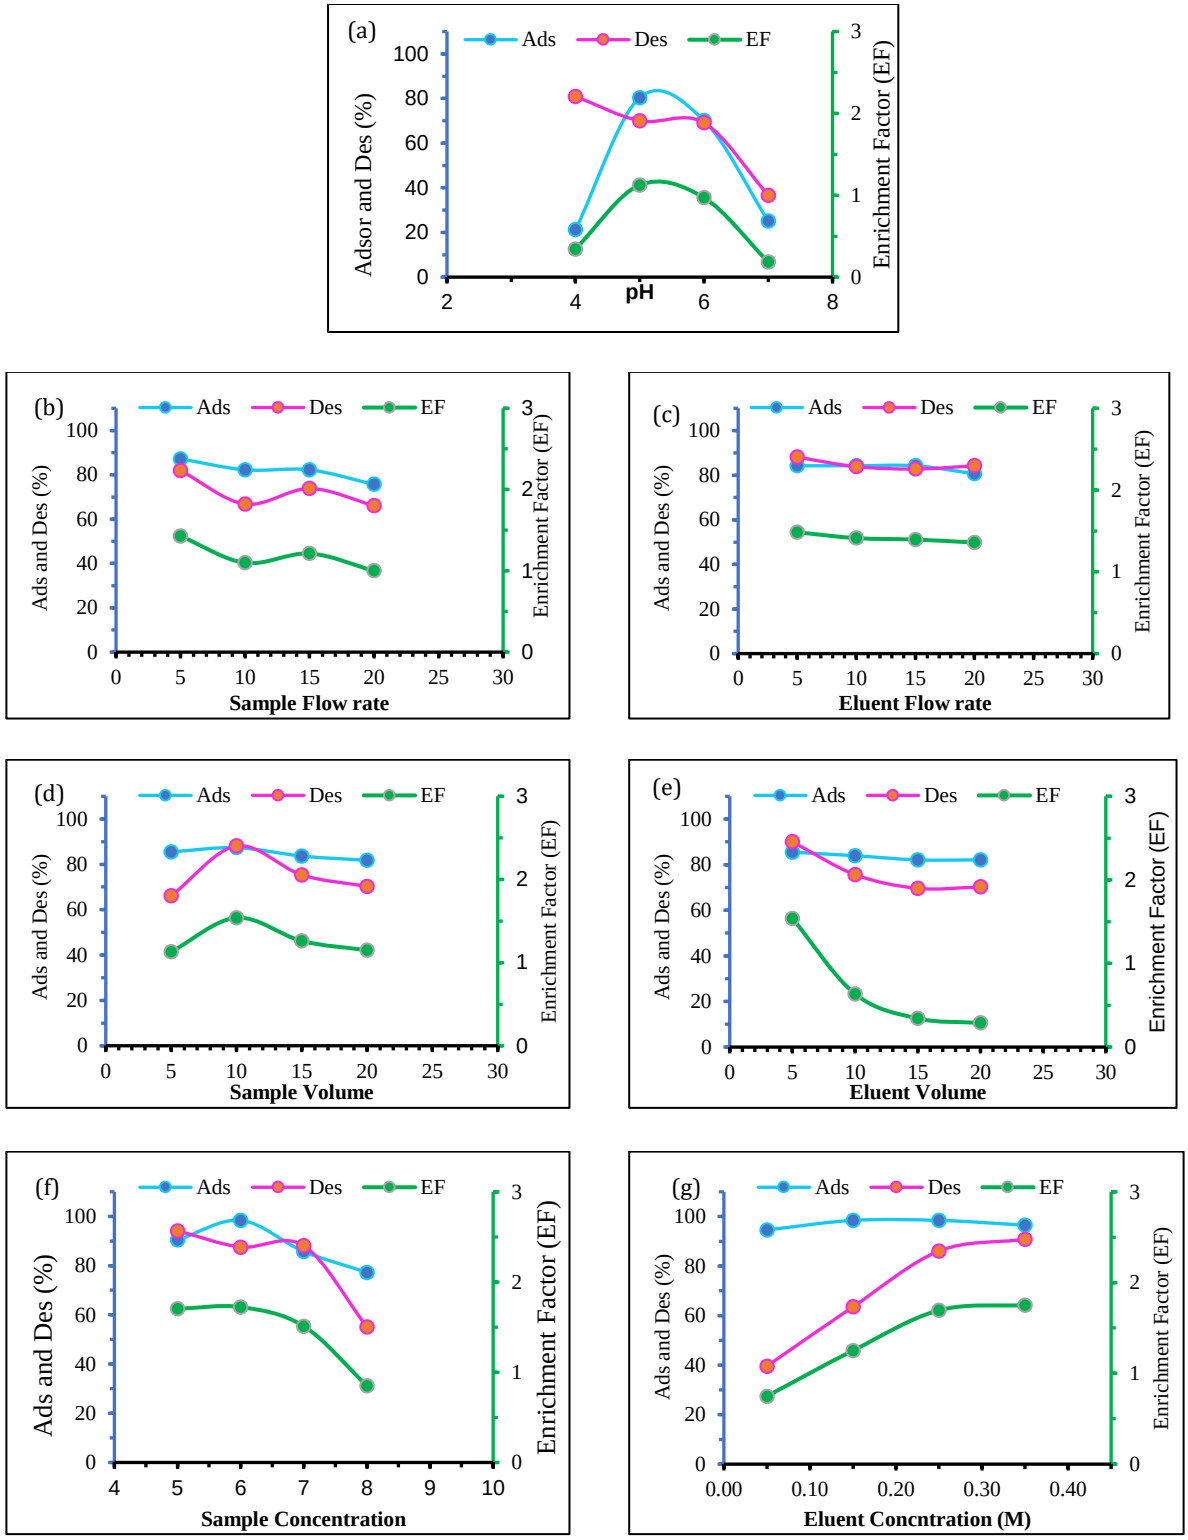

Figure 6. Effect of (a) pH (b) sample flow rate (c) eluent flow rate (d) volume sample (e) volume eluent (f) sample concentration (g) eluent concentration. (Ads is Adsorption, Des is Desorption, EF is Enrichment Factor)

Eluent concentration optimization

The eluent concentration used for desorption affected the desorption value and the factor in the SPE method. In this study, Na_2EDTA was used as the eluent because of its effectiveness compared to other solvents [31]. The optimal eluent concentration was tested with 0.05, 0.15, 0.25, and 0.35 M variations. Figure 6(g) showed that higher eluent concentrations resulted in higher desorption values and enrichment factors. The optimal eluent concentration was 0.35 M since higher concentrations fostered more interactions between the Na_2EDTA ligand and the TAC adsorbent, leading to a more effective desorption process [32]. The approximate interaction between the Na_2EDTA ligand and Pb(II) was shown in Figure 7.

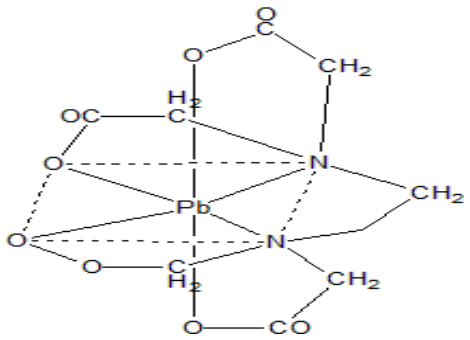

Figure 7. Approximate interaction between Na_2EDTA ligand and Pb(II)

Pre-concentration application to Pb(II)

Pre-concentration test was conducted to assess the effectiveness of SPE method with TAC adsorbent for pre-concentrating Pb(II) waste below the detection limit of the available AAS instrument (with a detection limit of 0.1 mg/L). Synthetic Pb(II) waste solutions were prepared with concentrations of 0.05 mg/L, 0.06 mg/L, and 0.07 mg/L, and were subjected to SPE using the TAC adsorbent under optimal conditions. Subsequently, desorption was performed using 5 mL of 0.035 M Na_2EDTA eluent, and the resulting samples were analysed using AAS.

Preconcentration test on Pb(II) waste showed the successful application of SPE method with TAC adsorbent. Table 2 shows the difference between the synthetic waste samples' initial and Pb(II) concentrations. The concentration was undetectable below the detection limit of the instrument but after preconcentration, Pb(II) was successfully detected. For the 0.05 mg/L, 0.06 mg/L, and 0.07 mg/L Pb(II) waste solution, the concentration was concentrated to 0.23 mg/L, 0.32 mg/L, and 0.038 mg/L with a factor of 5.6, 5.35, and 5.45, respectively. These concentration factor values obtained from the three waste variations closely approximate the theoretical factor of 6 times. Therefore, SPE method with TAC adsorbent is well-suited for preconcentration of Pb(II) metals. Preconcentration test results affirm the proposed method's efficacy and its potential for effectively concentrating Pb(II) below the detection limit of the AAS instrument.

Table 1. The result of TAC application on artificial wastewater

Wastewater Concentration (mg/L)	Wastewater Concentration (mg/L)		Enrichment Factors
	Initial	Final	
0.05	-	0.28	5.60
0.06	-	0.32	5.35
0.07	-	0.38	5.45

Conclusion

The synthesis of TAC as an adsorbent for pre-concentration using SPE method was successfully showed. The synthesized TAC adsorbent possessed active groups, including hydroxyl (–OH), amino (–NH_2), and carboxyl, which acted as effective metal chelators. By optimizing various parameters, the performance of the SPE method for pre-concentration had been significantly improved. The optimal parameters for pre-concentration using the SPE method were determined as follows pH 5, the sample flow rate of 5 mL/min, Na_2EDTA eluent flow rate of 5 mL/min, a sample volume of 10 mL, Na_2EDTA eluent volume of 5 mL, sample concentration of 6 mg/L, and Na_2EDTA concentration of 0.35 M. These parameters resulted in successful preconcentration of Pb(II) wastewater. For initial concentrations of 0.05 mg/L, 0.06 mg/L, and 0.07 mg/L, the concentrations were 0.28 mg/L, 0.32 mg/L, and 0.38 mg/L, with corresponding factors of 5.6, 5.35, and 5.45 times. Therefore, these concentration factors aligned with the theoretical value of 6 times. The results showed the effectiveness of the proposed SPE method using the TAC adsorbent for preconcentration of Pb(II). The technique offered a reliable and efficient method for preconcentration, allowing for the analysis of Pb(II) at concentrations below the detection limit of analytical instruments.

Abstract

In this study, the dispersive micro-solid phase extraction (D-µ-SPE) method was optimised and validated for preconcentration and determination of nicotine in tobacco samples, with the use of C_{18} as sorbent, coupled with gas chromatography-mass spectrometry (GC-MS). The optimisation of three extraction parameters, namely extraction time (min), mass of sorbent (mg), and desorption volume (mL), were investigated to provide better insight into its reliability as a low-consumption sorbent and rapid operation. The obtained parameters suitable for nicotine extraction were 10 min of extraction time, 50 mg of C_{18} sorbent, and 1.0 mL of desorption solvent. Nicotine was successfully extracted from tobacco samples with good linearity in the range of 0.1 – 500 mg/L, with a coefficient of determination (R^2) of 0.9997. The calculated LOD resulted in a value of 0.0983 mg/L, with the calculated LOQ being 0.2978 mg/L. The precision of the method revealed a percent relative standard deviation (% RSD) of 2.6%. In addition, good relative recovery (%) of nicotine in real samples was also achieved in the 75.5 – 96.4% range, with % RSD ranging from 3.1 - 5.7%. Hence, this study proposed an improvement to the green method towards nicotine analysis with low consumption of organic solvent, good sorbent absorptivity, and rapid and high selectivity for separation.

Keywords: Dispersive micro-solid-phase extraction, nicotine, tobacco samples, green method, C_{18} sorbent

Abstrak

Dalam kajian ini, kaedah pengekstrakan fasa pepejal-mikro dispersif (D-µ-SPE) telah dioptimumkan dan disahkan untuk pemekatan dan penentuan nikotin dalam sampel tembakau, dengan menggunakan C_{18} sebagai penjerap serta dicantumkan dengan kromatografi gas-spektrometri jisim (GC-MS). Pengoptimuman tiga parameter pengekstrakan, iaitu masa pengekstrakan (min), jisim penjerap (mg), dan isipadu penyaherapan (mL) turut dijalankan untuk memberikan gambaran yang lebih baik tentang kebolehpercayaannya sebagai penjerap yang dapat digunakan dalam kuantiti yang rendah serta operasi pengekstrakan yang pantas. Parameter yang diperoleh yang sesuai untuk pengekstrakan nikotin daripada sampel tembakau ialah 10 min masa pengekstrakan,

dengan penggunaan sebanyak 50 mg penjerap $C_{18,}$ dan isipadu penyaherapan sebanyak 1.0 mL. Nikotin berjaya diekstrak daripada sampel tembakau dengan kelinearan yang baik dalam julat 0.1 – 500 mg/L, dengan pekali penentuan (R^2) sebanyak 0.9997. Had pengesanan (LOD) yang dikira memberikan nilai 0.0983 mg/L, dengan had kuantitatif (LOQ) sebanyak 0.2978 mg/L. Ketepatan kaedah tersebut menghasilkan peratus sisihan piawai relatif (%RSD) sebanyak 2.6%. Di samping itu, pemulihan relatif (%) yang baik terhadap nikotin dalam sampel sebenar juga dicapai dalam julat 75.5 – 96.4%, dengan % RSD berjumlah dalam julat 3.1 - 5.7%. Oleh itu, kajian ini dapat mencadangkan penambahbaikan kepada kaedah hijau untuk analisis nikotin dengan penggunaan pelarut organik yang rendah, dapat memberikan penyerapan penjerap yang baik, kaedah yang pantas, dan kebolehasingan yang tinggi.

Kata kunci: Pengekstrakan fasa pepejal-mikro dispersif, nikotin, sampel tembakau, kaedah hijau, penjerap C_{18}

Introduction

Nicotine is a type of alkaloid mainly found naturally in plants from the Solanaceous family, including tobacco, tomato, potato, and green pepper [1]. Chemically known as 3-(1-methyl-2-pyrrolidinyl) pyridine, its content can reach 30-60 mg/kg, making it an immensely toxic alkaloid [2]. The human body absorbs approximately 1 mg of nicotine from smoking a cigarette, which typically contains between 8 and 20 mg [3].

The use of nicotine in tobacco products is undoubtedly a worldwide concern as it is known to cause various adverse health effects to consumers and people inhaling nicotine from second-hand smoke. It is highly addictive to its consumers, has severe systemic effects, and can also harm kidneys, lungs, reproductive systems, heart, and other vital organs [4]. Nicotine consumption also has the potential to be cancerous. It can impair the genome, interfere with cellular metabolic processes, and elevate the growth and spreading of altered cells, allowing nicotine to possess mutagenic and stimulate tumor-related activities in the body [5]. Nicotine, when acting on nicotinic cholinergic receptors, can endanger the body's systems, leading to its highly addictive nature [6]. Therefore, determining the content of nicotine in tobacco products is crucial as different brands of tobacco products, such as cigarettes, may vary in the amount of nicotine present in them [3]. Figure 1 shows the chemical structure of nicotine.

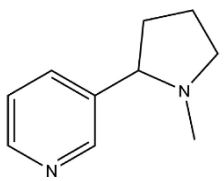

Figure 1. Chemical structure of nicotine

Sample preparation is a critical step in sample analysis. Previous studies have recorded solvent extraction as an extraction method for various samples, including nicotine in tobacco samples. A recent study utilized a solvent extraction method for the extraction of nicotine with ether, kerosene, and sulfuric acid as the extraction solvents [7]. Solvent extraction, or its other name which is liquid-liquid extraction (LLE), is an extraction technique that involves separation of compounds from two unidentical, immiscible liquids, about the liquids' respective relative solubility, typically with an organic solvent and water [8]. This extraction technique requires an extraction solvent, which is immiscible in the aqueous mixtures, to allow efficient separation of two differing liquids. In addition, the targeted analytes must be compatibly soluble and display a high partition coefficient in the extraction solvent [9]. This extraction technique involves shaking and inverting the mixture of two differing, immiscible liquids regularly for a few minutes to ensure the two liquid phases are well-mixed [9]. Expelling the solvent from the liquid phases can be done with a handheld pipette for less dense solvents than water, while denser solvents can be withdrawn from the bottom of a separatory funnel [9]. However, using organic solvents in this method may be toxic to the environment, time-consuming, and unable to separate many compounds with different polarity [8].

In recent years, dispersive micro-solid phase extraction (D-µ-SPE) has increased in recent years. D-µ-SPE is a method of extraction displayed in a miniaturized version of dispersive solid phase extraction (dSPE), extracting targeted analytes from samples rather than clean-up [11]. Sonication, stirring, vortex, or shaking are used to assist sorbent dispersion in the sample solution [11]. This is then followed by centrifugation, filtration, or

applying an external magnetic field to separate the solid sorbent [10]. The last step includes analysis of the analytes obtained in small volumes after being isolated from the sorbent [11]. D-µ-SPE absorbs fewer solvents, has a more straightforward procedure, and requires less time for operation in addition to minimizing solvent wastage, as opposed to the traditional solid phase extraction (SPE) method, which has some drawbacks involving solvent wastage, significant generation of secondary waste, apart from being lengthy and involving tedious procedures [10]. C_{18} silica, a micromaterial-type sorbent, is used for clean-up, in addition to primary-secondary amine (PSA), for the isolation of interference matrix from liquid extracts for the analysis of pesticides, specifically in vegetables [12]. As for the use of C_{18} in nicotine extraction, it has been reported in a study [13] in which nicotine was extracted from the hair of smokers and non-smokers with the use of SB-C_{18} column for SPE, assisted by molecularly imprinted polymer (MIP) as sorbent. Additionally, a study has also applied C_{18} as a sorbent through matrix solid-phase dispersion extraction method for the analysis of polyphenols in tobacco [14]. However, when it comes to the separation and preconcentration of nicotine from tobacco plants or products, there are still limited studies on the D-µ-SPE method and the use of C_{18} as a sorbent. The employment of D-µ-SPE for preconcentration of nicotine has been reported by a study [2] that applied graphene oxide as sorbent for separation and preconcentration of nicotine from environmental and biological water samples, which was then analyzed by gas chromatography with flame ionization detection (GC-FID). Other reported works did apply the D-µ-SPE method with C_{18} as a sorbent, even though it does not involve preconcentration and extraction of nicotine, such as the extraction and determination of ofloxacin and sparfloxacin from human plasma [15] and for determination of polycyclic aromatic hydrocarbon (PAHs) in water samples [16]. Considering the limitations of some sample preparation or extraction methods mentioned earlier, as well as the limited research on the efficiency of D-µ-SPE on the separation and preconcentration of nicotine in tobacco samples, it calls for an improved and alternative method to overcome these limitations.

The present study proposes an efficient technique using D-µ-SPE with C_{18} as the sorbent for preconcentration and determination of nicotine in tobacco samples, coupled with gas chromatography-mass spectrometry (GC-MS). C_{18} sorbent, commonly used in SPE [12], was studied for its potential as a quick and simple method for preconcentration and determination of nicotine in tobacco samples, utilizing D-µ-SPE. The method offers the possibility of an efficient clean-up procedure, utilizing C_{18} sorbent for a fast, easy, and cost-effective approach to preconcentration and determination of nicotine.

Materials and Methods

Chemicals and materials

Nicotine (≥ 99%), methanol (MeOH) of HPLC grade and DSC-18 (C_{18} sorbent, 50 µm particle size) were purchased from Sigma-Aldrich. Tobacco samples of different brands (labelled as 'M', 'G', and 'D') were obtained from the tobacco market available in Malaysia**.**

Preparation of standard and spiked solutions

1000 mg/L of nicotine stock solution was prepared in HPLC-grade methanol. The stock solution was stored in amber glass bottles in the refrigerator at 4 °C when not in use. A series of working standard solutions were prepared in methanol by dilution before analysis to prevent the decomposition of analytes. All spiked solutions were diluted with methanol and stored at 4 °C until further use.

Sample preparation and pre-treatment

Sample preparation was based on the methods described in the literature with some modifications [15, 17]. 2 g of tobacco samples were weighed and placed into 50 mL polyethene centrifuge tubes. 15 mL of methanol was then added to each sample and sonicated for 15 min. The resulting supernatant of each sample was then filtered through a 20-25 µm filter paper.

Optimization of parameters using one-factor-at-a-time (OFAT)

The optimization parameters used to determine the efficiency of C_{18} sorbent for the extraction of nicotine using the D-µ-SPE method were extraction time (min), mass of sorbent (mg), and desorption volume (mL). The

parameters were optimized using the One-factor-at-a-time (OFAT) approach. Each sample was spiked with 10 mg/L nicotine standard solution for the optimization study. The optimum results obtained from each parameter were used to implement subsequent parameters. The optimal conditions were then utilized for real sample analysis. For real sample analysis, the samples were spiked with 50 mg/L and 100 mg/L nicotine standard solutions. The concentration of nicotine in the filtrate and percent (%) relative recovery was calculated using the following equations:

$$\text{Concentration of nicotine} = \frac{\text{Peak area of spiked nicotine filtrate samples}}{\text{Retention factor}} \quad (1)$$

$$\%\ \text{Relative recovery} = \frac{\text{Amount recovered}}{\text{Actual amount of spiking}} \times 100 \quad (2)$$

Dispersive-micro solid phase extraction (D-µ-SPE) procedure

This part of the procedure was based on a method from the literature [15] with some modifications. 1 mL of 10 mg/L nicotine standard solution was spiked in a 50 mL centrifuge tube containing 4 mL of prepared tobacco sample filtrate and 50 mg of C_{18} sorbent. The samples were then sonicated for 10 min and centrifuged at 5000 rpm for 4 min. The sorbent was carefully collected and transferred into a microcentrifuge tube. To desorb the analytes, 1 mL of MeOH was added to the centrifuge tube containing the sorbent and vortexed for 5 min. Subsequently, to allow separation and settling of the sorbent, it was centrifuged again for another 5 min. The resulting supernatant was then filtered through a 0.22 µm nylon membrane filter before the analysis on GC-MS. Figure 2 shows the D-µ-SPE procedure by using C_{18} as a sorbent.

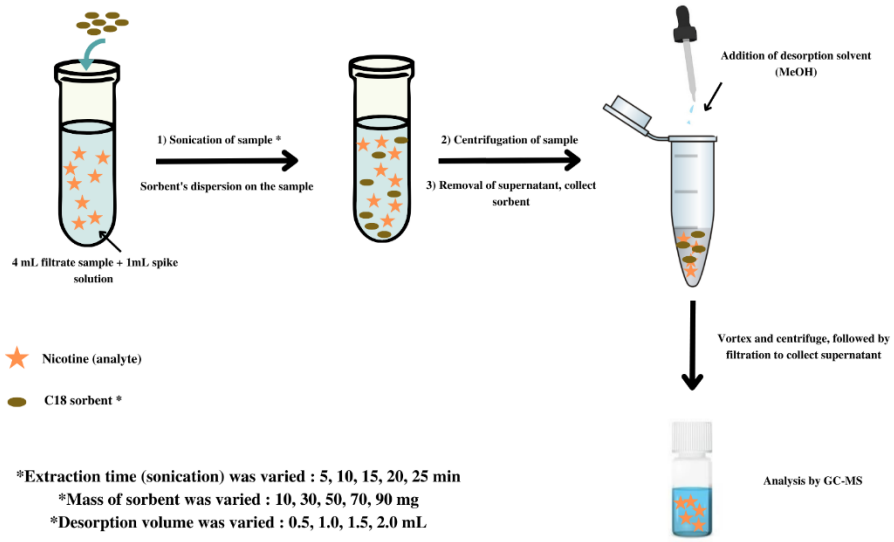

Figure 2. Dispersive micro-solid-phase extraction (D-µ-SPE) procedure by using C_{18} as sorbent

Chromatographic conditions

Chromatographic conditions were based on a method from the literature [18]. An Agilent 6890 gas chromatograph with 5973 inert mass spectrometers (USA) was used for analyzing nicotine in tobacco samples. The chromatographic separation was carried out on an InertCap 5MS/Sil column, with specifications of 0.25 mm I.D. x 30 m and df = 0.25 µm. Detection was done by MS scan (45 – 500 m/z) with an interface temperature of 280 °C. The carrier gas employed was helium, with a 36.5 cm/sec flow rate. An injection temperature of 250 °C was used. 1.0 µL of the sample

was injected into the GC-MS using splitless mode for 1 min, with a vent flow of 50 mL/min. The analysis of the samples was carried out under the following column temperature program; the initial temperature was set to 60 °C and held for 1 min, then ramped up at 10 °C/min, followed by raising the temperature to 280 °C and held for 7 min.

Validation of the analytical method

For the D-µ-SPE method, the efficiency of the analytical performance was assessed through linearity, the limit of detection (LOD), the limit of quantification (LOQ), precision, and accuracy. To assess the linearity of the analytical method, an eight-point calibration curve for nicotine was plotted by varying the concentrations of the spiked standards to achieve 0.1, 0.5, 1, 10, 50, 100, 200, and 500 mg/L in the filtrate solution (methanol obtained from the filtration of cigarette samples). Limit of detection (LOD) and limit of quantification (LOQ) were established through linear regression analysis. The precision of the method was calculated in terms of repeatability by determining the relative standard deviation (RSD). The RSD was then presented and expressed as a percentage (%RSD). The accuracy of the method was expressed in terms of percent relative recovery. Real samples were spiked with 50 mg/L and 100 mg/L nicotine standards, and the accuracy of the method was determined through percent relative recovery.

Results and Discussion

Optimization of dispersive-micro solid phase extraction (D-µ-SPE)

Optimization of D-µ-SPE parameters for the extraction of nicotine from tobacco samples was performed by varying the parameters, including extraction time, mass of sorbent, and desorption volume. These parameters were optimized based on the one-factor-at-a-time method (OFAT), where the other parameters were kept constant during the optimization of one parameter. The extraction of the samples was done in triplicates for each parameter optimized. Samples were also spiked with 50 mg/L and 100 mg/L nicotine standard solutions for real sample analysis using the optimized conditions and parameters obtained from the OFAT method.

Effect of extraction time

The effect of extraction time is vital in determining the extraction efficiency of the sample to extract the analyte selectively. For this research, the extraction efficiency was carried out by allowing the C_{18} sorbent to come into contact with nicotine (analyte) in the tobacco samples. The interaction between the sorbent and analyte in the samples was individually exposed for 5 min, 10 min, 15 min, 20 min, and 25 min. After each subsequent analysis, a graph of peak area (m/z) versus extraction time (min) was plotted to determine the optimized condition for the extraction time of nicotine. The effect of the extraction time, or the duration when the sorbent is in contact with nicotine in the samples, is shown in Figure 3.

From the results obtained for the extraction time of nicotine in tobacco samples, it was observed that the extraction efficiency of nicotine increased substantially from 5 min to 10 min. The highest extraction efficiency was acquired at the 10th minute, as shown in Figure 3(a). From 10 to 20 min, there was a gradual drop in the peak area of the analyte. The peak area remained constant from 20 min to 25 min. This implied that there was no significant improvement in the extraction efficiency of nicotine from tobacco samples, even when the extraction time was lengthened. The decline in extraction performance or efficiency in relation to its extraction time can be attributed to the back extraction of the analyte [11]. Hence, 10 min extraction time was chosen as the optimum extraction time to be used for further optimization of another parameter.

Effect of mass of sorbent

In the D-µ-SPE approach, it is necessary to consider the mass of sorbent as a crucial parameter since the amount of sorbent can significantly affect the efficiency of analyte extraction from the sample matrix through the number of adsorption sites [19]. The optimization of the mass of C_{18} sorbent involved varying the amount to 10, 30, 50, 70, and 90 mg. After each subsequent analysis, a graph of peak area (m/z) versus mass of C_{18} sorbent (mg) was plotted to determine the optimized condition for the mass of C_{18} sorbent used to adsorb nicotine from tobacco samples efficiently. The interaction mechanism between C_{18} sorbent and nicotine involves hydrophobic

interactions [13], π-π stacking, and Van der Waals forces. The hydrophobic alkyl chains of the C_{18} sorbent interact with the nonpolar regions of nicotine, while the aromatic rings in both the C_{18} sorbent and nicotine engage in π-π stacking interactions. Van der Waals forces further contribute to their attraction. The functional groups involved are the hydrophobic alkyl chains of C_{18}, the aromatic rings in both the sorbent and nicotine and the secondary amine group in nicotine. These interactions collectively facilitate nicotine's retention and separation on the C_{18} sorbent. Based on Figure 3(b), it can be observed that with an increasing mass of C_{18} sorbent up to 50 mg, the extraction efficiency of nicotine from tobacco samples increased significantly, with the highest extraction efficiency attained at 50 mg mass of C_{18} sorbent. This effect may be attributed to the increased likelihood of adsorbing analytes onto the sorbent due to the higher number of adsorption sites [19]. However, with an increasing mass of C_{18} sorbent beyond 50 mg (70 mg to 90 mg), the extraction efficiency started to decrease slowly. This condition may be due to the agglomeration of C_{18} sorbent that suppressed the action of the active sites of the sorbent, thereby lowering the extraction efficiency [15]. Furthermore, it is worth noting that samples may have trouble progressing through the system if the amount of sorbent increases [20]. Thus, to efficiently extract nicotine from tobacco samples, the mass of C_{18} sorbent of 50 mg was utilized as the second parameter for further optimization of another parameter and applied for subsequent use in real-sample analysis of tobacco samples.

Effect of desorption volume

The effect of desorption volume was also taken into consideration for efficiency studies in the extraction of nicotine in tobacco samples. This is because the efficiency of desorption capability is affected by the volume of desorption solvent used [21]. This study used methanol as the desorption solvent, and the desorption volume varied to 0.5 mL, 1.0 mL, 1.5 mL, and 2.0 mL. After each subsequent analysis, a graph of peak area (m/z) versus desorption volume (mL) was plotted to determine the optimized condition for the volume of desorption solvent used to adsorb nicotine from tobacco samples efficiently. Based on Figure 3(c), it can be observed that with an increasing desorption volume from 0.5 mL to 1.0 mL, the extraction efficiency of nicotine from tobacco samples also increased substantially. However, increasing the desorption solvent volume from 1.5 mL to 2.0 mL only lowered the extraction efficiency of nicotine from tobacco samples. This condition may be attributed to the maximum achievement of analyte enrichment when applying a lower volume of desorption solvent. Additionally, only a low volume of desorption solvent was necessary for achieving higher sensitivity of analyte extraction [22]. Hence, a desorption volume of 1.0 mL of methanol was utilized as the third parameter and applied for subsequent use in the real sample analysis of tobacco samples.

Optimum extraction conditions

The final applied C_{18}- D-μ-SPE conditions were as follows: extraction time, 10 min; mass of sorbent, 50 mg; and desorption volume, 1.0 mL. Thus, these optimum extraction conditions were applied for subsequent analysis on real samples.

Method validation and analytical performance of D-μ-SPE

Method validation was then carried out based on the optimum conditions obtained from the D-μ-SPE method. Relative recovery (%), linearity, precision, limit of detection (LOD), and limit of quantification (LOQ) were obtained for validation of this study. Good linearity in the range of 0.1 – 500 mg/L was obtained for the analyte of nicotine, with the coefficients of determination (R^2) of 0.9997. The calculated LOD was 0.0983 mg/L, while the LOQ was calculated to be 0.2978 mg/L. The precision of the method was measured through percent relative standard deviation (% RSD), which gave a value of 2.6%. Table 1 shows the validation data for D-μ-SPE of nicotine from tobacco samples using sample brand M.

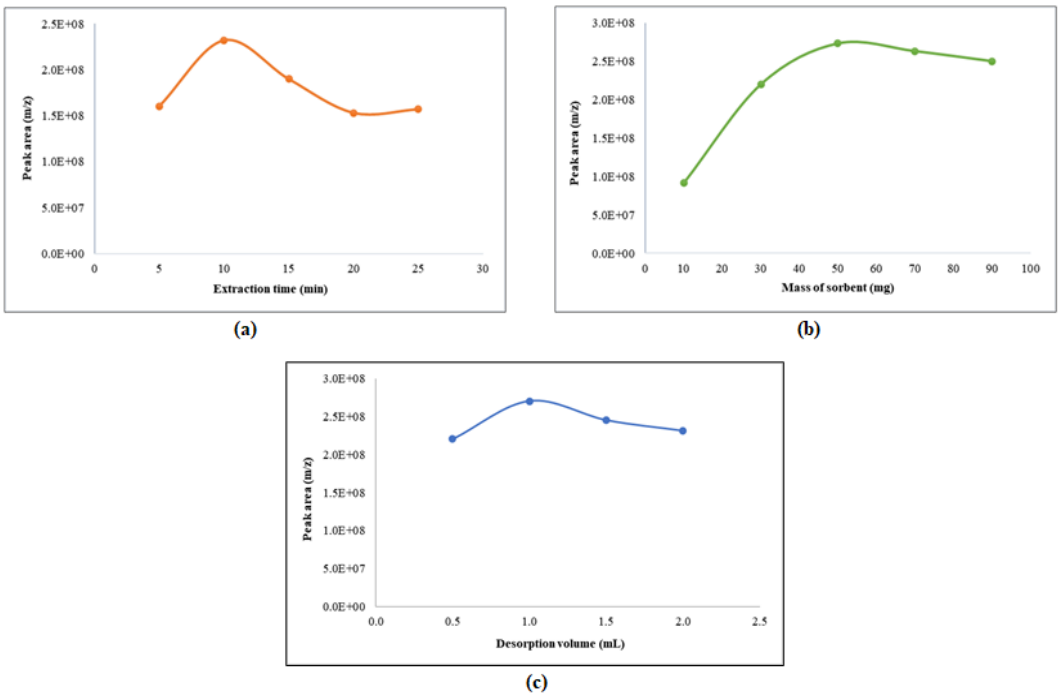

Figure 3. Optimization for the extraction performance of C_{18} using D-µ-SPE. (a) Effect of extraction time, (b) mass of sorbent and (c) desorption volume on C_{18}-D-µ-SPE of nicotine in tobacco samples.

Table 1. Quantitative results of D-µ-SPE for nicotine from tobacco samples

Sample	Analyte	Linear Range (mg/L)	Coefficient of Determination (R^2)	LOD (mg/L)	LOQ (mg/L)	RSD (%, n = 3)
Brand M	Nicotine	0.1 - 500	0.9997	0.0983	0.2978	2.6

Application of D-µ-SPE on real samples

The developed D-µ-SPE-GC-MS method was successfully applied to the extraction of nicotine from tobacco samples. The optimized parameters performed previously were used to obtain the actual concentration (mg/L) of nicotine in the tobacco samples. Relative recoveries (%) were also calculated on the real samples by spiking each real sample with 50 mg/L and 100 mg/L standard nicotine. Relative recoveries (%) of real samples showed good recoveries ranging from 75.5% to 96.4%. The analysis on real samples also displayed good repeatability with relative standard deviation (% RSD) ranging from 3.1% to 5.7%. Table 2 shows relative recoveries (%) of nicotine in tobacco real samples and % RSD (n = 3) of D-µ-SPE.

Table 2. Relative recoveries (%) of nicotine in tobacco real samples and %RSD (n = 3) of D-µ-SPE

Real samples	Spike Added (mg/L)	Actual Concentration (mg/L)	Relative Recoveries (%)	RSD (%) (n = 3)
Brand D	50	41.594	83.2	3.5
	100	84.793	84.8	4.5
Brand G	50	48.189	96.4	3.1
	100	75.489	75.5	5.7
Brand M	10	8.574	85.7	4.3

Comparison with other reported methods

Previous studies have applied various extraction methods for nicotine from different samples. A comparison study is outlined in Table 3, displaying the developed method from existing/published studies alongside the method proposed by this research for preconcentration and determination of nicotine in tobacco samples. As shown in Table 3, most of the extraction methods for nicotine from tobacco samples involve longer extraction time. For instance, a reported method [23] took 120 min to extract nicotine from waste tobacco samples using an aqueous two-phase system and solvent reverse extraction method. Extraction of nicotine by the HS-SPME method [24] and the electro-membrane extraction (EME) method [25] reported extraction time of 30 min and 20 min, respectively. In contrast, the proposed D-µ-SPE method exhibited a low extraction time of 10 min, which can significantly reduce tedious laboratory work. However, a method reported earlier using surface-enhanced Raman scattering (SERS) [26] showed the fastest extraction time, with nicotine extracted between 3 and 5 min. However, the present D-µ-SPE method demonstrated better % recovery of nicotine ranging from 75.5% to 96.4% from tobacco samples, compared to the previously developed method [26], which reported 51.47% nicotine recovery. Furthermore, the limit of detection (LOD) for the proposed D-µ-SPE method also showed a good detection limit.

Conclusion

In conclusion, the optimization and validation of the dispersive micro-solid phase extraction method using C_{18} as the sorbent have been successfully employed for the extraction and determination of nicotine in tobacco samples, coupled with gas chromatography-mass spectrometry (GC-MS) for chromatographic analysis. Three parameters were studied for optimization purposes: the effect of extraction time of the D-µ-SPE method, the effect of the mass of C_{18} sorbent, and the effect of desorption volume to extract and pre-concentrate nicotine from tobacco samples. An extraction time of 10 min, mass of C_{18} sorbent of 50 mg, and desorption volume of 1.0 mL were found to be the optimized conditions for extraction. Nicotine was successfully extracted using the above optimum conditions with the D-µ-SPE method. Good linearity in the range of 0.1 - 500 mg/L was also achieved for the analyte of nicotine, with a coefficient of determination (R^2) of 0.9997. The limit of detection (LOD) was calculated to be 0.0983 mg/L, and the limit of quantification (LOQ) was calculated to be 0.2978 mg/L. The precision of the method was measured through the percent relative standard deviation (% RSD), which gave a value of 2.6%. Additionally, good relative

recovery (%) of nicotine in real samples was achieved in the 75.5 - 96.4% range, with % RSD ranging from 3.1 - 5.7%. Hence, the D-µ-SPE method proves to be green, reducing excessive solvent consumption while being selective and rapid in preconcentration and determination of nicotine from tobacco samples. It shows promise as an alternative method for future analytical laboratory work in nicotine analysis. Compared to the previously reported methods, the D-µ-SPE method used in the present study demonstrated one of the fastest extraction times and one of the highest recoveries of nicotine from tobacco samples. A future extension to this research may be to explore more optimization conditions and study other parameters and factors that may contribute to improving the efficiency of C_{18} as a sorbent for nicotine extraction from tobacco samples using the D-µ-SPE method.

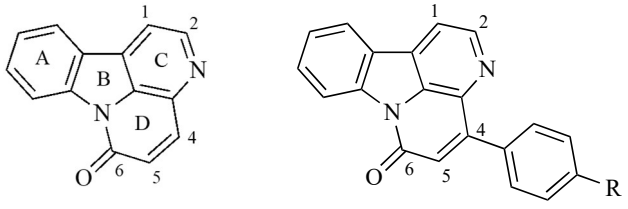
Abstract

This study presents a comprehensive synthesis of 4-aryl substituted canthin-6-one through a versatile Pictet-Spengler condensation and subsequent cyclization, involving the formation of 1-aroyl substituted β-carbolines as pivotal intermediates. β-Carbolines, as indole alkaloids, serve as fundamental building blocks with diverse biological activities. In particular, canthin-6-one and its derivatives exhibit a wide range of promising biological properties, which include anti-cancer, antibacterial, anti-inflammatory, and cytotoxic effects, thus making them valuable in pharmaceutical and medicinal chemistry applications. The method outlined herein involves the utilization of readily available starting materials in a direct reaction sequence, resulting in an efficient and moderate-yield access to 4-aryl substituted canthin-6-one. Synthesizing canthine was initiated by forming the intermediates, 1-aroyl substituted β-carbolines via Pictet-Spengler condensation of different substituted aromatic glyoxals with 5-hydroxy tryptophan in the presence of trifluoroacetic acid. This synthesis route avoids the formation of tetrahydro-β-carbolines. Subsequently, the series of 1-aroyl substituted β-carboline intermediates were cyclized to yield the desired 4-aryl substituted canthin-6-one derivatives. The reaction mechanism and key intermediates are discussed, providing insights into the synthesis pathway. The structure of the synthesized compounds were confirmed by using Infrared Radiation (IR) and Nuclear Magnetic Resonance (NMR) spectroscopy. This research not only contributes to the understanding of synthetic methodologies but also paves the way for the development of novel compounds with promising pharmaceutical properties.

Keywords: β-carboline, Pictet-Spengler condensation, cyclization, canthin-6-one

Abstrak

Kajian ini membentangkan sintesis komprehensif 4-aril digantikan kantin-6-satu melalui pemeluwapan Pictet-Spengler serba boleh dan kitaran seterusnya, melibatkan pembentukan 1-aroil digantikan β-karbolin sebagai perantaraan penting. β-karbolina, sebagai alkaloid indole, berfungsi sebagai blok binaan asas dengan pelbagai aktiviti biologi. Khususnya, kantin-6-satu dan derivatifnya mempamerkan pelbagai sifat biologi yang menjanjikan, termasuk kesan anti-kanser, antibakteria, anti-radang dan sitotoksik,



dengan itu menjadikannya berharga dalam aplikasi kimia farmaseutikal dan perubatan. Kaedah yang digariskan di sini melibatkan penggunaan bahan permulaan yang sedia ada dalam urutan tindak balas langsung, menghasilkan akses hasil yang cekap dan sederhana kepada 4-aril digantikan kantin-6-satu. Mensintesis kantin telah dimulakan dengan membentuk perantaraan, β-karbolina yang digantikan 1-aroil melalui kondensasi Pictet-Spengler bagi glioksal aromatik tersubstitusi berbeza dengan triptofan 5-hidroksi dengan kehadiran asid trifluoroasettik. Laluan sintesis ini mengelakkan pembentukan tetrahidro-β-karbolina. Selepas itu, siri perantaraan β-karbolina yang digantikan 1-aroil telah dikitar untuk menghasilkan derivatif 4-aril digantikan kantin-6-satu yang dikehendaki. Mekanisme tindak balas dan perantaraan utama dibincangkan, memberikan pandangan tentang laluan sintesis. Struktur sebatian yang disintesis telah disahkan dengan menggunakan spektroskopi sinaran inframerah (IR) dan resonans magnetik nuklear (NMR). Penyelidikan ini bukan sahaja menyumbang kepada pemahaman metodologi sintetik tetapi juga membuka jalan untuk pembangunan sebatian baru dengan sifat farmaseutikal yang menjanjikan.

Introduction

In field of medicinal chemistry, the search of novel compounds with therapeutic potentials never ends. Within this dynamic field, the synthesis of heterocyclic molecules has emerged as a promising pathway, offering new scaffolds for drug discovery. One such class of heterocycles, β-carbolines, has garnered increasing attention due to their diverse biological activities and potential applications in pharmaceutical research. In this work, we investigate the complex area of organic synthesis and chemical transformation to unlock the diverse potentials of β-carboline belongs to the indole alkaloid family and consists of an indole structure fused to a pyridine ring [1]. The structure of β-carboline is similar to that of tryptamine, with the ethylamine chain reconnected to the indole ring via an extra carbon atom, to produce a tricyclic ring structure [2]. Extensive studies on β-carboline have revealed exceptionally diverse biological efficacy of this natural compound.

β-Carboline has been isolated from *Peganum harmala*, a plant used as an emmenagogue and a digestive tract medicine, which is also known to evoke hallucinations. β-Carboline plays an important role in biological activities like antiparasitic, antitumor, antiviral, anti-inflammatory, and antibacterial. Although these alkaloids are highly represented in terrestrial species, large amounts of β-carboline are also isolated from marine invertebrates such as tunicates, bryozoans, soft corals, and sponges [3]. Canthine-6-one (Figure 1a) alkaloids belong to the tetracyclic subclass of β-carboline alkaloids with the addition of D ring, and have a peri-fused indolo[3,2,1-de][1,5]naphthyridine structure. They are widely found in Rutaceae and Simaroubaceae families. There are a lot of compounds that have been isolated due to their diversity in biological activities that act as anticancer, antibacterial, antifungal, anti-inflammatory, and cytotoxic agents [4]. The 4-aryl substituted canthin-6-one (Figure 1b) is one of the derivatives of β-carboline which consists of canthine as its monomer [5]. It is commonly formed by the cyclization of intermediate 1-substituted β-carboline. The derivatives of β-carboline with aroyl substitution at the C1 position were known to exhibit potent anti-inflammatory, anti-malarial, anti-cancer, anti-phospholipase, P-glycoprotein-inducer, and anti-microbial activities [6].

Figure 1. (a) Canthine-6-one structure and (b) 4-Aryl substituted canthin-6-one structure

Numerous efforts have been made to synthesize not only the parent structure of β-carboline but also a variety of synthetic β-carboline derived compounds due to their notable impact in life. One of the well-known reactions that has been used to prepare β-carboline is the Pictet-Spengler reaction. To date, it has remained as one of the most powerful methods for the formation of this ring system via C-C bond formation using indole-based compound as the starting material [7]. This reaction is the most direct, and efficient synthetic method for the construction of advantaged and widely synthesized pharmacophores such as tetrahydro-isoquinolines (THIQs), tetrahydro-β-carbolines (THβCs), and polyheterocyclic frameworks [8]. The application of the Pictet-Spengler condensation reaction was the most reported method to synthesize THβCs with the aid of strong Brønsted acids to promote the ring closure of the imine [9]. Generally, Pictet-Spengler reaction can be characterized by the formation of iminium salt after an acid-catalyzed condensation of β-arylethylamine with an aldehyde or a ketone, followed by ring closure [10]. This method continues to be a prominent focus of research over the years as scientists continue to refine the methodology by applying novel reaction conditions.

However, in this study, we attempted in a more practical and convenient synthesis of the aromatic β-carbolines using 5-hydroxytryptophan and various aromatic glyoxals in the desired Pictet-Spengler reaction, followed by formation of 4-aryl substituted canthin-6-one via cyclization. This work details the efficient Pictet-Spengler condensation catalyzed by TFA, without the use of expensive metal catalysts, prolonged reaction hours or critical reaction conditions. Thus, we report herein the successful application of this versatile method for the synthesis of naturally occurring 4-aryl substituted canthin-6-one derivatives using 5-hydroxy-L-tryptophan as the starting material.

Materials and Methods

Procedure for the synthesis of intermediate 1-formyl-β-carbolines (2a-e)

To a stirred suspension of 5-hydroxy-L-tryptophan (5.69 mol, 1.3 equiv.) in 1.0 equiv. of p-toluenesulfonic acid monohydrate (TFA) (1.5 equiv.), glyoxal (4.38 mol, 1.0 equiv.) in methanol (50 ml) was added. Then, the solution was heated to 50℃ for 4 hours and the presence of phenylglyoxal was monitored by TLC analysis until it was completely consumed. The reaction mixture was poured into water and the precipitate was filtered and purified by silica gel column chromatography eluted with a gradient of acetone and petroleum ether (1:1) to afford **2a-e**.

Procedure for the synthesis of 4-aryl substituted canthin-6-ones (3a-e)

The intermediate compounds **2a-e** (2.13 mol, 1.0 equiv.) in THF (5 mL) was added into NaH solution (60% dispersion in mineral oil) and stirred at 0℃ for 15 minutes. Then, acetic anhydride (1.54 mol, 1.5 equiv.) was added into the stirred solution and heated at 70℃ for 3 hours. The reaction was monitored by using TLC analysis, and upon completion, the reaction mixture was quenched with water (50 mL), extracted with ethyl acetate (2 x 50 mL) and dried over anhydrous Na_2SO_4. The organic layer was evaporated and purified by silica gel column chromatography eluted with a gradient of n-hexane and EtOAc (8:2) to obtain **3a-e**.

Results and Discussion

(6-hydroxy-9H-pyrido[3,4-b]indol-1-yl)(phenyl)methanone (**2a**). Yield: 53%, yellow solid. IR ν cm^{-1}: 3500, 3423, 1697cm^{-1}. ^{1}H-NMR (400 MHz, METHANOL-D4) ppm: δ 7.86 (dt, J = 8.4, 1.8 Hz, 2H), 7.59-7.54 (m, 3H), 7.29-7.27 (m, 1H), 7.17-7.06 (m, 2H), 6.01 (s, 1H), 3.65-3.53 (m, 2H), 3.23-3.12 (m, 1H). ^{13}CNMR δ (100 MHz, METHANOL-D4): 191.8, 163.0, 141.8, 137.2, 137.1, 135.9, 133.6, 131.0, 130.0, 129.0, 122.0, 120.3, 118.6, 113.6, 113.1, 55.7.

(6-hydroxy-9H-pyrido[3,4-b]indol-1-yl)(4-hydroxyphenyl)methanone (**2b**). Yield: 30%, light brown solid. IR ν cm^{-1}: 3499, 3456, 1678cm^{-1}. ^{1}H-NMR (400 MHz, METHANOL-D4) ppm: δ 12.18 (br s, 1H), 9.68 (br s, 1H), 9.23 (br s, 1H), 8.68 (d, J = 4.6 Hz, 1H), 8.51 (d, J = 7.4 Hz, 1H), 8.43 (d, J = 5.5 Hz, 2H), 8.32 (d, J = 3.6 Hz, 1H), 7.87 (d, J = 6.7 Hz, 1H), 7.52 (dd, J = 8.0 Hz, 3.2 Hz, 1H), 7.12 (d, J = 3.3 Hz, 2H). ^{13}CNMR δ (100 MHz, METHANOL-D4): 170.8, 165.0, 143.9, 138.2, 136.1, 135.2, 133.2, 131.8, 130.0, 129.0, 122.0, 120.8, 118.4, 113.6, 114.5.

(6-hydroxy-9H-pyrido[3,4-b]indol-1-yl)(4-methoxyphenyl)methanone (**2c**). Yield: 42%, brown solid. IR ν cm^{-1}: 3492, 3432, 1642, 1621cm^{-1}. ^{1}H-NMR (400 MHz, METHANOL-D4) ppm: δ 8.34 (d, J = 4.4 Hz, 1H), 8.15 (m, 3H), 7.51 (d, J = 8.4 Hz, 1H), 7.49 (d, J= 8.0 Hz, 1H), 7.10 (d, J = 4.9 Hz, 1H), 7.01 (d, J = 7.4 Hz, 2H), 4.60 (s, 1H), 3.85 (s, 3H). ^{13}CNMR δ (100 MHz, METHANOL-D4): 163.5, 151.5, 136.8, 136.1, 135.9, 133.8, 136.5, 130.0, 121.2, 118.7, 117.9, 112.2, 105.5, 100.3, 54.6.

(6-hydroxy-9H-pyrido[3,4-b]indol-1-yl)(4-bromophenyl)methanone (**2d**). Yield: 57%, brown solid. IR ν cm^{-1}: 3443, 3389cm^{-1}. ^{1}H-NMR (400 MHz, METHANOL-D4) ppm: δ 12.09 (br s, 1H), 9.19 (br s, 1H), 8.51 (d, J = 5.2 Hz, 1H), 8.44 (d, J = 4.4 Hz, 1H), 8.31 (d, J = 7.0 Hz, 1H), 8.15 (d, J = 5.5 Hz, 2H), 7.82 (d, J = 8.0 Hz, 1H), 7.77 (d, J = 5.4 Hz, 2H), 7.60 (t, J = 4.1 Hz). ^{13}CNMR δ (100 MHz, METHANOL-D4): 192.8, 141.9, 137.4, 136.6, 136.0, 133.0, 131.3, 131.2, 129.2, 126.5, 122.0, 120.4, 120.2, 119.3, 113.2.

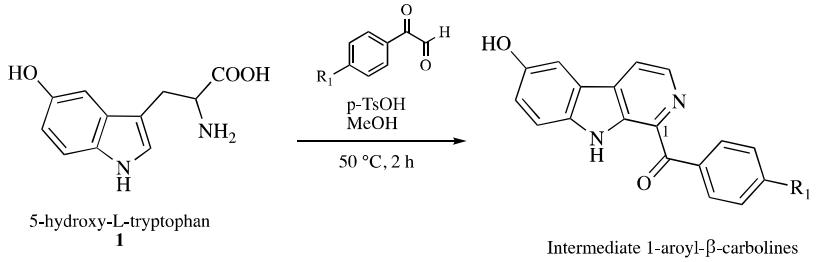
(6-hydroxy-9H-pyrido[3,4-b]indol-1-yl)(4-nitrophenyl)methanone (**2e**). Yield: 60%, brown solid. IR ν cm^{-1}: 3443, 3389cm^{-1}. ^{1}H-NMR (400 MHz, METHANOL-D4) ppm: δ 12.09 (br s, 1H), 9.19 (br s, 1H), 8.51 (d, J = 5.2 Hz, 1H), 8.44 (d, J = 4.4 Hz, 1H), 8.31 (d, J = 7.0 Hz, 1H), 8.15 (d, J = 5.5 Hz, 2H), 7.82 (d, J = 8.0 Hz, 1H), 7.77 (d, J = 5.4 Hz, 2H), 7.60 (t, J = 4.1 Hz). ^{13}CNMR δ (100 MHz, METHANOL-D4): 192.8, 141.9, 137.4, 136.6, 136.0, 133.0, 131.3, 131.2, 129.2, 126.5, 122.0, 120.4, 120.2, 119.3, 113.2.

10-hydroxy-4-phenyl-6H-indolo[3,2,1-de][1,5]naphthyridin-6-one (**3a**). Yield: 30%, light yellow solid. IR ν cm^{-1}: 3364.7, 3046.1, 1671.2, 1646.3, 1629.9, 686.6, 709.5 cm^{-1}. ^{1}H-NMR (400 MHz, METHANOL-D4) ppm: δ 8.60 (1H, d, J = 5.0 Hz, HCN), 8.31 (2H, dd, J = 8.5, 1.6 Hz, CH), 8.11 (1H, d, J = 5.5 Hz, CH), 7.91 (1H, d, J = 2.3 Hz, CH), 7.61-7.50 (5H, m, CH), 7.34-7.32 (1H, m, CH). ^{13}CNMR δ (100 MHz, METHANOL-D4): 118.8, 145.3, 132.5, 123.4, 114.5, 112.6, 128.1, 131.3, 138.1, 210.0.

10-hydroxy-4-(4-hydroxyphenyl)-6H-indolo[3,2,1-de][1,5]naphthyridin-6-one (**3b**). Yield: 16%, light brown solid. IR ν cm^{-1}: 3364.7, 3046.1, 1671.2, 1646.3, 1629.9, 686.6, 709.5 cm^{-1}. ^{1}H-NMR (400 MHz, METHANOL-D4) ppm: δ 8.60 (1H, d, J = 5.0 Hz, HCN), 8.31 (2H, dd, J = 8.5, 1.6 Hz, CH), 8.11 (1H, d, J = 5.5 Hz, CH), 7.91 (1H, d, J = 2.3 Hz, CH), 7.61-7.50 (5H, m, CH), 7.34-7.32 (1H, m, CH). ^{13}CNMR δ (100 MHz, METHANOL-D4): 118.8, 145.3, 132.5, 123.4, 114.5, 112.6, 128.1, 131.3, 138.1, 210.0.

10-hydroxy-4-(4-methoxyphenyl)-6H-indolo[3,2,1-de][1,5]naphthyridin-6-one (**3c**). Yield: 23%, brown solid. IR ν cm^{-1}: 3364.7, 3046.1, 1671.2, 1646.3, 1629.9, 686.6, 709.5 cm^{-1}. ^{1}H-NMR (400 MHz, METHANOL-D4) ppm: δ 8.60 (1H, d, J = 5.0 Hz, HCN), 8.31 (2H, dd, J = 8.5, 1.6 Hz, CH), 8.11 (1H, d, J = 5.5 Hz, CH), 7.91 (1H, d, J = 2.3 Hz, CH), 7.61-7.50 (5H, m, CH), 7.34-7.32 (1H, m, CH). ^{13}CNMR δ (100 MHz, METHANOL-D4): 118.8, 145.3, 132.5, 123.4, 114.5, 112.6, 128.1, 131.3, 138.1, 210.0.

10-hydroxy-4-(4-bromophenyl)-6H-indolo[3,2,1-de][1,5]naphthyridin-6-one (**3d**). Yield: 34%, brown solid. IR ν cm^{-1}: 3443, 3389cm^{-1}. ^{1}H-NMR (400 MHz, METHANOL-D4) ppm: δ 12.09 (br s, 1H), 9.19 (br s, 1H), 8.51 (d, J = 5.2 Hz, 1H), 8.44 (d, J = 4.4 Hz, 1H), 8.31 (d, J = 7.0 Hz, 1H), 8.15 (d, J = 5.5 Hz, 2H), 7.82 (d, J = 8.0 Hz, 1H), 7.77 (d, J = 5.4 Hz, 2H), 7.60 (t, J = 4.1 Hz). ^{13}CNMR δ (100 MHz, METHANOL-D4): 192.8, 141.9, 137.4, 136.6, 136.0, 133.0, 131.3, 131.2, 129.2, 126.5, 122.0, 120.4, 120.2, 119.3, 113.2.

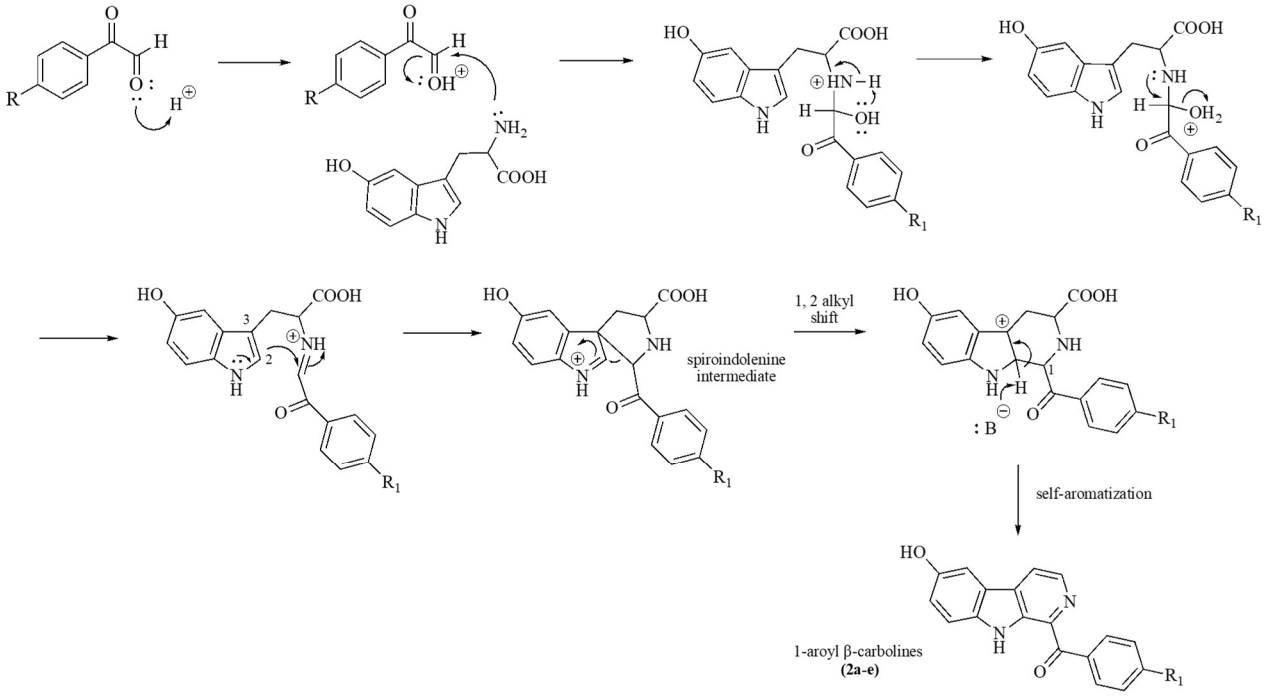


10-hydroxy-4-(4-nitrophenyl)-6H-indolo[3,2,1-de][1,5]naphthyridin-6-one (**3e**). Yield: 41%, brown solid. IR ν cm^{-1}: 3364.7, 3046.1, 1671.2, 1646.3, 1629.9, 686.6, 709.5 cm^{-1}. ^{1}H-NMR (400 MHz, METHANOL-D4) ppm: δ 8.60 (1H, d, J = 5.0 Hz, HCN), 8.31 (2H, dd, J = 8.5, 1.6 Hz, CH), 8.11 (1H, d, J = 5.5 Hz, CH), 7.91 (1H, d, J = 2.3 Hz, CH), 7.61-7.50 (5H, m, CH), 7.34-7.32 (1H, m, CH). ^{13}CNMR δ (100 MHz, METHANOL-D4): 118.8, 145.3, 132.5, 123.4, 114.5, 112.6, 128.1, 131.3, 138.1, 210.0.

The Pictet-Spengler reaction is indeed a valuable chemical transformation for the synthesis of β-carboline ring systems, and it is particularly useful when the starting materials are tryptophan or tryptophan

derivatives. This reaction involves the process of acid-catalyzed condensation of β-carboline with an aldehyde, a ketone or a glyoxal, resulting in the formation of a C-C bond and a series of analogues with a β-carboline ring system. This method has been widely used by chemists in producing new canthine derivatives. Subsequently, it continues with endo cyclization reaction between a carbon nucleophile of a sufficiently reactive aromatic moiety and an activated iminium ion resulting in formation of N-heterocyclic ring through a new C-C bond that directly forms tetrahydro-β-carboline. The tetrahydro-β-carboline (THβC) continues to undergo aromatization to form fully aromatic β-carboline [11,12]. It is important to note that the approach continues to be a prominent topic of research as chemists continue to improve the methodology by applying new reaction conditions. Several groups have been investigating the detailed mechanistic features of this reaction over the years [13].

Meanwhile, in our study, by performing the versatile route of Pictet-Spengler reaction where p-TsOH.H_2O was used as catalyst and methanol was used a medium, this simple method produces a fully aromatic β-carboline instead of the tetrahydro β-carboline. Two reactions were performed to convert intermediate 1-aroyl β-carbolines into 4-aryl substituted canthin-6-ones. In this study, a useful approach for the preparation of 1-aroyl β-carboline derivatives via acid-mediated coupling of 5-hydroxy-L-tryptophan and substituted phenylglyoxal's was described. As a result, the conversion of 5-hydroxy-L-tryptophan and phenylglyoxals directly to 1-substituted β-carboline in the presence of acid via a single step Pictet-Spengler reaction. This strategy refines the scope of Pictet-Spengler cyclization as the THβC intermediate directly oxidized to the targeted β-carboline in one-pot oxidation reaction, which also allows for product diversification at C-1 position.



Scheme 1. The synthesis of 5-hydroxy-L-tryptophan with different substituted phenylglyoxals

Entry	R_1	Yield (%)

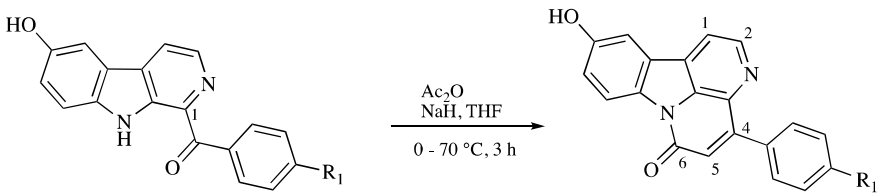
2e	NO_2	65

This approach is concise and most preferred due to its simplicity since no heat is involved to drive the reaction. Based on the results obtained, a general conclusion on the electronic effects of electron-withdrawing group (EWG) and electron-donating (EDG) could be deduced. The inductive and resonance effects cause the yields to vary correspondingly. Having EDG as substituent reduced the electrophilicity of the carbonyl carbon, resulting in a weaker reactivity with the nucleophile and hence, gave lower yield products (**2b** and **2c**) than that of using standard phenylglyoxal (**2a**). On the contrary, phenylglyoxal bearing electron-withdrawing group (**2d** and **2e**) gave higher product as anticipated. Despite being to an inductive electron-withdrawing group, halogens are activators since their ability to donate electrons to the aromatic ring via resonance is much greater.

The reaction mechanism occurs by the initial formation of iminium ion followed by electrophilic addition at the C-2 position to directly yield the six-membered ring intermediate. However, both carbon-2 and -3 of 5-hydroxy-L-tryptophan are nucleophilic. Therefore, the reaction can also proceed by the attack of carbon-3 to yield a spiroindolenine intermediate that would then undergo a 1,2-alkyl shift to form the product as depicted in Scheme 2. Both mechanisms have been proven to be true, yet the prevailing mechanism is still unknown [14].



Scheme 2. Mechanism of Pictet-Spengler reaction with electrophilic addition using phenylglyoxal at carbon-3

Having the series of intermediates 1-aroyl β-carbolines (**2a-e**), the synthesis of 4-aryl substituted canthin-6-ones was performed through the cyclization in dry reaction condition for 3 hours as shown in Scheme 3. The use of sodium offers the advantage of the reaction being carried out in a nonhydrolytic solvent. It was thought that the use of sodium hydride would offer similar advantage and simultaneously would be safer and easier to handle than using the metal. The intermediate compounds (**2a-e**) were reacted with acetic anhydride in the base by using THF as the medium to get the desired target compounds in lower yields.

The synthesis of compounds (**3a-e**) was achieved by intramolecular nucleophilic substitution. The reaction mechanism begins by addition reaction whereby the nucleophilic amine of the intermediate compound attacked the acetic anhydride to form new C-C bond. Accordingly, a series of proton transfers, electron movement and intramolecular cyclization led to the formation of an Aldol intermediate via enolate ion formation. A more stable enone form of the anticipated product was eventually obtained by elimination of water.

Scheme 4. Mechanism of Pictet-Spengler reaction with electrophilic addition using phenylglyoxal at carbon-3

Dighe et al. [6], had successfully discovered an effective iodine-mediated oxidative Pictet-Spengler reaction in DMSO using terminal alkynes as a substitute the glyoxal to produce an intermediate of 1-aroyl-β-carboline, then it underwent cyclization to yield 4-aryl substituted canthin-6-ones. Shashikant et al. [15] their

investigations by reacting 1 with phenylacetylene in the presence of 50 mol of iodine in DMSO as the medium at 100℃ for 6 hours to yield **2a-e**. They continued their study and discovered that reacting of substituted 1-aroyl β-carbolines **2a-e** with Ac_2O in the presence of NaH as the base in THF at 70℃ for 12 hours produced the desired products in a good yield of **3a-e** in 83%. However, by employing the same procedure, we only managed to get the 4-aryl substituted canthin-6-ones in much lower yields (15-41%). This is due to the substituents on C-1 which influences the reactivity of the nucleophilic substitution in both reactions. The reaction time also affects the product yields.

Conclusion

In conclusion, we have successfully synthesized a series of 4-aryl substituted canthine-6-one derivatives through a versatile Pictet-Spengler condensation from 5-hydroxy tryptophan and subsequent cyclization using NaH, involving the formation of 1-aroyl β-carbolines as pivotal intermediates in moderate yields. This alternative is an improved Pictet-Spengler reaction in producing 1-substituted β-carboline in which tetrahydro-β-carboline. Further application of the scope and mechanism of reaction in the study towards total synthesis of novel canthine-6-one and other additional biologically active natural products are currently in progress.

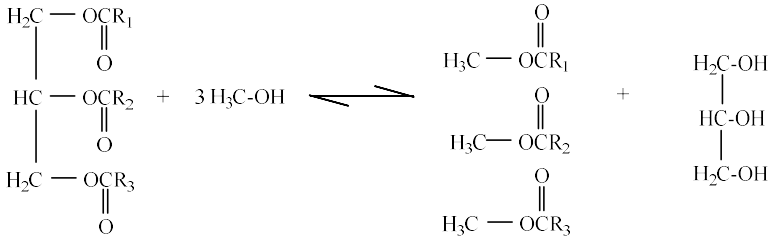
Abstract

In this study, spent bleaching clay doped with potassium hydroxide and sodium hydroxide (SBC/KOH and SBC/NaOH) were used as catalysts in the transesterification process of low-grade cooking oil to produce biodiesel. The physicochemical properties of the catalyst were studied using Fourier Transform Infrared Spectroscopy (FTIR), Thermogravimetric Analysis (TGA), X-ray Diffraction (XRD), Brunauer-Emmett-Teller (BET), and Field Emission Scanning Electron microscopy with Energy Dispersive X-ray Spectroscopy (FESEM-EDX). Several parameters including the types of catalyst, calcination temperature of the catalyst, catalyst dosage, ratio of oil to methanol, reaction time, and reaction temperature were used to determine the optimal conditions for the transesterification reaction. According to the experimental findings, the catalyst effectively converted free fatty acids (FFA) into fatty acid methyl esters (FAMEs). The maximum biodiesel yield of 47.66 % was obtained at optimum reaction conditions: catalyst amount 2 wt.% of SBE/KOH calcined at 500 °C (SBC/KOH 500), reaction time 2 h, reaction temperature 55 °C and oil to methanol molar ratio 1:20.

Keywords: clay, cooking oil, biodiesel, transesterification, catalyst

Abstrak

Dalam kajian ini, tanah liat peluntur bekas yang didop dengan kalium hidroksida dan natrium hidroksida (SBC/KOH dan SBC/NaOH) digunakan sebagai mangkin dalam proses transesterifikasi minyak masak gred rendah untuk menghasilkan biodiesel. Sifat fizikokimia mangkin dikaji menggunakan spektroskopi inframerah transformasi Fourier (FTIR), analisis termogravimetrik (TGA), pembelauan sinar-X (XRD), Brunauer-Emmett-Teller (BET), dan mikroskop elektron pengimbasan pancaran medan dengan serakan tenaga sinar-X (FESEM-EDX). Beberapa parameter termasuk jenis mangkin, suhu pengkalsinan mangkin, dos mangkin, nisbah minyak kepada metanol, masa tindak balas, dan suhu tindak balas telah digunakan untuk menentukan keadaan



optimum bagi tindak balas transesterifikasi. Menurut penemuan eksperimen, mangkin secara berkesan menukar asid lemak bebas (FFA) kepada asid lemak metil ester (FAMEs). Hasil biodiesel maksimum sebanyak 47.66 % diperoleh pada keadaan tindak balas optimum: jumlah mangkin 2 wt.% SBE/KOH dikalsinkan pada 500 °C (SBC/KOH 500), masa tindak balas 2 jam, suhu tindak balas 55 °C dan minyak kepada metanol nisbah molar 1:20.

Kata kunci: tanah liat, minyak masak, biodiesel, transesterifikasi, mangkin

Introduction

The search for alternative fuels has gotten a lot of attention recently due to environmental concerns about the increasing uncertainty of global energy supply and production, the high price of petroleum products, and the usage of fossil fuels. Biodiesel has recently acquired appeal in both developed and developing countries' marketplaces. Biodiesel is made from vegetable oil or animal fat, which is derived from monoalkyl esters from long-chain fatty acids [1]. Biodiesel is becoming more popular as an alternative fuel due to its appealing chemical properties, such as biodegradability, non-toxicity, and carbon neutrality [2]. Biodiesel has a lot of the same qualities as petrodiesel, but it's free of harmful components like sulfur and aromatics. Diesel and biodiesel are both fuels used in internal combustion engines, but they have significant differences in terms of their origin, composition, production, and environmental impact .Biodiesel produces less NOx gases and emissions less than petrodiesel. Furthermore, biodiesel helps to reduce pollution and may reduce the effects of global warming. In comparison to petrodiesel, it is less toxic and easy to store [3]. However, there are a few disadvantages to using petrodiesel. Petrodiesel may contain a tremendous degree of pollutants and greenhouse gas (GHG) emissions, which could negatively affect individual well-being and the environment. Studies have shown that petrodiesel may emit dangerous contaminants. such as nitrogen oxide (NO), carbon monoxide (CO), sulfur dioxide (SO_2), particulate matter, and hydrocarbons [4].

Vegetable oils and animal fats must require severe transesterification to reduce oil viscosity and prevent serious damage to biodiesel. Transesterification of animal fats and vegetable oils with presence of alcohol and a catalyst produces biodiesel, a popular alternative fuel. Methanolysis, also known as transesterification, is a catalyzed reaction that produces biodiesel and glycerol. The reaction causes short-chain alcohol to replace the glycerol in the triglycerides. The process begins with three reversible processes that convert triglycerides to diglycerides, to monoglycerides, and to glycerol. From a single triglyceride molecule, each step produces an ester, giving three ester molecules [5]. The reaction is shown in scheme 1.

Triglyceride Methanol Methyl ester Glycerol

Scheme 1. Methanolysis reaction of triglyceride

In this study, heterogeneous base catalyst, potassium hydroxide (KOH), and sodium hydroxide (NaOH) were studied because it produces high biodiesel yield, high glycerol purity, low cost, and are environmentally friendly [6]. Furthermore, the heterogeneous catalyst has a larger surface area than the homogeneous catalyst. Low-grade cooking oil was selected as a feedstock due to its low viscosity and easy to obtain and spent bleaching clay (SBC) was used as a supporting catalyst.

SBC is a type of industrial waste produced by bleaching of crude palm oil in the vegetable oil refining sector [7].

SBC undergoes refining process in the palm oil industry before it is used for other purposes. SBC output is estimated to be between 1.6 and 2.0 million tonnes per year, based on oil production of 128.2 million metric tonnes in 2007 [8]. Moreover, SBC includes 20–40 % colored pigments, fat, and oil by weight, and it contains MgO, which could be used as a catalyst to speed up the production of biodiesel. Therefore, this study aims to produce biodiesel from low grade cooking oil with a highly efficient SBC nanocatalyst. Various analytical technologies were used to characterize catalysts and analyse products.

Materials and Methods

Chemicals and materials

SBC was collected from PGEO Edible Oils, Perai, Penang and low-grade cooking oil was purchased from the nearest shop. All the analytical grade chemicals (KOH, NaOH, methanol, n-hexane) were purchased from Merck.

Catalyst preparation

SBC was dried at 65 ℃ overnight in an oven before it was used for further experiments. SBC doped KOH and NaOH (SBC/KOH and SBC/NaOH) were synthesized via wet impregnation method. About 8g of calcined SBC, 8g KOH, and 120 mL deionized water were mixed and placed in a 250 mL beaker, heated at 70 ℃ for 3 hours with constant stirring. The obtained mixture was filter using filter paper and dried at 65 ℃ in an oven overnight. Next, it was ground and heated to 600 ℃ for 2 hours at a rate of 5 ℃/min in a furnace with a flow of nitrogen [9]. The same procedure was repeated with SBC/NaOH catalyst using 8g of NaOH instead of 8g of KOH during the impregnation process.

Transesterification process and identification of biodiesel products

About 0.2g of catalyst and 1:20 molar ratio of oil to methanol was added to 10g of oil. The catalyst was activated by dispersing methanol at 50 ℃ for 20 min at constant stirring. The reflux process was conducted at 55 ℃ with continuous stirring for 2 hours [10]. Once the transesterification process was completed, the product was cooled down and filtered with filter paper to separate the catalyst. The filtered liquids were placed in the separatory funnel and left overnight. After overnight, the liquids would be separated and formed into 2 layers. The lower layer was removed, and the upper layer was taken to separate the biodiesel from excess methanol and by-product. The extraction of biodiesel was conducted using Heidolph Hei-VAP rotavapor at 40 ℃ with 80 rpm. The biodiesel liquid was obtained, and by using Equation 1 below, the weight percent of FAME was calculated.

$$\text{Weight percent of FAME} = \frac{\text{Weight of transesterified liquid}}{\text{Weight of low-grade cooking oil used}} \times 100\ \% \quad (1)$$

Optimization parameters

This study was investigated with different parameters such as the effect on the type of catalyst (SBC/KOH and SBC/NaOH), calcination temperature (500 and 600 °C), catalyst dosage (1-4 wt.%), ratio of oil-to-methanol (1:12-1:20) and reaction time (1-3 hours) to predict the optimized condition for transesterification reaction. The range of each parameter was determined from previous studies [11, 12].

Characterization methods

The catalysts were characterized using several characterization methods such as Fourier-transform infrared spectrometer (FTIR), thermogravimetric analysis (TGA), X-ray diffraction (XRD), field-emission scanning electron microscopy with energy dispersive X-ray (FESEM-EDX) and Brunauer-Emmett-Teller (BET) to study the physical and chemical properties of the catalyst. The cooking oil and biodiesel were tested using Fourier-transform infrared spectrometer (FTIR) and gas chromatography with flame ion detector (GC-FID).

Results and Discussion

Characterization of catalysts

The functional groups on the surface of the catalysts were identified using FTIR spectrometer. Figure 1 shows the FTIR spectrum of pure SBC and SBC/KOH 500 catalysts. According to Cong et al. for pure SBC catalyst, there is a peak at 464 cm^{-1}

which indicates the bending vibration of Si-O-Si, while the peak at 1656 cm^{-1} refers to the stretching vibration of S=O [13]. The S=O bond was observed in SBC due to phyllosilicates group components presence in bleaching material of SBC [14]. Furthermore, the band at 3485 cm^{-1} for the SBC/KOH 500 corresponds to Si-O-H stretching vibration due to a water molecule absorbed on its surface [13]. In SBC/KOH 500 catalyst, S=O vibration can also be seen at around 1410 cm^{-1}.

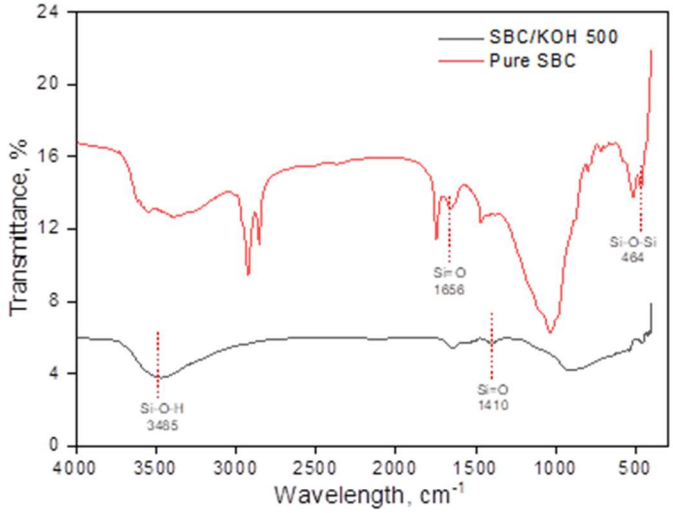


Figure 1. FTIR spectrum of pure SBC and SBC/KOH 500 catalysts

The TGA curve was obtained using thermogravimetric (TG) and derivative thermogravimetric (DTG) analysis. The weight loss curve for SBC was produced and examined using the TGA technique. The weight of SBC drops rapidly from 220 °C to 380 °C, which is due to volatile matter evaporation [13]. The second-phase weight loss indicates that the adsorbed oil on the bleaching clay contributes about 40% of the total weight. Figure 2 shows the DTG pattern in the black line suggests that peak weight loss is observed at 350 °C under an O_2 atmosphere.

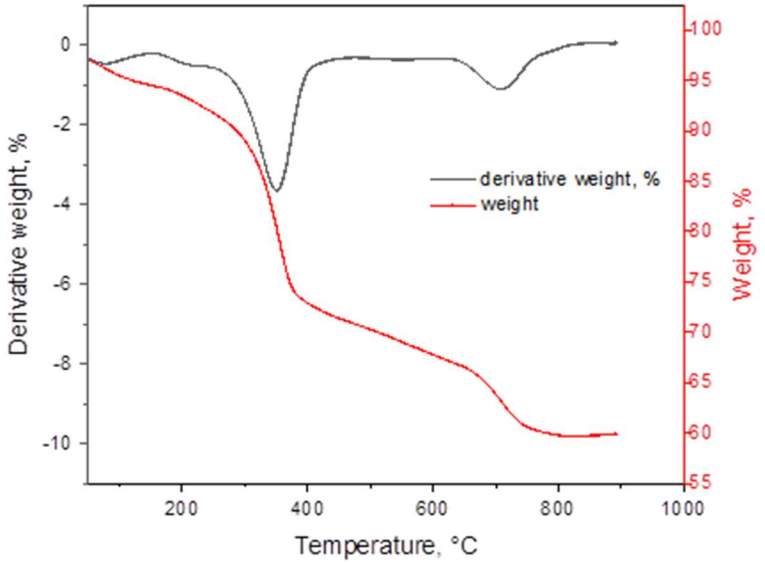

Figure 2. TGA profile of SBC as catalyst

The surface morphology and elemental compositions of the SBC/KOH 500 catalyst were identified using FESEM and EDX spectroscope. Figure 3 shows the micrograms of the SBC/KOH 500 catalyst in two different magnifications. Based on Figure 3, SBC/KOH 500 catalyst was found to have non-uniform irregular agglomerated flaky-like structures. This can be due to the calcination process, which affects the surface texture and increases the surface area for catalytic activity [11].

Next, EDX analysis was used to predict the elemental composition of the SBC/KOH 500 catalyst. The analysis result is shown in Table 1. The result proved that all elements such as K, Fe, Ca, Mg, Na, Al, and Si exist in the clay. Based on the BET analysis, SBC/KOH 500 catalyst has a higher surface area due to the higher composition of K in the catalyst (15.7 wt.%). The catalytic site for reaction increases with surface area, enhancing the productivity of the catalyst.

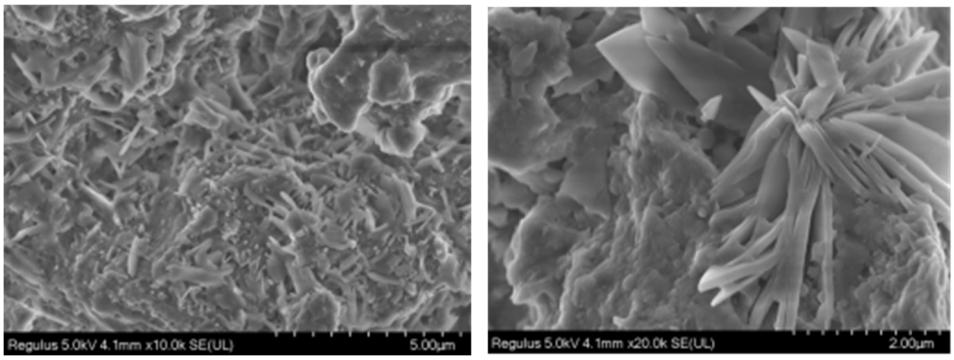

Figure 3. FESEM micrograms of SBC/KOH 500 catalyst: (i: small magnification (10k); ii: big magnification (20k))

Table 1. Elemental compositions of SBC/KOH 500 catalyst by EDX analysis

Elements	**O**	**Si**	**Al**	**Mg**	**Na**	**Fe**	**Ca**	**K**
Loading, wt.%	42.7	7.4	2.9	1.6	0.1	0.58	4.8	15.7

The XRD analysis of the SBC/KOH 500 catalyst is shown in Figure 4. The XRD pattern of SBC/KOH 500 represented the crystalline phases of quartz (SiO_2) and potassium peroxide (K_2O) [15]. The characteristic diffraction peaks for quartz (SiO_2) were found at 2θ= 20.87and 39.48° while the diffraction peaks for K_2O were observed at 2θ = 26.65, 29.46, and 36.07°. This result shows that the main component of the SBC/KOH 500 catalyst was K_2O with a small contribution from SiO_2.

The surface area, pore volume, and pore width of the catalysts were determined using BET analysis. The BET results for SBC, SBC/KOH, and SBC/NaOH catalysts were tabulated in Table 2. The surface area, pore volume, and pore width obtained for SBC/KOH catalyst were 22.62 m^2/g, 0.10 cm^3/g, and 21.05 nm, respectively. The surface area of SBC/NaOH is smaller than SBC/KOH. The higher surface area of the SBC/KOH catalyst is caused by the presence of more active sites [16]. The pore size distribution of both catalysts is represented in Figure 5.

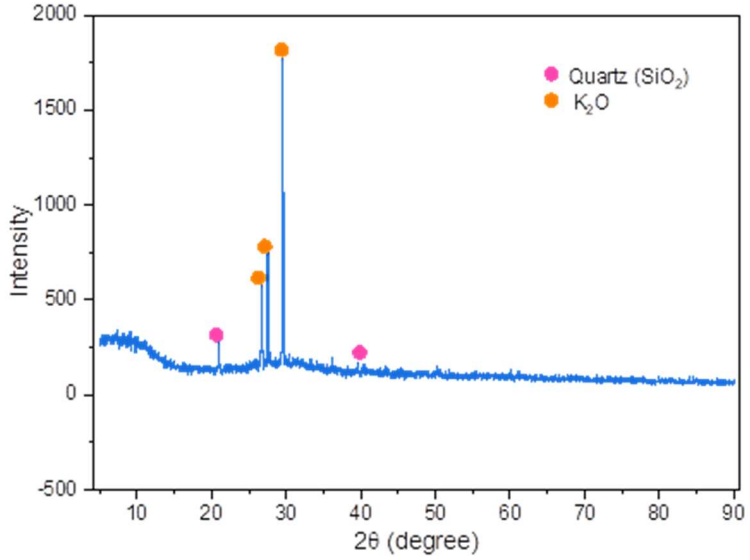

Figure 4. XRD diffractograms of SBC/KOH 500 catalyst

Table 2. Surface areas, pore volume, and pore width of the catalysts

Catalysts	BET Surface Area (m^2/g)	Pore Volume (cm^3/g)	Pore Width (nm)
SBC	3.77	0.02	21.60
SBC/KOH	22.62	0.10	21.05
SBC/NaOH	8.88	0.05	26.27

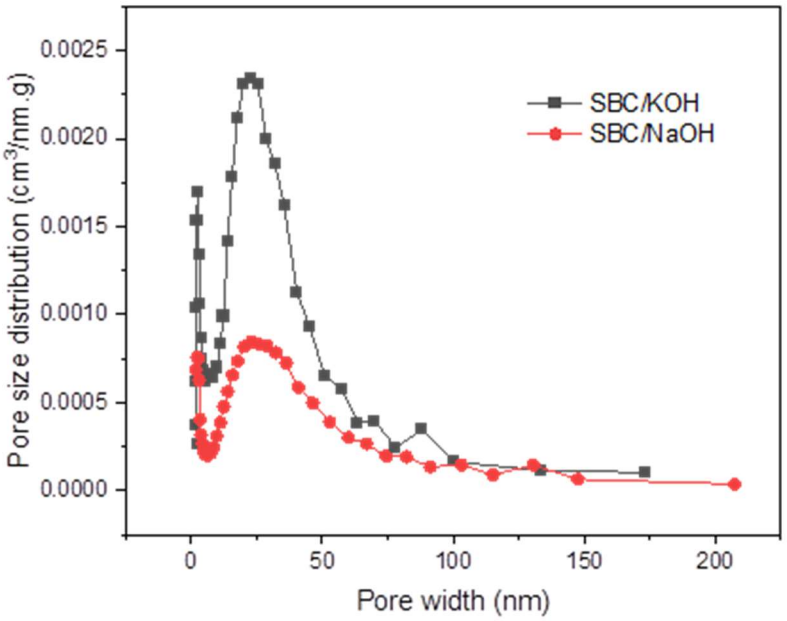

Figure 5. Pore size distribution plot of SBC/KOH and SBC/NaOH catalysts

Characterization of oil and biodiesel

Figure 6 shows the FTIR spectra of low-grade cooking oil and biodiesel produced from the SBC/KOH 500 catalyst. The stretching vibration at 1748 cm^{-1} in the FTIR spectrum indicates the presence of the C=O bond [17]. This group indicates that carbonyl functional groups are present in the oil and biodiesel. The characteristic peaks found in the region 2912 cm^{-1} and 2849 cm^{-1} indicate stretching vibrations of CH_3 and CH_2 while bending vibrations of CH_3 and CH_2 groups were found at the peak 1375 cm^{-1} and 1164 cm^{-1} respectively. The FTIR spectrum of synthesized biodiesel was found to be very similar to low-grade cooking oil due to the chemical nature similarities of the methyl esters and triglycerides. Therefore, further analysis by gas chromatography is required to support the results.

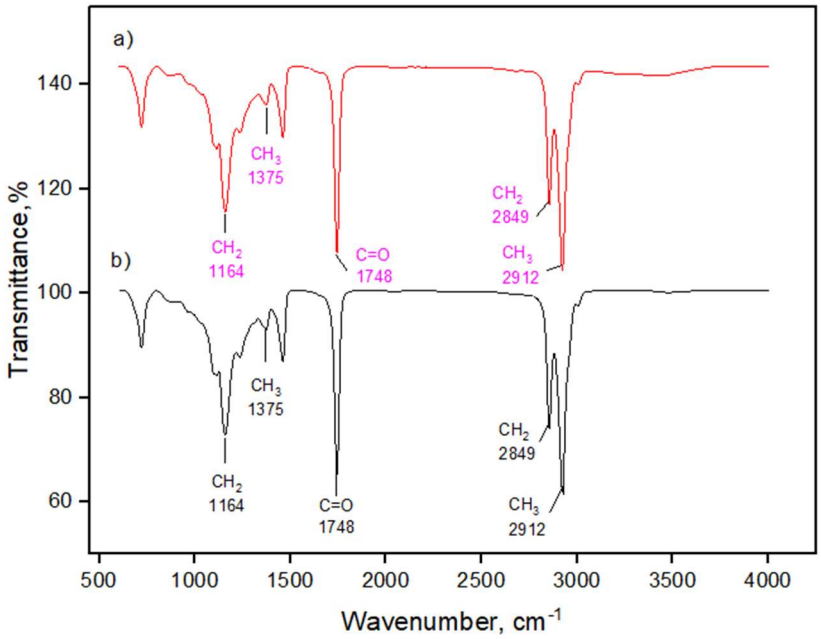

Figure 6. FT-IR spectra of low-grade cooking oil and biodiesel produced from SBC/KOH 500 catalyst

Figure 7 shows the fatty acid methyl ester (FAME) compound present in the biodiesel for SBC/KOH 500 catalyst. As described by Enguilo Gonzaga et al. low-grade cooking oil contains major fatty acids such as palmitic acid (16:0), stearic acid (18:0), oleic acid (18:1), linoleic acid (18:2), and linolenic acid (18:3) [18]. From Figure 7, the identified compounds in biodiesel were methyl myristate, methyl palmitate, methyl heptadecanoate, methyl stearate, methyl oleate and methyl linoleate. The details of the composition are tabulated in Table 3. This data was consistent with the research reported by Roschat et al. regarding the biodiesel production of Krabok seed oil through transesterification reaction using CaO as a catalyst [19]. In comparison, the biodiesel from Krabok seed oil demonstrated the major fatty acid methyl ester, namely methyl decanoate, methyl myristate, methyl palmitate, methyl heptadecanoate, methyl oleate, methyl palmitoleate, methyl stearate and methyl linoleate. The derived biodiesel using SBC/KOH 500 catalyst showed presence of similar fatty acids methyl ester. Therefore, this result shows good agreement with previous research.

Table 3. Fatty acid methyl ester (FAME) compounds present in the sample using gas chromatography with flame ion detector (GC-FID)

Sample	Tr, Retention Time (min)	ID (Peak)	FAME Compound
Biodiesel	4.376	C14:0 (8)	Methyl myristate
	5.726	C16:0 (12)	Methyl palmitate
	6.234	C17:1 (15)	Methyl heptadecanoate
	6.680	C18:0 (16)	Methyl stearate
	6.858	C18:1 (18)	Methyl oleate
	7.852	C18:3 (21)	Methyl linoleate

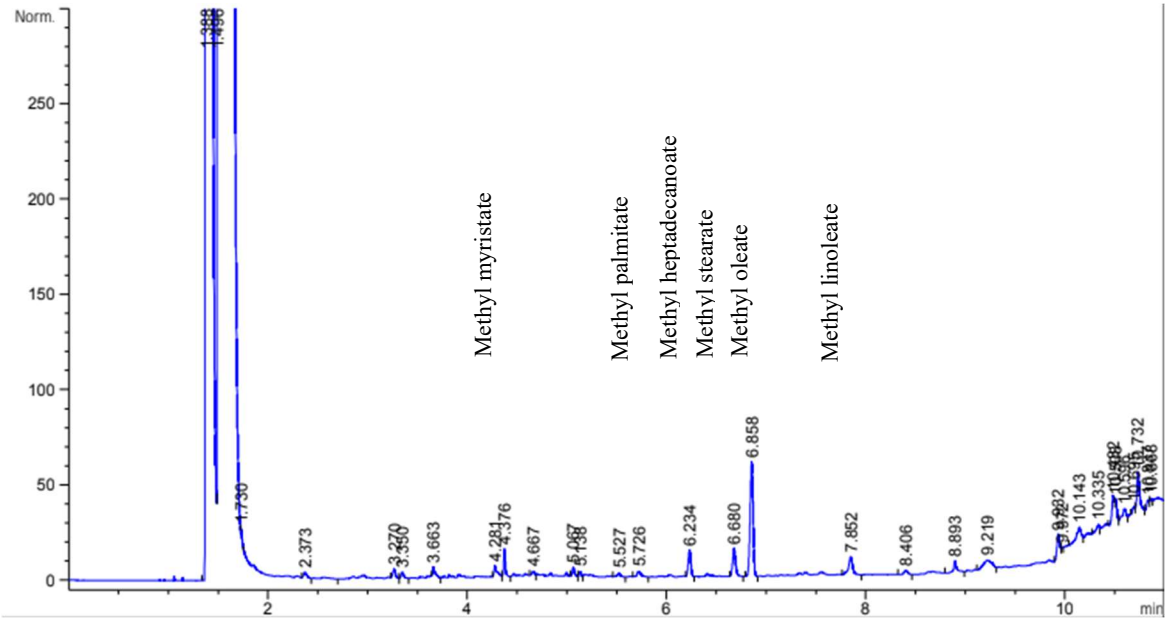

Figure 7. Characterization of biodiesel using gas chromatography using flame ion detector (GC-FID) for SBC/KOH 500 catalyst

Transesterification of low-grade cooking oil into biodiesel

Two different types of SBC catalysts were employed to study the effect of catalysts on the transesterification reaction. Figure 8 illustrates the biodiesel yield percentages obtained using SBC/KOH and SBC/NaOH. Based on the results, it is evident that the SBC/KOH catalyst outperforms the SBC/NaOH for biodiesel production, yielding a higher percentage of biodiesel (39.06%). These observations indicate that the SBC/KOH catalyst exhibits superior performance when compared to the SBC/NaOH catalyst. The high fundamental strength observed is attributed to the K^+ and OH^- pairs [18]. Besides, the higher yield can be attributed to the higher surface area of the catalyst, which provides a higher active site for the reaction. This result agrees with the findings obtained from the BET analysis. Therefore, the SBC/KOH catalyst was selected as the best catalyst for further experiments.

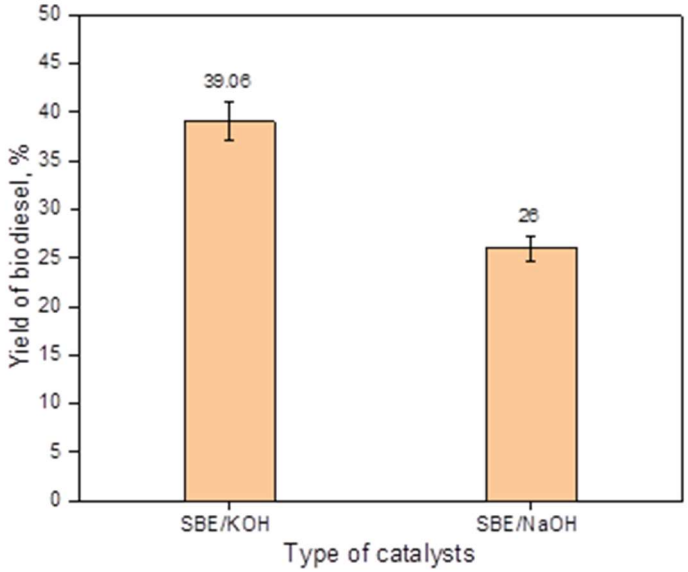

Figure 8. Effect of SBC/KOH and SBC/NaOH catalyst on biodiesel yield

The effect of calcination temperatures, specifically 500°C and 600°C, was studied using SBC/KOH. The selection of this calcination temperature was based on the findings of Cong et al., who reported it as the optimum calcination temperature for achieving high biodiesel production [13]. Hence, low calcination temperatures were chosen for energy conservation and cost reduction [20]. Figure 9 shows that the percentage biodiesel of SBC/KOH 500 and SBC/KOH 600 were found to be 47.66 and 39.06%, respectively. This finding was supported by the XRD pattern in Figure 4. The presence of SiO_2 and K_2O in XRD patterns has been found to increase the surface area of the catalyst [15]. Therefore, it can be concluded that the SBC/KOH catalyst 500 exhibits superior performance compared to the SBC/KOH 600, thereby making it the best catalyst for further experiments.

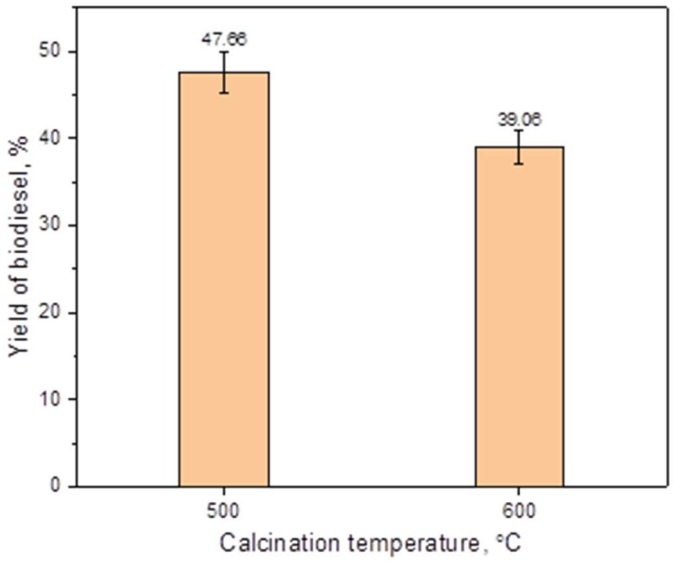

Figure 9. Effect on calcination temperature of SBC/KOH

Figure 10 displays the effect of varying the catalyst loading at 1, 2, and 4 wt.% of SBC/KOH 500. The highest biodiesel recorded was 47.66% when utilizing a catalyst consisting of 2 wt.% of SBC/KOH 500. This finding indicated that the interaction between the reactants and the solid catalyst was limited to a maximum catalyst loading of 2 wt.%, resulting in a discernible effect on the rate of the forward transesterification reaction. However, upon increasing the catalyst loading to 4 wt.%, a decrease in biodiesel production to 16.03% was observed. This is due to mixing inefficiencies resulting from the increased viscosity in the reaction vessels, which is a direct consequence of the increased catalyst concentration [21]. Since the maximum biodiesel yield was obtained when the catalyst loading was 2 wt.%, this value was chosen as the best catalyst loading for further optimization of the remaining reaction parameters.

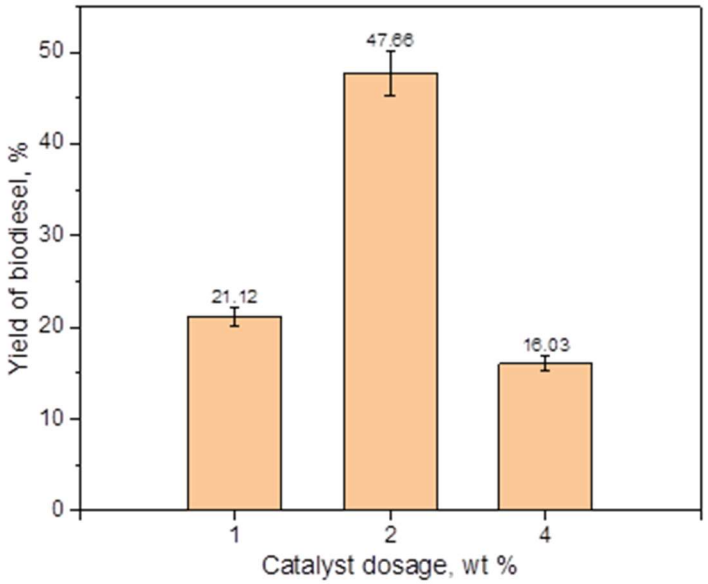

Figure 10. Effect of catalyst dosage on biodiesel yield

The effect of the ratio of oil to methanol from 1:12 to 1:20 was studied in this experiment. Based on the result in Figure 11, the percentage yield of biodiesel for the ratio of 1:12, 1:16, 1:18, and 1:20 were 30, 46.82, 47.14, and 47.66%, respectively. When the ratio of oil-to-methanol increased, the product yield also increased indicating that a large amount of methanol is required to reduce the viscosity of the reaction media and to enable the contact between the two phases [22]. Therefore, the 1:20 ratio of oil to methanol was chosen as the optimal value for the following studies.

The present study examined the effect of reaction time, with the corresponding result shown in Figure 12. The biodiesel production increased from 26.88 to 47.66% as the reaction time was increased from 1 to 2 hours. The likely reason for this observation can be attributed to the presence of the heterogeneous mass transfer system of the catalyst [18]. At 3 hours of reaction time, the biodiesel production decreased to 4.94% due to the backward reaction in the methyl ester, which produces more glycerol than methyl ester [19]. Hence, the reaction time of 2 hours was selected as the optimum time.

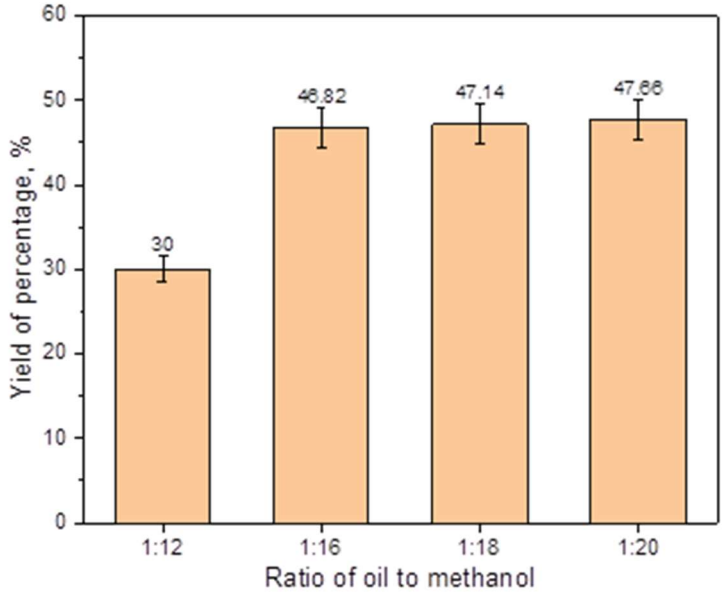

Figure 11. Effect of ratio oil to methanol in transesterification

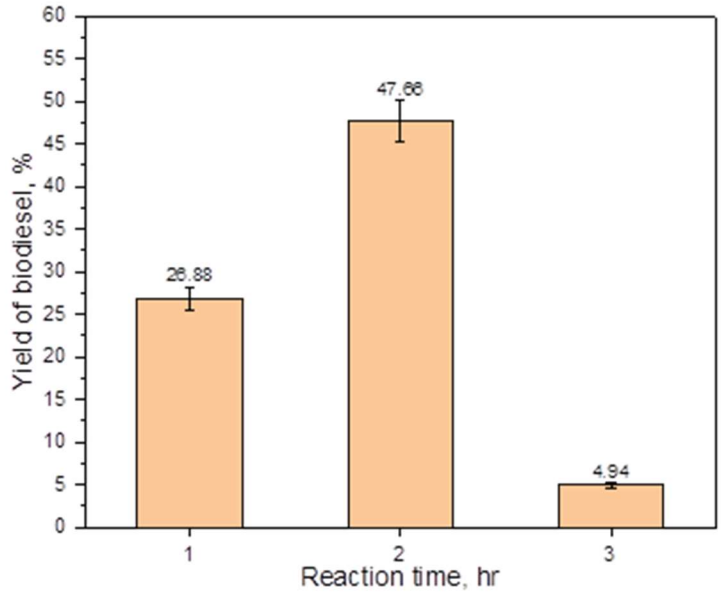

Figure 12. Effect of reaction time on the transesterification process

Conclusion

In this study, the catalytic activity of the SBC/KOH 500 catalyst for the transesterification of cooking oil to FAME was investigated. Based on the result, the SBC/KOH 500 showed the potential as a catalyst in the transesterification process and can be used as an alternative catalyst to produce biodiesel from low-grade cooking oil. The highest yield of biodiesel was 47.66% with transesterification reaction condition of 2 hours reaction time, 1:20 oil to methanol ratio, 2 wt.% catalyst loading, and temperature of 55 °C.

Abstract

Examining the questioned documents can offer essential scientific proof that the documents are authentic. Examining inks and handwriting to establish authenticity, authorship, suspected counterfeiting, and/or modifications are forensic problems that require critical attention. Due to gel pens popularity and widespread usage, their emergence in criminal cases associated with questioned documents are therefore anticipated. A dissolution test by dissolving gel ink into organic solvent can sometimes be used for rapid discrimination of gel ink into either pigment-based or dye-based colourants. However, due to its extremely destructive nature, this test is unfavourable for forensic document examination purposes. The main aim of this study was to develop a model that could be used to determine the nature of colourant in black gel ink without having to perform the destructive dissolution test. To achieve this, black gel pen inks of different brands/models (n = 30) that were procured from 23 different manufacturers from Malaysia, India, and China were initially dissolved in a series of organic solvents, and the nature of their colourants was recorded. Thereafter, their infrared (IR) spectra profiles were acquired using the attenuated total reflectance - Fourier transform infrared (ATR-FTIR) spectroscopy, and then preprocessed prior to feature selection using the principal component analysis (PCA). The selected features were used for the development of a classifier using the linear discriminant analysis (LDA), whereby 98.1% of correct classification was recorded for the cross-validated samples. Furthermore, it signified the potential of this approach for rapid screening of black gel ink without having to perform the destructive dissolution test, which could be utilised by forensic document examiners.

Meneliti dokumen yang dipertikai boleh memberikan bukti saintifik penting bahawa dokumen itu sahih. Memeriksa dakwat dan tulisan tangan untuk menentukan keaslian, kepengarangan, disyaki pemalsuan dan/atau pengubahsuaian adalah masalah forensik yang memerlukan perhatian kritikal. Disebabkan oleh populariti pen dakwat gel dan penggunaannya yang semakin meluas, kemunculan mereka dalam kes jenayah yang berkaitan dengan dokumen yang dipertikai adalah dijangkakan. Ujian pembubaran

dengan melarutkan dakwat gel ke dalam pelarut organik kadangkala boleh digunakan untuk diskriminasi pantas dakwat gel kepada sama ada berasaskan pigmen atau pewarna. Walau bagaimanapun, disebabkan sifatnya yang sangat merosakkan, ujian ini tidak sesuai untuk tujuan pemeriksaan dokumen forensik. Matlamat utama kajian ini adalah untuk membangunkan model yang boleh digunakan untuk menentukan sifat pewarna dalam dakwat gel hitam tanpa perlu melakukan ujian pelarutan yang merosakkan. Untuk mencapai matlamat ini, dakwat pen gel hitam daripada jenama/model berbeza (n = 30) yang diperoleh daripada 23 pengeluar berbeza dari Malaysia, India, dan China, pada mulanya dilarutkan dalam satu siri pelarut organik, dan sifat pewarnanya direkodkan. Berikutan itu, profil spektrum inframerah (IR) mereka diperoleh menggunakan spektroskopi jumlah pemantulan yang dilemahkan - inframerah transformasi Fourier (ATR-FTIR), dan kemudian pra-diproses sebelum pemilihan ciri menggunakan analisis komponen utama (PCA). Ciri-ciri yang dipilih telah digunakan untuk pembangunan pengelas menggunakan analisis diskriminasi linear (LDA), di mana 98.1% pengelasan yang betul telah direkodkan untuk sampel-sampel yang disahkan silang, yang menandakan potensi pendekatan ini untuk pemeriksaan pantas dakwat gel hitam tanpa perlu melakukan ujian pelarutan yang merosakkan, yang boleh digunakan oleh pemeriksa dokumen forensik.

Kata kunci: dakwat gel hitam, sains forensik, dokumen yang dipersoalkan, spektroskopi inframerah jumlah pemantulan yang dilemahkan, analisis komponen utama

Introduction

Nowadays, increase in document forgery activities and fight against these illegal activities causes serious problems and negatively affects individuals, including the private and government institutions [1]. Any documents related to criminal cases that are doubtful of authenticity and authorship, are known as questioned documents [2]. It also refers to any objects bearing handwriting, typed, and printed materials. Document examination offers a great deal of interest in the forensic document examiners' community. It includes examining of the ink written on documents, signatures and handwriting, and determining the age of the ink written on paper [3]. The commonality for forensic document examiners is to test for document alteration and defacement, distinguishing between inks with identical impressions, and determining whether the provenance of the two ink samples is either identical or otherwise [4]. All of these processes require ink analysis, which serves to discover the authenticity of documents [5]. The chemistry of ink is determined by its composition, which is different for each brand/model. Nonetheless, the existence of colours, pigments, solvents, and additives in ink recipes aids forensic document examiners in the discrimination, and classification of confiscated pens in actual cases [6].

There are several types of writing instruments used in a document, such as roller ball pens, ballpoint pens, fountain pens, and gel pens. However, gel pens are popular writing material due to their smooth and interesting writing appearance [2]. Due to this, the usage of gel pens in documents is increasing. The history of the gel pen began in 1984, whereby the Japanese Sakura Colour Products Corporation introduced the first gel pen, a type of writing instrument that used a rolling ball mechanism to transfer ink from the reservoir to paper [7]. Gel ink often contains colouring ingredients, such as dyes and pigment, a water-based solvent as a vehicle or carrier, and additional additives, such as plasticisers, surfactants, waxes, and driers to enhance its writing performance and appearance [8]. The uniqueness of each manufacturer is the type of colourant used, and the quality and quantity of additives, such as surface activators, fluorescent material, solubilisers, preservatives, and anti-corrosion agents added to the ink composition [9]. Dyes and pigments are preferred over other components since they can be seen by the naked eye, making them the most prominent aspects in the ink analysis. This feature enables the examiners to make a quick decision, and straightforward comparisons between the various inks, which is helpful for the initial assessment of an ink analysis.

The subjective judgement of forensic document examiners regarding ink analysis has somewhat diminished due to the advancement of analytical techniques. The latter technique is gaining popularity because other than being straightforward, it requires no or minimal sample preparation, and most importantly it maintains the integrity of documents [10]. Amongst the methods are the attenuated total reflectance-Fourier transform infrared (ATR-FTIR) spectroscopy [4, 11–15], and surface increase Raman scattering [10, 16–20].

Due to these, the non-destructive method is often preferred over the destructive method for document analysis.

The ATR-FTIR spectroscopy has been proven as an effective tool for ink analysis, which offers a simple tool that can provide qualitative and quantitative information for comparative analysis of ink. Additionally, these methods work in combination with the chemometrics methods, such as the principal component analysis (PCA) [5, 15], [21, 22], linear discriminant analysis (LDA) [14], and partial least square-discriminant analysis (PLS-DA) [4] for discrimination and classification of ink. Consequently, a mixture of statistical and analytical methods has been consistently applied to achieve substantial outcomes in forensic questioned document examination [4]. Despite numerous studies demonstrated a successful combination of ATR-FTIR analysis with chemometrics methods, there was a noticeable research gap that explored the practical significance of these results in effectively distinguishing between different types of inks, as the preliminary stage in ink analysis. This is significant considering that ATR-FTIR offers a non-destructive approach, and has the potential to replace traditional, destructive techniques to discriminate the ink at an early stage.

Chemometrics are mathematical and statistical approaches to chemical data that provide reliable tests for classification, discrimination, or model development for sample datasets [23]. In ink analysis, the main principle of chemometrics is to analyse and examine the data obtained from analytical methods to avoid making an unbiased decision about similarities between the ink samples. Chemometrics have a positive influence on the forensic examination of various inks. It is also a powerful tool when dealing with multi-component systems and allows for extracting maximum information from complicated datasets.

The PCA is a widely used method for pattern recognition in chemometrics. It allows for a large number of datasets, and reduces data dimension by transforming the original set of correlated variables into orthogonal variables, known as the principal components (PCs) [24]. This process is achieved by removing the noise, redundant, and highly correlated data [25]. Each PC is calculated to describe the highest proportion of variance, and most of the information is stored in the first few PCs. The number of useful PCs is less than the number of original variables [26].

The LDA is a well-known method for pattern recognition [15]. Additionally, it is a powerful classification method that applied linear classification structure that can separate a series of samples within different classes based on their spectral features. In LDA, the dimensional embeddings are reduced in a manner that effectively separates orientations of the classes projected data on any given line or space. The maximum ratio of within-class variability to between-class variability in the training set serves as the criterion for determining these vectors.

Prior to analytical analysis, the standard procedure in ink analysis commences with the dissolution test, which serves as a rapid screening technique to differentiate between unidentified ink sources and categorises ink by its colourant composition. This preliminary test was conducted by observing the degree of ink solubility that was deposited on paper after it was submerged in organic solvent. Dye-based ink readily dissolved in the solvent, causing a noticeable change in the solvent colour, whereas the pigment-based ink remained adhere to the paper substrate. A study by Mohammad Asri et al. [16] found that red gel ink dissolved in acetone compared to other organic solvents. This result was also supported by Reed [27] who claimed that acetone and hydrochloric acid were able to dissolve red and blue gel inks, respectively.

This screening test could provide rapid discrimination between unknown ink, but it is not recommended for it could obliterate the document. Therefore, this study proposed the development of a non-destructive screening test protocol based on dissolution test data. Consequently, a screening test was performed on 30 different brands of black gel ink pens to determine the colourant nature of each ink; these inks were then deposited on paper and subjected to non-destructive ATR-FTIR analysis. The ATR-FTIR data mining was

performed using PCA and LDA, and a classification model was developed. The outcome of this study would provide valuable insights of screening test using the non-destructive approach. The developed model could be utilised by forensic document examiners, as a rapid screening tool to identify the nature of colourant in black gel ink without having to perform the destructive dissolution test.

Materials and Methods

Sample collection

Thirty different brands and models of black gel inks were purchased from stationery stores and online. In this study, seven pens from each brand/model were used, totaling 210 samples of black ink. For reference, a code was assigned to each brand or model. The information and IDs used in this study are shown in Table 1.

Dissolution test

In questioned document examination, this test acts as a screening step to distinguish inks that are similar in colour, but with different ink colourant composition [16]. Gel ink colourants were either pigment- or dye-based. While pigment-based ink does not dissolve in organic solvents, dye-based ink does. This test aimed at identifying the colourants used in each ink sample based on their solubility in organic solvents. The results could provide an early insight to discriminate the ink samples into two groups; ink that was soluble in an organic solvent, classified as dye-based ink, whereas ink that was insoluble in organic soluble had pigment-based colourant. This test was adapted from a study by Reed [27] that used a variety of organic solvents to discriminate gel ink samples of red, blue, and black. The solvents used were polar organic solvents, such as methanol and ethanol.

Each ink was scribbled on a 4 mm x 4 mm square on a 70 gsm A4 paper until the entire square was thoroughly inked. After drying at room temperature for 10 min, the square sheet was cut and placed in a glass vial. Thereafter, 2 mL of solvents (methanol and ethanol) were drawn into the sample vial with a pipette, and subsequently stirred vigorously using a vortex mixer for 1 min. After leaving each sample at room temperature for 5 min, the solubility of ink samples in these solvents was observed and recorded. The outcomes of the dissolution test were compared with ATR-FTIR analysis and chemometrics results, which were crucial as they served as a reference point to demonstrate that ATR-FTIR analysis could provide equivalent results. Furthermore, they had the potential to substitute the dissolution test as a screening method for forensic ink analysis.

Infrared (IR) spectral acquisition

In forensic science, problems arose when the reference and unknown samples contained the same type of colourant. Therefore, discrimination of the ink by dissolution test is irrelevant. This could be resolved by using the Fourier transform infrared (FTIR) analysis to separate the ink samples, depending on the functional groups present in each sample. FTIR is preferable as it is a non-destructive analysis and requires no sample preparation. Consequently, the integrity of the document as evidence is maintained. Each absorbance spectrum was collected in the range of 4000 cm^{-1} – 600 cm^{-1} wavelengths using a LUMOS FTIR microscope (Bruker, Germany) equipped with an ATR. The ink line samples were prepared by drawing seven lines with seven gel pens from the same brand/model on a white A4 70 gsm paper. Before the spectra acquisition, all samples were stored in normal laboratory environment. The environmental conditions were maintained the same for all the samples, as they could offer an equal effect of moisture content and other environmental factors [4]. The sample was then placed on the stage under a microscope, and the seven lines drawn from each pen were measured in a low ATR pressure mode with 64 background sample scans at a resolution of 4.0 cm^{1}. In each sample measurement, the background was measured according to the aperture. All collected spectra were baseline corrected using the OPUS 7.5 software connected to the instruments.

Data preprocessing and analysis

The absorption spectrum acquired from the LUMOS FTIR microscope instrument was saved in a *.dpt format and converted into an Excel spreadsheet. The spectral range from this analysis was collected in the range of 4000 cm^{-1} – 600 cm^{-1}. However, for observation purposes and data analysis, the fingerprint region in the range of 1500 cm^{-1} – 600 cm^{-1} was selected, as this region exhibited characteristic peaks for each sample. The data from each spectrum were then preprocesses to normalised dataset. The ATR-FTIR spectra obtained from the ink samples might contain broad, low resolution, and merged peaks. Therefore, the normalised preprocessing of numerical data was necessary to minimise and refine the results [4].

Principal component analysis (PCA)

In this study, the statistical software package, Unscrambler (Version 10.4) 2016 was used to process normalised dataset. The average value from each sample spectrum was inputted to the Unscrambler to run PCA. A score plot was used to display the clustering outcome, as the samples with similar scores were placed close to each other, while those with dissimilar scores were located apart.

Linear discriminant analysis (LDA)

The classification model was built on the normalised FTIR dataset to observe whether all the IR data could be classified according to their colourant nature. The IBM Statistical Package for the Social Sciences, also known as IBM SPSS (Version 26) was used that applied the Fischer's function coefficient algorithm and leave-one-out approach, which is one of the types of cross-validation techniques.

Results and Discussion

Dissolution test

Typically, black gel pen ink contains multiple dye components, or pigments of various hues that are combined proportionally to produce black colour. To ascertain the degree of dissolution of the black gel ink samples, the colour changes in the organic solvents were observed, as the ink was introduced. In this test, 21 black gel inks failed to dissolve effectively, which suggested that they might contain pigments as colourants, whereas nine black gel inks (Codes C, D, E, H, O, U, V, W, and D') dissolved in methanol and ethanol, indicating that they contained dyes. The observation made from this test concurred with a study conducted by Reed [27]. From this test, the ink samples were able to discriminate based on the type of colourant contained in the ink.

Spectral characterization

Figure 1 and Figure 2 show the spectra from dye-based black gel ink and pigment-based black gel ink, respectively. None of the sample's spectra displayed any discriminating peaks between 4000 and 1600 cm^{-1}. The cellulose band presence in the range of 3000 cm^{-1} – 3500 cm^{-1} and 2880 cm^{-1} – 2890 cm^{-1} characterised the C-H and O-H stretching, which was from the paper composition [14]. The fingerprint region from 1500 cm^{-1} – 600 cm^{-1} exhibited the most characteristic peaks of ink [28]. Peaks in the range of 1300 cm^{-1} – 1500 cm^{-1} could be attributed to the vibration of carbon compounds, such as CH-stretching and bending vibrations in the aliphatic and aromatic compounds. Presence of peaks in the range 1550 cm^{-1} – 1610 cm^{-1} was due to nitrogen bonding in azo compounds used in ink. Primary, secondary, and tertiary alcohols appeared in the region of 1600 cm^{-1} – 1000 cm^{-1} with the presence of C-O bond peaks in stretching mode. The region below 1000 cm^{-1} was due to C-H bond in the bending mode that indicated alkenes. Lastly, the epoxy group existed in the region of 800 cm^{-1} – 900 cm^{-1}. It was suspected that this might be due to the source of additives in the gel pen ink composition. Based on the spectra observations, there were no discernible differences between the dye-based ink and pigment-based ink samples. Unfortunately, this observation was unsuccessful in distinguishing against all the black ink samples. These findings were supported by Reed [27], as visual discrimination of the spectra based on the presence or absence of peaks, and their intensities were challenging and difficult.

Principal component analysis (PCA)

The score plot of normalised dataset is reported in Figure 3, showing visual pattern recognition of normalised dataset plotted using the first two principal components, namely PC1 and PC2. The first two PCs explained 89% (PC1 75% and PC2 14%) of the total variance. A close observation of this score plot clearly showed two well-separated clusters corresponding to the dye-based groups (Group I) and pigment-based group (Group II), which were in line with the results obtained from the dissolution test. The score plot separated Group I mostly as negative value, while most of Group II as positive value at PC1. The PCA could discriminate these samples based on their colourant types. Additionally, it clearly demonstrated the link between the samples (Code D and Code E) and (Code V and Code W), which originated from the same brand located near each other under the same cluster (Group I), as they had similar ink formulation. In contrast, samples (Code F and Code G) and (Code J, Code K, and Code L) in cluster Group II were separated despite belonging to the same brand. This trend might be impacted by the presence of additive ingredients in the ink to enhance their appearance and writing performance. Code R and Code X were pigment-based ink, but their positions were distant from the cluster, suggesting that they might not be gel ink. As observed, a small number of Group II samples overlapped with each other, indicating that the samples from different brands might have varying proportions, but with similar ink compositions. Gawad et al. [29] achieved 100% discrimination power for ink

differentiation amongst 33 pens by integrating ATR-FTIR data with PCA. Qureshi et al. [6] also applied PCA with pre-treated ATR-FTIR spectral data for discrimination of local and foreign ballpoint inks. The PCA scatter plot exhibited a cumulative variance of 97% of the first two principal components. PCA with ATR-FTIR data demonstrated a significant contribution of non-destructive approaches, as useful tool for ink discrimination.

Linear discriminant analysis (LDA)

The Wilks' Lambda measures how well each function separates cases into groups. It is equal to the proportion of the total variance in the discriminant scores that are not explained by differences amongst the groups. It shows whether these two groups (dye and pigment) differ significantly based on their means value on a set of continuous variables, which indicated the significance of the discriminant function. The value ranges from 0 to 1; the smaller the value of Wilks' Lambda indicates the greater discrimination ability of the function. Table 2 shows a high significance function (p<0.05), and provided a small Wilks' Lambda value, which was 0.254 that indicated greater discrimination ability of the function.

Table 2. Wilks' Lambda table from linear discriminant analysis

Test of Function(s)	Wilks' Lambda	Chi-square	df	Sig.
1	.254	201.661	6	.000

The classification in Table 3 reveals the results using the generated discriminant model. Of the original group used to create this model, 43 from 45 dye-based ink samples were classified correctly, and 106 from 107 pigment-based ink were classified correctly. Overall, 98% of the original group cases were classified correctly. On the other hand, the cross-validated group cases that applied leave-out-one approach, however, showed similar discriminating power (98%). Pigment colourants were perfectly classified with a good accuracy (99.1%) than dyed colourants (95.6%). The model validation for 30 unknown samples showed 100% classification. All the unknown samples were correctly assigned into its designated group according to its colourant nature. In the realm of ink analysis, previous studies have yielded promising results through the utilisation of LDA in conjunction with ATR-FTIR spectral data. Specifically, Kher et al. [30] demonstrated that 48.4% of blue ballpoint pens could be accurately classified using this approach. Furthermore, Silva et al. [14] applied LDA with ATR-FTIR data for pen classification, and reported a remarkable outcome, achieving a perfect 100% in their classification model.

These findings underscored the robustness and efficacy of LDA for ink classification.

Table 3. Classification table generated from normalized dataset of black gel ink samples

			Pigment	Dye	Total
Original	Count	Pigment	106	1	107
		Dye	2	43	45
	%	Pigment	99.1	.9	100.0
		Dye	4.4	95.6	100.0
Cross-validated	Count	Pigment	106	1	107
		Dye	2	43	45
	%	Pigment	99.1	.9	100.0
		Dye	4.4	95.6	100.0

a. 98.0% of original grouped cases correctly classified.
b. Cross validation is done only for those cases in the analysis. In cross validation, each case is classified by the functions derived from all cases other than that case.
c. 98.0% of cross-validated grouped cases correctly classified.

Conclusion

The development of classification model to discriminate the black gel ink based on its colourant nature as an alternative destructive screening test holds a significant promise. By applying this model, the screening test of the unknown ink samples could be conducted without damaging or altering the integrity of the sample. Furthermore, ATR-FTIR spectroscopy in combination with chemometrics techniques could be successfully used for the discrimination of ink when it involved large datasets. Additionally, PCA was applied resulting in good clustering of all samples based on the nature of ink colourants. The LDA classification model could quantify the predictive ability for correct classification rate of the gel ink samples by providing higher discrimination rate, which was 98% for both the original and cross-validated group cases.

Abstract

Microplastics (MPs) constitute an emerging class of pollutants that have garnered significant attention due to their omnipresence in marine and freshwater ecosystems. Particles with a diameter of less than 5 mm result from the degradation of larger plastic debris and the production of commercial plastic products. The pervasive occurrence of MPs in the environment is a primary concern due to their potential adverse effects on marine organisms and human health. MPs' high specific surface area and hydrophobicity make them effective adsorbents of other pollutants. Consequently, ingestion of MPs by organisms can lead to enhanced toxicity and bioaccumulation of these pollutants, causing significant harm to the ecosystem. This study offers a comprehensive overview of the properties of MPs, the routes of their entry into the environment, their impacts on environmental and human health, and current approaches for their removal. Physical, chemical, and biological methods for MP removal are discussed, including their benefits and drawbacks. However, there is an urgent need to develop novel, efficient, and cost-effective techniques for MP removal. The insights presented in this review aim to guide policymakers, scientists, and stakeholders in promoting sustainable management practices.

Keywords: microplastics, chemical contaminants, wastewater treatment plants, removal techniques

Abstrak

Mikroplastik (MP) merupakan kelas pencemar yang muncul dan telah mendapat perhatian utama pada masa ini kerana kehadirannya di dalam ekosistem marin dan air tawar. Zarah-zarah dengan diameter kurang daripada 5 mm ini terhasil daripada degradasi serpihan plastik yang lebih besar dan pengeluaran produk plastik komersial. Kemunculan MP yang berleluasa di alam sekitar ini telah menimbulkan kebimbangan kerana ianya berpotensi memberi kesan buruk terhadap organisma marin dan kesihatan manusia. Luas permukaan spesifik yang tinggi dan hidrofobik MP menjadikannya sebagai penjerap yang berkesan bagi bahan

pencemar lain. Oleh itu, pendedahan MP terhadap organisma boleh membawa kepada peningkatan ketoksikan dan bioakumulasi bahan pencemar ini, dan seterusnya menyebabkan kemudaratan yang ketara kepada ekosistem. Ulasan ini memberikan gambaran menyeluruh tentang sifat-sifat MP, laluan masuk ke alam sekitar, kesannya terhadap alam sekitar dan kesihatan manusia, dan pendekatan semasa untuk penyingkiran mereka. Kaedah fizikal, kimia dan biologi untuk penyingkiran MP dibincangkan, termasuk kelebihan dan kelemahannya. Walau bagaimanapun, terdapat keperluan mendesak untuk membangunkan teknik baru yang cekap dan kos yang efektif untuk penyingkiran MP. Ulasan ini memberikan pandangan yang berharga untuk penggubal dasar, saintis dan pihak berkepentingan untuk menggalakkan amalan pengurusan yang mampan dan mengurangkan percambahan MP dalam alam sekitar.

Kata kunci: mikroplastik, pencemar kimia, loji rawatan sisa air, teknik penyingkiran

Introduction

Global plastic production has grown rapidly in the past few decades. According to the United Nations, plastic production reached 359 million metric tons in 2018, a significant increase from 1.5 million metric tons in 1950 [1]. This substantial growth, amounting to over 200 times in just 68 years, can be attributed to several factors, such as population growth, urbanization, and the ascendancy of the global consumer culture. However, if the current rate of plastic production persists, experts predict that plastic waste production will triple by 2050 [2].

The increase in plastic production has led to a global surge in plastic waste generation, becoming a significant environmental concern due to the inadequate management of plastic waste. As a result, plastic debris has accumulated in various environmental matrices, such as marine and terrestrial environments. Plastic waste can persist for decades in the environment, with several harmful impacts on the environment and biota. In marine environments, the accumulation of plastic debris has been found to cause entanglement and ingestion by marine animals, leading to physical injuries, suffocation, and mortality [3]. The ingestion of plastic debris can also negatively impact the health of these organisms, such as reduced feeding efficiency, malnutrition, and reproductive impairment [4]. Additionally, plastic debris can act as a carrier for invasive species and pathogens, resulting in ecological disruptions and the spread of diseases [5,6]. In terrestrial environments, plastic debris can lead to soil and water pollution, which, in turn, can have harmful effects on soil quality, crop productivity, and human health [7, 8].

Plastic debris undergoes a process of degradation, leading to the formation of microplastics (MPs), which are defined as plastic particles smaller than 5 mm [9, 10]. MPs can be classified into two categories based on their origin: primary and secondary (Figure 1a). Primary MPs are deliberately manufactured and added to products, such as microbeads in personal care items or plastic pellets used in production processes [11, 12]. Secondary MPs are produced by the fragmentation, degradation, and weathering of larger plastic debris through natural and anthropogenic processes [13-15]. These small plastic particles enter the aquatic, terrestrial, and air environments through several activities on land and in the marine environment (Figure 1b). Table 1 summarizes the potential roots of primary and secondary MPs in the environment. Additionally, MPs are categorized according to their physical properties, including shape, size, and chemical composition. They can have either spherical or irregular shapes. They may contain various additives, such as plasticizers, stabilizers, and flame retardants, which can leach into the environment, posing potential risks to human health and ecosystems, as presented in Figure 1c [16].

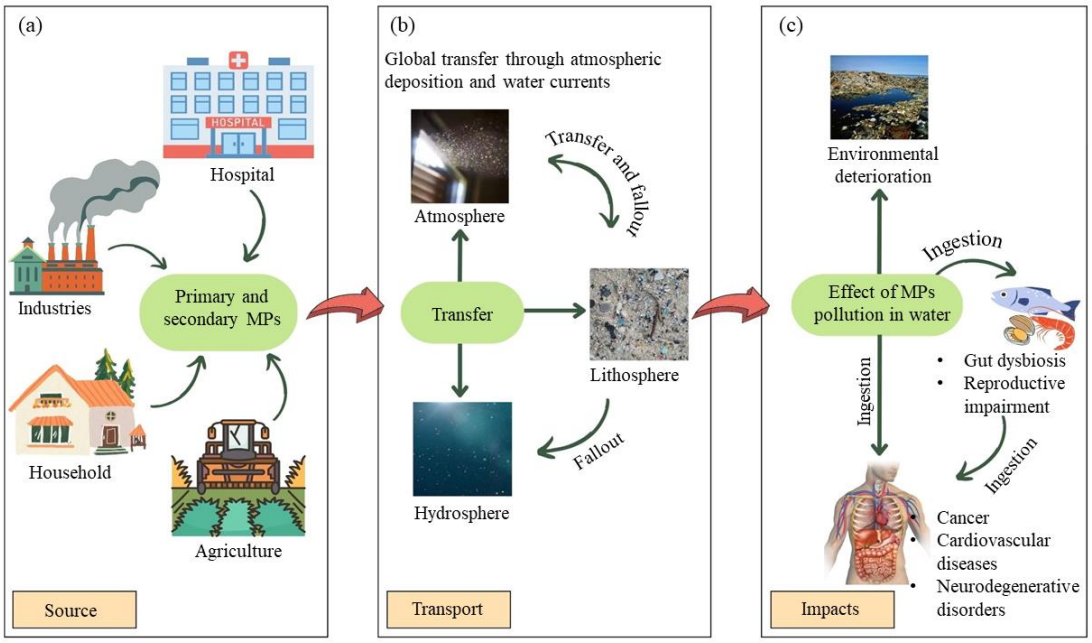

Figure 1. The schematic diagram of (a) the main sources of MPs, (b) transportation of MPs into the environment, and (c) environmental impacts and health effects on living organisms

Table 1. Summary of the potential roots of primary and secondary MPs in the environment

Primary MPs	**Secondary MPs**
Microfibres detached from synthetic textiles [17]	Degradation of larger plastics [18, 19]
Microbeads usually used in personal care, such as face scrub, body wash, toothpaste, etc. [12, 20]	Poor management of single-use plastics such as PPE [21]
Resin particles are used as industrial feedstock [22]	Aged and broken plastic debris due to environmental pressure [23, 24]
Medical applications such as dentistry products [25]	Tiny particles from the weathering of agricultural plastic film [22]
Dust from abrasions on car tires [26]	Plastic mulch film (PE) is used to improve water use efficiency and crop yield [8]
Ingredients that have been used for plastics production [2]	Plastic release during the mechanical recycling process [25]

The presence of MPs in the environment is a growing concern, and their detection has become increasingly common in various environmental compartments such as water, sediment, and soil. Among the different types of MPs, polyethylene (PE) and polypropylene (PP) are frequently detected in environmental samples, and their abundance is linked to their widespread use in products such as plastic bags, food packaging, and bottles [8, 24,

27]. Similarly, polystyrene (PS), commonly used in disposable food containers, cups, and packaging materials, is also frequently found in environmental samples, including freshwater and marine systems. Nylon (PA), utilized in textiles, fishing nets, and ropes, is another type of microplastic commonly detected in environmental samples, including water, sediment, and biota [28]. Polyethylene terephthalate (PET), used in water bottles, food packaging, and textiles, has also been found in various environmental compartments [25, 29, 30]. PET is known to resist environmental degradation, and studies have estimated its half-life to be hundreds of years under certain conditions. Table 2 summarizes the types of MPs, their applications, and estimated degradation time in the environment.

Table 2. Summary of the types, applications, and estimated degradation time of MPs

Type of Polymers	Chemical Formula	Application	Estimated Degradation Time	References
Polyvinyl chloride (PVC)	$(C_2H_3Cl)_n$	Building and construction sector	Up to 100 years	[28, 31]
Polyamide (PA) or nylon	$(C_{12}H_{22}N_2O_2)_n$	Gears, bushings, bearings, stockings, fabric, carpets, fishing line, and cable coatings	20 – 200 years	[31]
Polyethylene (PE)	$(C_2H_4)_n$	Shopping bags, cosmetic products, bottles, food packaging	Up to 1000 years	[28, 31]
Polypropylene (PP)	$(C_3H_6)_n$	Medicine bottles, bank notes, hinged caps	20-30 years	[28, 31]
Polystyrene (PS)	$(C_8H_8)_n$	Building insulation, inner line of fridge, food packaging	Up to 500 years	[28, 31]
Polyethylene terephthalate (PET)	$(C_{10}H_8O_4)_n$	Personal care products, water bottles, food packaging films	Up to 450 years	[28, 32]

Physicochemical properties of microplastic

The diverse range of MPs in the environment can be classified based on their distinctive shapes, including fibers, fragments, pellets, films, microbeads, and foams. These various shapes can result from the different types of transformations that MPs undergo, which can alter their physicochemical properties [33]. Among the various transformation processes, a previous study reported that chemical degradation induced by UV radiation is the most critical, initiating the initial degradation processes of microplastic particles [34]. The degradation of MPs can result in the formation of smaller particles, which can further contribute to the accumulation of MPs in the environment and increase the risk of exposure to humans and wildlife.

Polymers also possess unique physicochemical properties, including crystallinity, density, surface charge, surface area, surface hydrophobicity, and additives, influenced by their chemical compositions [23, 35]. The crystallinity of a polymer is a crucial characteristic that can affect the density of MPs. For instance, semi-crystalline polymers like PE and PP have low densities and tend to float in water [13, 16]. However, the crystallinity of a polymer can be altered by various environmental pressures, which can have significant implications for its other physicochemical properties [36]. Other physicochemical properties of MPs include surface charge, surface area, surface hydrophobicity, and the presence of additives, which can impact their stability, reactivity, and fate in the environment [37].

On the other hand, polymers with highly aromatic structures, such as PS, have unique physicochemical properties that make them highly adsorbent and susceptible to environmental pressures [38, 39]. In the case of PS, the strong π-electron-rich aromatic rings within the polymer structure trigger its sorption capacity and enable it to selectively adsorb certain pollutants, including aromatic organic pollutants [40]. However, environmental factors such as temperature, pH, and salinity can alter the π-electron density of the polymer, leading to changes in the sorption capacity and selectivity of the material [35]. Therefore, understanding the physicochemical properties of MPs is crucial in evaluating their fate and transport in the environment and their potential impacts on ecosystems and human health [23, 35].

Routes of entry to the environment

MPs have been identified as a pervasive and persistent form of pollution across the hydrosphere, lithosphere, and atmosphere worldwide. Figure 2 presents a schematic diagram illustrating the transportation of MPs into the environment. According to a global review by Fadare et al., MPs have been detected in various aquatic environments, including oceans, rivers, lakes, and estuaries, as well as in terrestrial environments such as soil and air [41]. A study by Zhang et al. found that MP concentrations in soils from urban areas in China ranged from 8 to 1730 particles/kg, with higher concentrations near plastic waste recycling facilities [42]. In a study on sediments from the Mekong River Delta in Vietnam, Kieu-Le et al. discovered MPs in all samples collected, with a mean concentration of 6.0 ± 2.0 particles per/g of dry sediment [43].

Similarly, microplastic concentrations ranging from 9.73 to 89.16 particles/m^{-3} were found in nine estuaries in Jakarta Bay, Indonesia [44]. MPs can be transported over long distances and accumulate in various aquatic organisms in aquatic environments, posing potential ecological and health risks. A study by Lahive et al. found widespread MP contamination in Asian freshwater ecosystems, with high concentrations detected in sediments and benthic organisms such as snails and worms. The study also revealed that MPs transferred up the food chain to fish and other aquatic organisms, potentially exposing humans through consumption [45].

Wastewater treatment plants (WWTPs) have been identified as significant contributors to MP release into the environment, releasing approximately 1,500 trillion microplastic particles annually [46]. MPs enter WWTPs through the direct discharge of microplastic-containing wastewater from domestic and industrial sources and the shedding of MPs from synthetic textiles during washing. Several studies have reported the abundance of MPs in WWTPs, highlighting their significant contribution to the overall pollution of the aquatic environment. For instance, Li et al. found that the concentration of MPs in WWTP influent ranged from 1.5 to 21.3 particles/L, with an average of 7.5 particles/L. The study also noted an increase in MP concentration in the effluent, with an average of 22.2 particles/L [47]. Mason et al. conducted a study in 17 wastewater treatment facilities in the United States, revealing an average of 0.05 MP/L in the final effluent, equating to a daily discharge into the environment of more than 4 million MPs, with microfibers identified as a dominant type of MPs in the influent and effluent of WWTPs. Regarding MP size, they also found that 57% had a size between 0.125 mm and 0.355 mm, while 43% of MPs were larger than 0.355 mm [48]. Another study by Deng et al. analyzed the influent and effluent of WWTPs in Shaoxing City, China, and found that the mean concentration of MPs in the influent was 334 particles/L, with a range of 1 to 16 particles/L from a textile dyeing WWTPs [49].

The shape and types of MPs found in WWTPs vary depending on their sources and treatment processes. For example, a study by Alvim et al. identified microbeads and fragments of larger plastic debris as the dominant types of MPs in WWTP effluent, while microfibers were more prevalent in the influent [50]. The study also found that the MPs' shape was mainly irregular, with sizes ranging from 1 to 5 mm. Another study by Viitala et al. found that fibers were the dominant shape of MPs in WWTP effluent, accounting for 77% of the total MPs, followed by fragments. Most MPs were smaller than 1 mm, with sizes ranging from 100–500 µm [51].

In the atmosphere, MPs can be transported over long distances and have been detected in remote areas such as the Arctic and Antarctic. The main sources of MPs in the atmosphere are synthetic fabrics, tire deterioration from synthetic rubber, and urban dust [52]. A study by Klein & Fischer in urban areas in Hamburg, Germany, found 2652 MPs particles in atmospheric fallout samples, with a median abundance of 275 MPs/m^2/day [53]. Sridharan et al. found that the MPs and micro rubber (MR) particles predominated in street dust samples retrieved from 15 sites in Asaluyeh, southern Iran, with average concentrations as high as 900 MPs and 250 MRs per 15g of the sample, respectively [54]. In another study by Kacprzak & Tijing, the findings demonstrate that the concentration of microfibers in the indoor environment, ranging from 1 to 60 particles/m^3, was higher compared to outdoors, with a range of 0.3 to 1.5 particles/m^3. The sizes ranged from 50 to 3250 µm indoors and 50 to 1650 µm outdoors [34]. The study also found that the concentration of microfibers in the indoor environment was higher, possibly due to friction, heating, lighting, or wear and tear of various plastic items. A previous study by Sangkhram et al. reported that airborne MPs were mostly PE, PS, PET, and other fibers, with sizes ranging from 10 to 8000 µm [55].

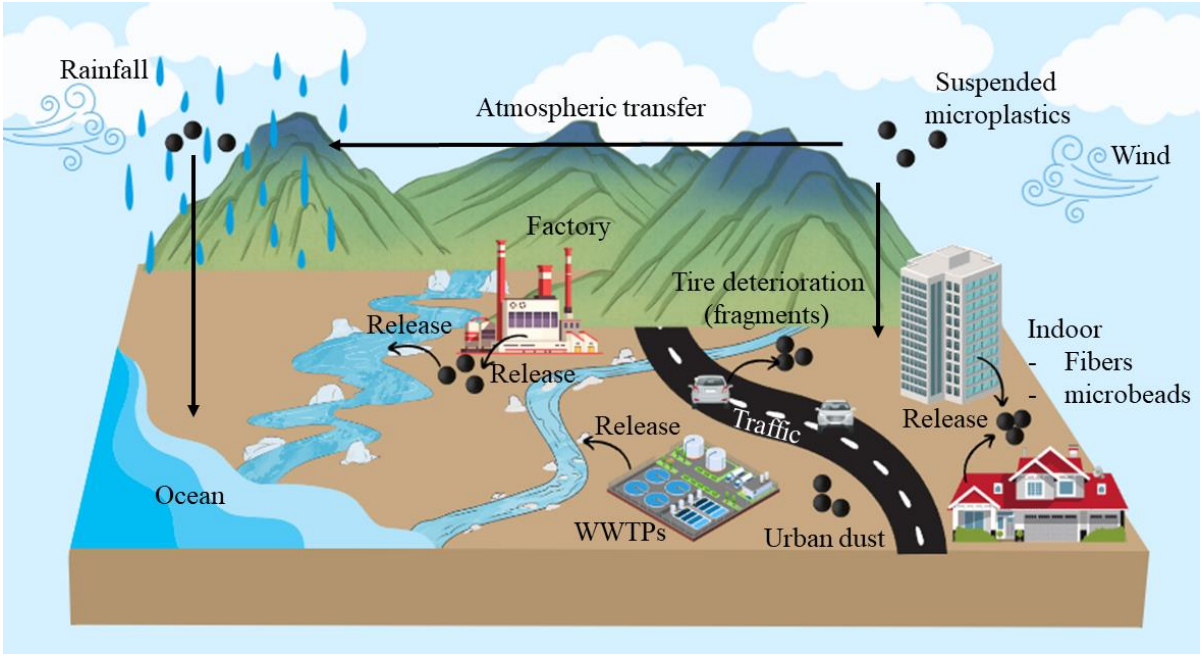

Figure 2. Schematic diagram of the transportation of MPs into the environment

Microplastics as vectors for chemical contaminants

MPs pose a significant and widespread environmental challenge. Due to their relatively high specific surface areas and hydrophobicity nature, MPs are highly effective at adsorbing various contaminants [56]. MPs are composed of various additives, such as plasticizers, fillers, and stabilizers, which complicate their composition. Moreover, when released into the environment, MPs provide surface area for the adsorption of numerous compounds from the surrounding environment. Examples of chemical pollutants that can adhere to plastics include polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), polybrominated diphenyl ethers (PBDEs), and persistent bioaccumulative and toxic substances (PBTs) [57]. When MPs absorb contaminants from the environment, their toxicity rises, potentially causing harmful effects on human health and aquatic organisms [58] [59]. The sorption of the chemical contaminants on the surface of MPs is influenced by various factors, including the type of polymers, the nature of chemical contaminants, and the

environmental conditions [60]. In this section, we explain the factors that influence the sorption behavior and mechanisms of chemical contaminants on the surface of MPs.

The functional groups of the polymers play a crucial role in the adsorption [61]. The formation of pores and oxygen-containing functional groups (including –OH, –COOH, and C–O) may increase the polarity of MP surfaces, enhancing the impact of hydrogen bonding on adsorption and decreasing their ability to adsorb weak polar organic contaminants [62, 63]. Liu et al. highlighted that their polymer types and features can influence the adsorption ability of MPs toward heavy metals. Different polymer types of MPs, including PE, PP, PS, and PVC, exhibit variations in their chemical compositions and surface properties, affecting their adsorption capacity for heavy metals. For instance, similar to the adsorption of aromatic pollutants, MPs with a higher density of oxygen-containing functional groups, such as carboxyl, hydroxyl, and amino groups, tend to exhibit enhanced adsorption capacities due to the availability of more binding sites for metal ions [64]. For example, PS, a common type of microplastic, has an aromatic compound that triggers its sorption capacity. PS tends to sorb organic aromatic pollutants at different polarities due to π-π electron interaction, making it an effective carrier of these contaminants [40]. Recent research has also demonstrated that MPs can carry hydrophilic pollutants in aqueous environments. Anastopoulos et al. have shown that PE, PVC, and polynorbornene (PN6) can transport azo dye, a model textile wastewater contaminant. PN6 demonstrated the highest sorption capability, followed by PE and PVC, due to electronegative N and O atoms in the PN6 polymeric structure, which can easily form hydrogen bonds with electropositive azo dye atoms [65]. Furthermore, biofilm formation on the surface of the MPs may affect the physical and chemical characteristics, including morphological surface and hydrophobicity, impacting the transportation, sinking, weathering, and fragmentation of MPs in the environment [66]. Cui et al. also report that the sorption of PBDEs, PCBs, α-hexabromocyclododecane (HBCDD), and organophosphate flame retardants (OPFRs) is influenced by the presence of biofilm on the surface of high-density polyethylene (HDPE) compared to virgin HDPE [36].

In the literature, it is established that the functional groups and ionic properties of chemical contaminants influence their polarity [61]. Different polymers may exhibit varying sorption capacities for hydrophobic organic contaminants [67]. The log K_{ow} is commonly used to describe the polarity of the contaminants, where organic contaminants with a higher log K_{ow} are classified as hydrophobic and are more prone to adsorption on the surface of MPs [68]. For example, a study conducted by Li et al. demonstrated that hydrophobic antibiotics with higher log K_{ow} values were more attracted to PP, PS, PE, and PVC [69]. On the other hand, the sorption behaviors of organic contaminants on the surface of MPs are significantly influenced by the molecular structure of organic pollutants. For instance, sulfanilamide antibiotics, composed of bonded carbon and hydrogen atoms, readily adhere to and bind on the surface of MPs in the environment [70].

In addition to the properties of MPs, environmental variables such as pH and salinity significantly influence the adsorption of heavy metals onto MPs. Liu et al. emphasized that the pH of the solution affects both the surface charge of MPs and the speciation of metal ions, thereby influencing their electrostatic interactions and complexation processes. Generally, MPs exhibit higher adsorption capacities for heavy metals under acidic conditions (lower pH) due to increased positive surface charge and higher concentrations of metal ions. On the other hand, the salinity of the environment can also impact heavy metal adsorption by MPs. Elevated salinity levels increase the ionic strength of the solution, leading to competition between metal ions and salt ions for adsorption sites on MPs. As a result, the adsorption of heavy metals by MPs may decrease under high salinity conditions [64]. Furthermore, the size and shape of MPs play a crucial role, with smaller MPs possessing larger surface areas and, consequently, higher adsorption capacities. Irregularly shaped MPs with rough surfaces also provide more active sites for metal binding than their spherical counterparts.

Effects of microplastics pollution in water

The presence of MPs in aquatic environments has been extensively documented in numerous studies. In a recent investigation conducted by Hu et al. [16], the influence of environmental variables on the adsorption of heavy metals onto MPs was explored. Additionally, Liu et al. emphasized that the pH of the solution affects both the surface charge of MPs and the speciation of metal ions, thereby influencing their electrostatic interactions and complexation processes. Generally, MPs exhibit higher adsorption capacities for heavy metals under acidic conditions (lower pH) due to an increased positive surface charge and higher concentrations of metal ions. On the other hand, the salinity of the environment can also impact heavy metal adsorption by MPs. Elevated salinity levels increase the ionic strength of the solution, leading to competition between metal ions and salt ions for adsorption sites on MPs. As a result, the adsorption of heavy metals by MPs may decrease under high salinity conditions [16]. This distribution of polymer types and shapes also highlights MPs' widespread contamination of freshwater ecosystems. The small size of MPs enables their easy entry into aquatic environments, where they can persist for extended periods and potentially pose significant risks to the ecosystem and human health. This section will concisely elaborate on the effects of MP pollution in water.

Effects of microplastics on the aquatic environment

MPs pose a growing concern in marine ecosystems due to their small size, making them easily mistaken for food by various marine species. The ingestion of MPs by marine organisms, such as zooplankton [71], bivalves [72] [73, 74], fishes [75], and shrimps [76], can lead to detrimental effects on their physiological functions. MPs with sharp edges can cause mechanical injuries in the digestive tract, leading to inflammation and other complications. Additionally, MPs can act as carriers of harmful chemicals, including heavy metals, organic pollutants, and plasticizers. These chemicals have the potential to pass through the gut wall and enter the circulatory system of marine organisms, leading to disruptions in reproductive and nutritional systems, as well as inducing inflammation in essential organs [4].

The vulnerability of marine organisms to the detrimental effects of MPs extends to critical stages of their life cycles. Zhang et al. highlighted the high susceptibility of sea turtle eggs to the permeation of pollutants from microplastics. MPs near sea turtle nesting areas pose a significant threat to embryonic development, diminishing hatching success and ultimately jeopardizing population sustainability. The chemicals present in MPs can interfere with embryonic development, disrupt hormonal balance, and compromise sea turtle embryos' overall health and survival [77].

Effects of microplastics on humans

The ingestion of MPs is recognized as the primary route of human exposure to these particles. Recent research has shed light on the extent of this exposure pathway and its potential implications for human health. Research indicates that the average person consumes approximately 39,000 to 52,000 synthetic plastic debris particles annually, with age and gender also having an effect [42]. Furthermore, MPs have been detected in various food items, including seafood, table salt, honey, and beverage packaging, suggesting that dietary intake is a significant contributor to human exposure [41, 78-82]. Once ingested, MPs can translocate from the gastrointestinal tract to various organs and tissues within the body. Turroni et al. emphasized that MPs can enter organs such as the liver, kidneys, and gastrointestinal tract, potentially leading to health effects [83]. The physical presence of MPs in these organs can induce mechanical damage, leading to tissue inflammation and impairing normal physiological functions [84]. Additionally, chronic exposure to MPs has been associated with impaired nutrient absorption in the gastrointestinal tract, disrupting metabolic processes and overall health [85].

Bhatt et al. [4], Golwala et al. [86], and Rahman et al. [87] highlighted the potential harm caused by the release of pollutants, including endocrine disruptors, heavy metals, and persistent organic pollutants from MPs. These pollutants accumulate in various tissues and organs, posing significant risks to human health. Chronic exposure to MPs carrying these pollutants can lead to adverse effects on tissues and systems in the

body, including inflammation, oxidative stress, and disruption of hormonal balance. MPs can potentially cause physical harm to organs by blocking the digestive tract, harming intestinal tissues, and affecting cells' filtering and phagocytic activity [88]. Moreover, in vitro studies have demonstrated that exposure to MPs and nano-plastics can trigger cytotoxic effects on cerebral and epithelial human cells through the generation of oxidative stress [89]. This type of stress arises from an imbalance between reactive oxygen species (ROS) production and the cellular ability to detoxify them, leading to the oxidation of vital cellular components such as lipids, proteins, and DNA [90]. The resulting damage can lead to various adverse health outcomes, including cell death, inflammation, and the development of chronic diseases like cancer, cardiovascular disease, and neurodegenerative disorders [91].

Microplastics removal approaches

Removing MPs in WWTPs involves implementing different physical, chemical, and biological techniques. These methods aim to effectively reduce the concentration of MPs in wastewater before its discharge into the environment. In Table 3, a summary of the existing removal techniques in WWTPs can be found, illustrating the range of approaches employed for this purpose.

Physical techniques

Filtration is a widely recognized and effective method for removing MPs from various sources. The principle behind filtration involves passing a liquid through a filter medium with pores smaller than the particle size of the target contaminants. Standard filtration tools include a funnel, filter membrane, and vacuum pump [92]. In the case of MPs, the liquid containing MPs is poured into the funnel, and the vacuum pump creates a pressure difference that drives the liquid through the filter membrane [93]. As the liquid containing MPs flows through the ultrafiltration membrane, the smaller pores of the membrane selectively block the passage of the MPs while allowing the liquid to pass through [94]. This process ensures the separation and removal of MPs, contributing to the purification of the liquid. The captured MPs remain on the surface or within the membrane, forming a retained fraction that can be subsequently collected and properly disposed of. Figure 3a clearly illustrates how membrane filtration acts as an effective barrier to the passage of MPs, highlighting its potential as a valuable method for MP removal.

Adsorption has emerged as a promising method for effectively removing MPs from aqueous solutions due to its potential for high efficiency and cost-effectiveness. In a recent study conducted by Tang et al. [59], the use of magnetic carbon nanotubes (M-CNTs) as an adsorbent material for the complete removal of three common types of MPs: polyethylene (PE), polyethylene terephthalate (PET), and polyamide (PA), was investigated. The experimental setup involved mixing 5g/L of each type of MP with 5g/L of M-CNTs and allowing them to adsorb for 300 minutes. The study revealed that the strong hydrophobic nature of the MPs played a crucial role in their adsorption onto the M-CNTs. Specifically, for PE MPs, the hydrophobicity of the particles was identified as the primary driving force behind their adsorption. The hydrophobic nature of the M-CNTs facilitated the attraction and binding of the hydrophobic MPs, leading to their effective removal from the aqueous solution. In the case of PET MPs, the adsorption mechanism involved a combination of hydrophobic interaction and π-π electron conjugation, facilitating their interaction and adsorption. Additionally, the presence of π-π electron conjugation, referring to the interaction between the aromatic rings of the MPs and the M-CNTs, further enhanced the adsorption process. Therefore, the combination of hydrophobic interaction and π-π electron conjugation contributed to the efficient removal of PET microplastics.

Similarly, for PA MPs, the adsorption mechanism was found to be more complex, attributed to multiple factors, including π-π electron interaction, complexation, electrostatic interaction, and hydrogen-bond interaction occurring on the surface of the microplastics. The π-π electron interaction involved the interaction between the aromatic rings of the PA molecules and the M-CNTs, facilitating their adsorption. Complexation, electrostatic interaction, and hydrogen-bond interaction between the functional groups present on the surface of the MPs and

the M-CNTs also contributed to the adsorption process [20].

Biochar has gained attention as a potential material for removing MPs, offering a promising alternative in addressing the growing concern of MP pollution. A recent study by Wang et al. demonstrated that biochar could remove more than 95% of MPs, making it a highly efficient solution for mitigating MP contamination. The remarkable MP removal efficiency of biochar can be attributed to several factors. The flaky-shaped particles of biochar possess unique properties that facilitate MP removal. These flaky particles can detach themselves from the main biochar structure, increasing surface area exposure and creating more binding sites for MP adsorption. This characteristic enhances the contact between biochar and microplastics, leading to a higher adsorption capacity and more effective removal. Furthermore, the van der Waals forces in the biochar structure play a significant role in MP removal. These intermolecular forces, arising from fluctuations in electron density, contribute to the attractive forces between the biochar and MPs. As a result, MPs experience reduced immobilization through mechanisms such as “Trapped” and “Entangled” (Fig. 3b), where MPs become trapped within the biochar structure or entangled with the biochar particles [96].

Chemical techniques

Coagulation and flocculation techniques have long been recognized as effective methods for removing MPs in WWTPs. The coagulation process involves the addition of coagulants, typically metal salts such as aluminum sulfate ($Al_2(SO_4)_3$) or ferric chloride ($FeCl_3$), to the wastewater. During coagulation, MPs encounter the Al^{3+} ions present in the coagulant. Figure 3c shows the illustration for the coagulation process for MPs removal. The Al^{3+} ions bind to the surfaces of the MPs through interactions with oxygen-containing functional groups, such as carboxyl, hydroxyl, or carbonyl groups. These functional groups are often present on the surface of MPs, resulting from weathering and degradation processes. The binding of Al^{3+} ions to the MPs forms complex species, such as Al-PET in the case of PET MPs, altering the surface properties of the MPs, leading to increased particle size and improved settling characteristics. Additionally, the complexation between Al^{3+} ions and MPs reduces repulsive forces between individual MP particles, promoting their aggregation and the formation of larger flocs. These larger flocs are more easily separated from the wastewater, resulting in the near-complete removal of MPs, as reported by Lu et al. [97].

The electro-coagulation technique is a recent advancement and an effective method for removing MPs from aqueous environments. The electro-coagulation process is based on the principle of electrolysis, where an electric current is applied to electrodes submerged in the wastewater. The electrodes, typically made of aluminum or iron, dissolve electrolytically, generating metal ions in the surrounding solution. The electro-coagulation process offers several mechanisms for the removal of MPs. For instance, the generated metal ions, such as Al^{3+} and Fe^{3+}, can undergo hydrolysis reactions, forming metal hydroxide species, such as $Al(OH)_3$ and $Fe(OH)_3$. These metal hydroxide species can adsorb onto the surface of MPs, promoting the accumulation and subsequent removal of the particles. In addition, the metal hydroxide species can act as coagulants, neutralizing the charge on the MPs and causing their aggregation through charge neutralization mechanisms. Various operational parameters influence the effectiveness of the electro-coagulation process for MP removal. Elkhatib et al. reported a high removal efficiency of 98.5% under specific conditions, including adjusting the initial pH to 4 and applying a current density of 2.88 mA/cm^2 to the reactor. The pH adjustment helps create favorable conditions for generating and precipitation metal hydroxide species, which aids in MP removal. The current density applied to the reactor affects the rate of metal ion generation, which, in turn, influences the coagulation and removal of MPs [98].

Photocatalytic degradation is another promising technology for efficiently removing MPs from aqueous environments. This technique harnesses the power of light to activate a catalyst, leading to the generation of electron-hole pairs that can oxidize MPs. Figure 3d demonstrates the process of photocatalytic degradation of MPs. Among the various photocatalysts investigated,

carbon and nitrogen-doped titanium dioxide (TiO_2) have shown exceptional performance in visible light absorption and the separation efficiency of electron-hole pairs, making them highly effective for photocatalytic activity. In a study by Tarazona et al., researchers examined using carbon and nitrogen-doped TiO_2 in conjunction with visible light from an LED lamp to remove MPs. The photocatalytic degradation of MPs was evaluated over 50 hours. The results indicated that the green N-TiO_2 semiconductor exhibited a reduction in the mass of high-density polyethylene (HDPE) MPs within the range of 1-6%. Furthermore, when carbon and nitrogen-doped TiO_2 were employed for a reaction time of 50 hours, the removal efficiency increased significantly to 71.77% [99]. Similarly, Nabi et al. reported a high removal efficiency of more than 95% for PS MPs using TiO_2 nanoparticle films for photocatalytic degradation [100].

Biological techniques

Microalgae have been identified as a promising bio-alternative for various wastewater treatment stages and functionalities due to their potential for removing pollutants from water bodies. While microalgae are already used for water treatment, they have been identified as a potential solution for MP removal due to their ability to interact with and aggregate with MPs, as shown in Figure 3e. Cunha et al. reported on the potential of microalgae for microplastic removal [101]. In a study conducted by Cheng and Wang, *Scenedesmus abundans* was found to effectively remove more than 85% of PS, poly(methyl methacrylate) (PMMA), and polylactide (PLA) microparticles. Hetero-aggregation was identified as the main mechanism of MP removal, wherein microalgae and MPs form aggregates through electrostatic attraction, hydrogen bonding, and van der Waals forces, leading to their separation from the water [102]. Another study by Adegoke also reported that marine seaweed, *Fucus vesiculosus*, was used to determine whether MPs could be removed by translocation in algal tissues. Small canals in the algal cells restricted the flow of MPs, causing the MP particles to become trapped. The study shows that algae removal efficiency was around 94.5% in certain regions [103]. However, MPs' removal efficiency was influenced by several factors, including microalgal density, microplastic concentration, and contact time.

.

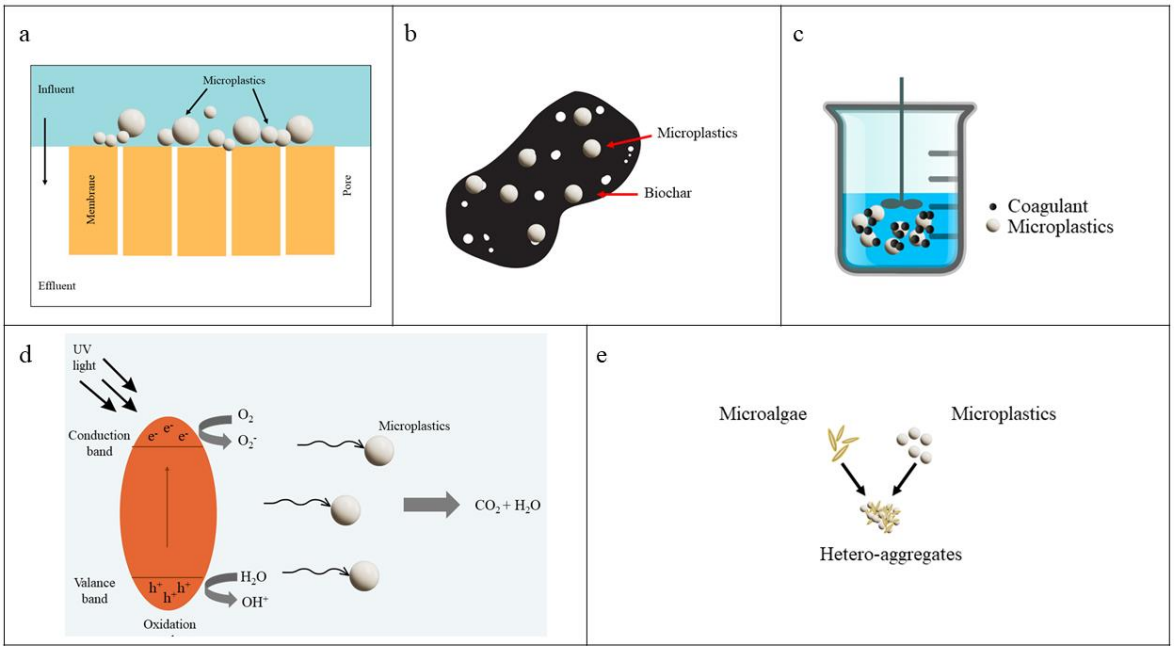

Figure 3. Schematic diagram of main MPs removal approaches (a) membrane filtration, (b) biochar adsorption, (c) coagulation treatment, (d) photocatalytic degradation, and (e) microalgae treatment.

Table 3. Summary of physical, chemical, and biological techniques for MP removal

Removal Techniques Approach	Type of MPS	Mechanisms	Efficiency	References
Filtration by biochar	PS microsphere	The van der Waals forces have resulted in less immobilization by the "Trapped" and "Entangled" mechanisms	<95%	[96]
Adsorption by magnetic carbon nanotube	PE, PET, and PA	The strong hydrophobicity of MPs caused M-CNT adsorption by PE, hydrophobic interaction and π-π electron conjugation caused MCNT adsorption by PET, and π-π electron interaction, complexation, electrostatic interaction, and hydrogen-bond interaction on the PA surface all contributed to M-CNT adsorption.	100%	[20]
Coagulation process	PET	The Al was used as a coagulant to form complexes with MPs by exchanging ligands.	Nearly 100%	[97]
Electro-coagulation	MPs from synthetic and real wastewater	Metal ions (Al^{3+}) discharged from the electrode react with the hydroxide coagulant in the water stream to generate sludge blankets for adhering MPs.	98.5%	[98]
Photocatalytic degradation by carbon and nitrogen-doped TiO_2	HDPE	Degradation of primary HDPE MPs can be accelerated and promoted by altering operational parameters such as temperature and pH during photocatalysis.	1-6% for green N-TiO_2, 71.77% for carbon and N-TiO_2	[99]
Photocatalytic degradation by TiO_2 nanoparticles film	PS	Surface hydrophilicity can facilitate the interaction between semiconductors and plastic particles, resulting in charge transfer and separation, leading to MPs' rapid breakdown.	<95%	[100]
Adsorption on microalgae	PS, PMMA, and PLA	Multiple types of MPs were removed by the microalgae *Scenedesmus abundans*, and the main mechanism of MP removal was identified as hetero-aggregation.	<85%	[102]
Adsorption on microalgae	MPs from environment	Marine seaweed, *Fucus vesiculosus*, was used to remove MPs from the environment by translocation in algal tissues.	94.5%	[103]

Limitation of different techniques and green strategies

Microplastic pollution poses a pressing environmental challenge, demanding effective management strategies. We advocate for the future emphasis on green and environmentally friendly approaches. The following outlines some research challenges and goals to reduce MPs in the environment.

Physical methods commonly used for MP removal have proven effective in eliminating high-density MPs. However, they face limitations in dealing with low-density MPs, generating secondary waste, and exhibiting varying efficacy under different environmental factors [104]. Therefore, a comprehensive approach that integrates multiple methods, such as biological treatment and chemical oxidation, becomes necessary. This integration maximizes MP removal efficacy while minimizing environmental impacts. Integrating physical methods with complementary techniques provides a more sustainable solution for microplastic removal in aquatic systems. Moreover, using environmentally friendly and biology-based materials, including starch and biochar, holds promise as adsorbents and coagulators for MP removal due to their biodegradability and environmental friendliness in aquatic environments [105].

Chemical methods, including photocatalytic oxidation and oxidation removal techniques, promise to eliminate MPs from water. However, their large-scale implementation presents challenges due to their high energy consumption, cost implications, and the potential generation of harmful by-products leading to secondary contamination. Thus, a careful evaluation of the practicality and sustainability of chemical approaches is essential to ensure their effective implementation. Additionally, selecting appropriate catalysts, optimizing operating conditions, and integrating suitable treatment technologies can further enhance the effectiveness of these methods. Regarding environmental impact assessment during sample preparation, the software tool AGREEprep may be considered in the future [106].

Biological approaches, particularly biodegradation by microorganisms, have emerged as promising and eco-friendly strategies for MP removal from aquatic systems. However, the practical implementation of this method can be impeded by the slow rate of complete degradation, leading to the release of toxic metabolites and subsequent secondary contamination [56]. Additionally, the efficacy of biological approaches is affected by multiple factors, including the type of MPs, microbial community composition, and environmental conditions like temperature, pH, and nutrient availability. Therefore, optimizing biodegradation methods, microbial communities, environmental conditions, and operational parameters is crucial to enhancing the potential of biological approaches and making them more suitable for large-scale applications.

Conclusion and Future Perspectives

The contamination of the environment with MPs, caused by anthropogenic activities, is a pervasive problem that affects all environmental matrices. MPs possess unique physicochemical properties that enable them to adsorb other pollutants and act as carriers, leading to their accumulation in the food chain and potentially causing adverse effects on human health and aquatic organisms. While biological techniques hold promise for MP remediation, their removal efficiency still lags behind physical and chemical techniques. Therefore, a multifaceted approach integrating various technologies and strategies is urgently needed. A combination of physical, chemical, and biological methods is necessary to achieve optimal removal of MPs from aquatic and terrestrial systems.

However, a careful evaluation of the limitations and potential environmental impacts of each method is crucial, and the integration of complementary methods is necessary for sustainable remediation. Moreover, effective monitoring and assessment techniques must be developed to determine the extent and sources of MP pollution, enabling the implementation of targeted management strategies to reduce and eliminate sources of contamination. Continued research is also required to identify the long-term effects of MPs on aquatic and terrestrial ecosystems and human health. Furthermore, exploring alternative materials and promoting the circular economy presents a viable solution for reducing plastic waste, significantly reducing MP pollution.

Abstract

Citrus hystrix is a famous aromatic plant that comprises biological properties such as antioxidant, antibacterial, antileukemic, and antitussive properties. Several conventional extraction methods like hydro-distillation, steam distillation and Soxhlet distillation have been used to extract essential oils (EOs), but they are time-consuming, expensive and necessitate the use of numerous solvents. Therefore, this study focused on the use of ultrasound-assisted extraction (UAE) which is a novel extraction method that has lower operating costs and shorter extraction time. UAE was performed to extract the EOs from *C.hystrix* peels by using methanol and petroleum benzine. The yield of extracted EOs were 9.43% and 2.36%, respectively. After extraction, a qualitative phytochemical analysis was carried out to detect chemical constituents in the EOs. Both EOs showed positive results in the tests of alkaloids and terpenoids. Besides, the surface morphology of fresh *C.hystrix* powder before extraction and the residual powder after extraction were compared by using a scanning electron microscope (SEM). SEM photographs of both residual powders revealed pores that appeared because of peel surfaces implosion which occurred during extraction. Functional groups at the configuration peaks were characterised by using Fourier transform infrared (FTIR) spectroscopy and chemical constituents in the EOs were analysed by using gas chromatography-mass spectrometry (GCMS). Results for both extracted EOs demonstrated the presence of OH stretching at 3625-3025 cm^{-1}, CH_3 stretching at 2939-2834 cm^{-1}, C=O stretching at 1721-1719 cm^{-1} and C=C stretching at 1624-1622 cm^{-1}. The GCMS result indicated that the main chemical compounds of both EOs were d-limonene, citronellal, and terpinen-4-ol. According to the findings, UAE extraction method was recommended due to its environmental friendliness and short extraction time.

Abstrak

C. hystrix merupakan tumbuhan aromatik terkenal yang terdiri daripada sifat-sifat biologi seperti sifat antioksidan, antibakteria, antileukemik dan antitusif. Beberapa kaedah pengekstrakan konvensional seperti penyulingan hidro, penyulingan wap, dan penyulingan soxhlet telah digunakan untuk mengekstrak minyak pati (EOs) namum memerlukan penggunaan banyak pelarut, memakan masa, dan mahal. Oleh itu, kajian ini tertumpu kepada penggunaan pengekstrakan bantuan ultrasonik (UAE) yang merupakan kaedah pengekstrakan novel yang mempunyai kos operasi yang lebih rendah dan masa pengekstrakan yang lebih singkat. UAE telah digunakan untuk mengekstrak EOs daripada kulit *C.hystrix* menggunakan metanol, dan petroleum benzine. Hasil kedua-dua EO yang diekstrak adalah 9.43% dan 2.36%. Selepas pengekstrakan, analisis fitokimia kualitatif telah dilakukan

untuk mengesan konstituen kimia dalam EOs. Kedua-dua EOs menunjukkan keputusan positif dalam ujian alkaloid dan terpenoid. Selain itu, morfologi permukaan serbuk *C.hystrix* segar sebelum pengekstrakan dan serbuk sisa selepas pengekstrakan telah dibandingkan dengan menggunakan pengimbas mikroskopi elektron (SEM). Gambar-gambar SEM bagi kedua-dua serbuk sisa menunjukkan liang yang hadir disebabkan oleh letupan permukaan kulit yang berlaku semasa pengekstrakan. Kumpulan-kumpulan berfungsi pada puncak konfigurasi telah dicirikan menggunakan spektroskopi inframerah transformasi Fourier (FTIR), dan juzuk-juzuk kimia dalam EOs dianalisis menggunakan kromatografi gas-spektrometri jisim (GCMS). Hasil kajian menunjukkan kehadiran regangan OH pada 3625-3025 cm^{-1}, regangan CH_3 pada 2939-2834 cm^{-1}, regangan C=O pada 1721-1719 cm^{-1}, and regangan C=C pada 1624-1622 cm^{-1} untuk kedua-dua EO yang diekstrak. Data GCMS menunjukkan komposisi kimia utama bagi kedua-dua EOs adalah D-limonene, sitronelal, dan terpinen-4-ol. Berdasarkan penemuan, kaedah pengekstrakan UAE disyorkan kerana mesra alam dan masa pengekstrakan yang singkat.

Introduction

In Malaysia, 17,000 tonnes of food wastes are reported per day [1]. Fruit peels are one of the wastes produced. Nowadays, fruit peels are collected and processed to extract EOs, which are applied in food and beverage industries, cosmetic industries and pharmaceutical industries. *C. hystrix*, or known as *kaffir lime*, is an aromatic plant part of the Rutaceae family with a green and bumpy peel. EOs of *C. hystrix* have bioactivities such as antioxidant, antibacterial, antileukemic and antitussive, which are functions in aromatherapy, insect repellent and additive in cosmetic products [2, 3].

Extraction methods such as hydro-distillation, steam distillation, and Soxhlet distillation [4] have been used to extract EOs from *C. hystrix* with a high yield production of EOs. However, the extraction period is quite long, and it requires a high operating cost [4]. The UAE extraction method extracts compounds from plants in a solvent by using soundwave at 20 kHz to 100 MHz frequency. Mass transfer occurs due to the ultrasound, which allows the solvent to access plant material cell components faster. Ultrasound also allows the process of erosion to occur, in which the cavitation bubbles produced by ultrasound will make the surface of plant tissues undergo implosion [5]. UAE is a beneficial method that has a short extraction time and high production yield [5]. It can provide a large yield of oil in a short extraction time by imploding cavitation bubbles caused by the ultrasound and triggering fissions at plant cell walls, whereby the percentage yield of oil obtained in 120 min of kaffir lime leaves was 1.75% and the percentage yield of oil obtained in 30 min of rapeseed oil was 21.36% [6, 7]. In this study, the peels of *kaffir lime* were employed to extract EOs with a high yield production in a short period by using UAE.

Solvent used in the extraction process is determined by the type and part of plant, bioactive chemicals of plant, compounds to be extracted from the plant, and availability of solvent [8]. Different types of solvents have different polarities. The bonds between atoms in polar solvents contain very different electronegativities while the bonds between atoms in non-polar solvents contain similar electronegativities. Quantitative and qualitative extraction of plant compounds is affected by the polarity of solvent [9]. Therefore, the yield of EOs extracted from plants by using solvents of varying polarities depends on solubility of plant compounds with the solvent. Polar solvents such as methanol and ethanol are frequently used to extract polyphenols like antioxidant compounds from a plant [7]. Non-polar solvents such as *n*-hexane and petroleum ether are used to extract alkaloids, terpenoids, coumarins and fatty acids from a plant [8]. Purity and quality of the extracted compounds might be impacted because the polarity of a polar solvent like methanol could lead to an unintended chemical reaction, decomposition or degradation of the extracted compounds [8].

Phytochemicals are compounds present in plants which give colours, aromas and flavours, such as phenolics, flavonoids, terpenoids, alkaloids, steroids, proteins and tannins. The main phytochemical contained in *C. hystrix* peel is terpenoids such as β-pinene, limonene, citronellal and sabinene [10]. Terpenoids are the largest group found in natural products, which are known as oxygen-containing terpenes. A study by Soib et al. [11] showed that the UAE method could extract the same secondary metabolites from *Carica papaya Linn* leaves like reflux and agitation methods in terms of saponins, flavonoids, glycosides, alkaloids and phenolics. According to Pandhi and Poonia [12], several phytochemical compounds, including alkaloids, phenol, tannins and flavonoids were detected in Jamum seed extracts by using the UAE method, except saponins, phytosterols, carbohydrates, glycosides and protein. Another study by Mutalib [13] discovered that the UAE approach produced the same favourable findings in photochemical screening tests of *Rosmarinus officinalis*

leaf extracts as by using the conventional methods for extraction, such as maceration, decoction, infusion, regular reflux, and Soxhlet distillation. It can be concluded that the novel UAE extraction method has great possibility of extracting secondary metabolites from plant material with its unique advantages.

In this study, the UAE technique was applied to produce a high yield in a brief amount of time with a small peel-to-solvent ratio. The findings by Kasuan et al. [3] showed that a mere 1.87% of *kaffir lime* oil was extracted from 350g of peels in 10l solvent by using an automated steam distillation process at temperature of 80 ℃ in 75 min. Comparatively, in the present study a better yield of *kaffir lime* EOs was produced by using UAE method despite only 50 min of extraction time and a lower raw material-to-solvent ratio of 1:30 g/mL. The different polarity of solvents was utilised to investigate the effectiveness of different solvents to extract the compounds. Methanol (polar solvent) and petroleum benzine (non-polar solvent) were used in the extraction of EOs from *C. hystrix* with a ratio sample (g) to solvent (ml), was 1:30. Methanol was chosen to extract EOs from C. *hystrix* peels due to its high production yield and effectiveness in extracting phenolic, flavonoid, alkaloid and terpenoids. Petroleum benzine was used to extract EOs from C. *hystrix* peels due to its low boiling point and efficacy in removing alkaloids and terpenoids [8]. Continuously, the presence of alkaloids, protein and amino acids, phenolic compounds, saponins, tannins, flavonoids and terpenoids in the EOs was demonstrated by using phytochemical screening. The morphological properties of C. *hystrix* peels before and after extraction were examined by using SEM. The presence of functional groups in the EOs was confirmed by using FTIR. The analysis of the compounds in EOs extracted was conducted by using Gas chromatography-mass spectrometry (GC-MS).

Materials and Methods

Materials

Methanol (99.9 wt.%) (LabServ) and petroleum benzine (Supelco/Germany) were used as solvents. Sodium hydroxide (98%) (Emory), copper (II) sulfate pentahydrate AR ($CuSO_4 \cdot 5H_2O$) (Emory), iron(III) chloride hexahydrate (Supelco), potassium sodium tartrate ($C_4H_4KNaO_6 \cdot 4H_2O$) Grade AR (QreC), potassium iodide (99.9%) (R&M Chemicals), iodine (PC Laboratory Reagent), sulfuric acid, chloroform, and hydrochloric acid were chemicals used in the phytochemicals screening testing.

Kaffir lime sample preparation

Fresh *kaffir lime (C. hystrix DC)* peels were purchased from a local supermarket located in Pagoh, Johor, Malaysia. The collected peels were washed several times with tap water to remove the remaining dust particles and impurities before the flesh were removed [10]. Following that, the washed peels were oven dried at 60 ℃ for 1 h to remove excess water [14]. The dried peels were blended until smooth and sieved by using an electric grinder to obtain uniform powders (Figure 1c) [15]. Then, the powders were weighed and sealed in an airtight container and stored at room temperature until ready to be used for extraction [16].

Extraction method

The extraction process was performed by using UAE method. Methanol was used as the polar solvent and petroleum benzine was used as the non-polar solvent for the extraction of *kaffir Lime* EOs. Then, 5g of powders were weighed and added into a conical flask which contained the solvents. The ratio of powder to solvent and extraction time was fixed at 1:30 g/mL and 50 mins [14, 17]. According to Liew et al. [14], the optimal raw material-to-solvent ratio for the extraction of kaffir lime peel was 1:30 g/mL. This was because when the volume of solvent increased, the contact area between solute and solvent increased, resulting in a greater mass transfer or driving force to extract bioactive compounds from the plant cells to solvent [14]. Then, the mixture sample was vortexed by using a vortex machine (Wiggens, Vortex Model 3000) at 800 rpm for 2 min as the pre-treatment of extraction. Then, the mixture was immersed into an ultrasonic bath (Wiggens Eco Series, Model UE10SFD) with ultrasonic power at 40 kHz (Figure 1e).The extracts were subsequently centrifuged at 20 ℃ with 3500 rpm for 20 min by using a centrifuge model (MPW-352R), as shown in Figure 1f. Then, the extracts were filtered to separate the solid residue from supernatant layers. The supernatant was concentrated by using a rotary evaporator (Eyela OSB-2200) equipped with a vacuum pump (Figure 1h) at 25 °C and 25 rpm by using a polar solvent [15]. Meanwhile, for the non-polar solvent extraction a reciprocal shaker water bath (Yihder, Model BT-150D) (Figure 1I) was used at 60 °C for 1 h[18]. Both extracts were concentrated by using different techniques because the boiling point of petroleum ether is lower than that of methanol; hence, it can be removed from EOs even with the water bath. To ensure that the EOs quality was consistent across all batches, the extraction process applied the same raw materials, sample preparation techniques, and UAE parameter conditions. The EOs were kept in a vial and stored at 4 ℃ until analysis [3].

Scanning electron microscope (SEM)
The surface morphology of fresh *kaffir lime* powder before extraction and residual powder after extraction were analysed by using SEM (Model EM-30N COXEM).

Fourier transform infrared spectroscopy (FTIR)
The existence of functional group in the extracted *kaffir lime* EOs was characterised by using FTIR spectrophotometer (Perkin Elmer UATR Two) under wavelength ranges between 400 cm^{-1} and 4,000 cm^{-1}.

Gas chromatography-mass spectrometry
Gas chromatography-mass spectrometry (GC-MS, GC Agilent® 7890B, MS Agilent® 5977B, Agilent Technologies, Santa Clara, CA, USA) was used to determine the chemical constituents of *kaffir lime* EOs. Firstly, the EOs were mixed with methanol in the ratio of 2:3. Head column pressures for the HP-5ms (30m x 0.25mm x 0.25µm film thickness) panel were 70kPa. GC-MS was acquired on the following conditions: Carrier gas He; flow rate 1.0 ml/min; split 1:100; injection volume 1.0 µl; injection temperature 280 °C; oven temperature progress included an initial hold at 70°C for 2 min, then increased to 7 °C/min to 320 °C for 1 min. The temperature of ion sources was maintained at 250 °C. The mass spectrum was obtained by electron ionisation at 70 eV, and the detector operated in scan mode 30 to 500 Da atomic units [18]. Chemical constituents of EOs were identified by comparing retention indices with mass spectral database libraries National Institute of Standards and Technology (NIST) [2]. Chromatograms from GC and GC-MS captured the existing sample oil constituents in terms of peak area count.

Phytochemical screening
Qualitative phytochemical analysis was performed to detect the presence of chemical constituents in extracted *kaffir lime* EOs, including alkaloids, flavonoids, terpenoids, saponins, tannins, phenols, and proteins as follows:

Test for alkaloids
10% KI was mixed with 5% iodine for the preparation of the iodine test reagent. Next, 2 to 3 drops of EOs were added to 1 mL reagent and then boiled in a water bath until the colour disappeared. The alkaloid content in the sample was indicated by the formation of a blue-black colour once the mixture cooled down [19].

Test for flavonoids
The intense yellow colour was formed when a few drops of EOs were added to 2 mL of 2% of NaOH solution. Following that, a few drops of diluted HCl resulted in the solution turning colourless. The formation and disappearance of intense yellow colour during the alkaline reagent testing indicated the presence of flavonoids in the extract [4].

Test for terpenoids
1 mL EOs was mixed with 2 mL chloroform and shaken well, followed by the addition of a few drops of concentrated H_2SO_4. Salkowski test showed a positive result when a reddish-brown colouration of the interface or golden-yellow precipitate was formed [8].

Test for saponins
1 mL of EOs was mixed with 3 mL of distilled water and the mixture was vigorously shaken for 30 s. If persistent foam or bubbles were formed for several minutes, it indicated the presence of saponins in the extract [20].

Test for tannins
A few drops of EOs were mixed with 5 mL of distilled water and then boiled in a water bath. Following that, the cooled filtrate was mixed with 5 mL of 1% w/v $FeCl_3 \cdot 6H_2O$ solution. A positive result showed a blue-green, green-black, dark blue, blue-black or dark brown formation [21].

Test for phenols
2 mL of 5% w/v aqueous $FeCl_3 \cdot 6H_2O$ solution was mixed with a few drops of EOs. The formation of a blue colour indicated a positive result [19].

Test for proteins
1.5g $CuSO_4 \cdot 5H_2O$, 6 g of $KNaC_4H_4O_6 \cdot 4H_2O$, and 2 M NaOH were mixed and then added with 1000 mL distilled water for the preparation of Biuret test reagent. Then, 2 to 3 drops of EOs were mixed with 1 mL of reagent. The formation of a purple solution indicated that the result was positive [22].

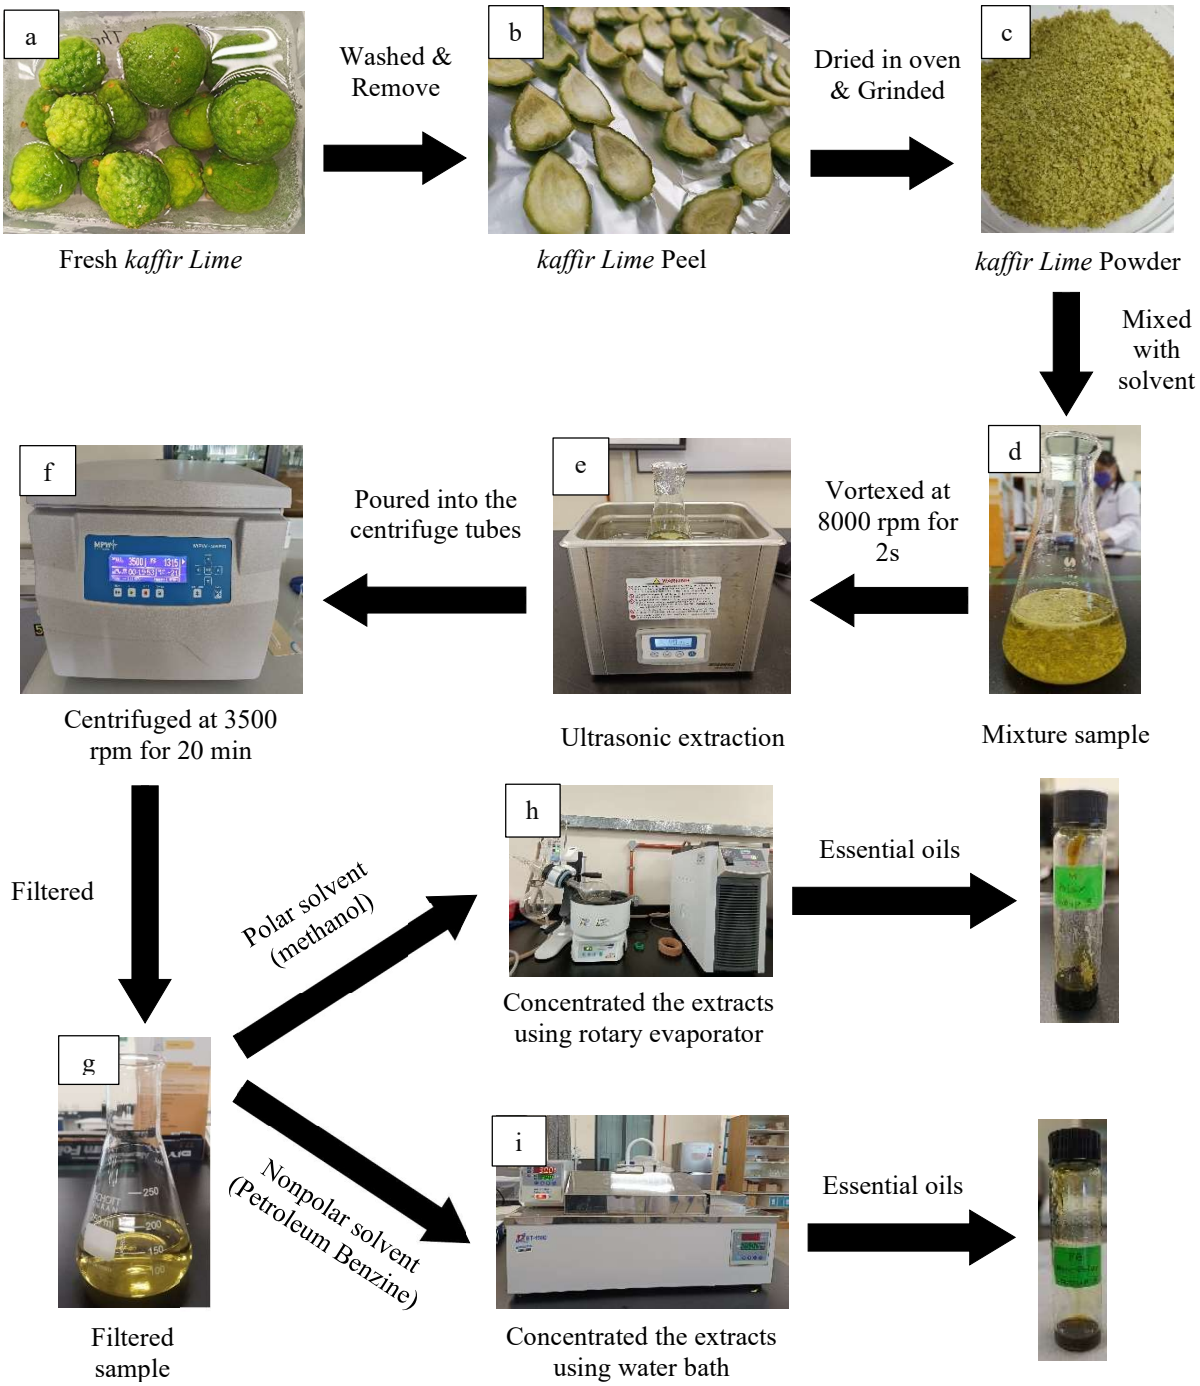

Figure 1. Schematic diagram of the extraction of the *kaffir Lime* essential oil using different polar solvents

Analytical method

The performance of the different polar solvents used in the extraction was evaluated according to the percentage yield of EOs obtained by calculated using Equation (1). The weight of extracted oil was based on fresh *kaffir lime* peels. The density of *kaffir lime* oil is in the range of 0.871g/ml [3]. From that, the weight of the obtained essential oil can be calculated by multiplying the density of the *kaffir lime* oil (0.871 g/ml) with the volume (ml) of EOs obtained.

$$\%\, Yield = \frac{Weigh\ \ of\ essential\ oil\ obtained\ (g)}{Weigh\ \ of\ fresh\ Kaffir\ Lime\ peel\ used\ (g)} \times 100\% \quad (1)$$

Results and Discussion

Percentage yield of EOs obtained

Table 1 shows the percentage yield of EOs obtained from extraction with methanol and petroleum benzine solvents. The mass and percentage yield of EO extracted by methanol (6.62 g, 9.43%) was greater than the EO extracted by petroleum benzine (1.66 g, 2.36%). This could be explained by the fact that the EOs were organic constituents, which were more likely to dissolve in organic or non-polar solvents by following the concept of like dissolving like [23]. Solutes or bioactive compounds from *kaffir lime* peels tended to dissolve more easily in the solvent close to its polarity, and thus increased the yield of EOs [24]. The dielectric constant (ε) is the important key parameter to measure the interaction between solute and solvent, which would affect the percentage yield of extracted EOs [25]. Non-polar solvents are those with dielectric constants lower than 15 [26]. Therefore, methanol is a polar protic solvent with a dielectric constant of 32.7 [27] while petroleum benzine is a non-polar solvent with a dielectric constant of 1.9 [26]. Polar protic solvents can be identified by the presence of hydrogen bonds such as the hydroxyl group (OH), whereas non-polar liquids possess similar electronegativities between atoms, such as carbon and hydrogen [28]. As a consequence, the OH group of the methanol molecule enables it to attract polar solutes and form hydrogen bonds, and thus increases the oil production. A solvent that is more likely to dissolve the solute provides a better potential to break down cell walls and extract the oil; hence, increases the amount of oil extracted [28]. According to Taesotikul et al. [29], the methanol extract yielded the most EOs with 68.86 ± 7.31% as compared to the other solvent fractions such as butanol, hexane, aqueous, and dichloromethane during the maceration technique extraction of *C. hystrix* peels oil. Furthermore, Tir et al. [25] reported that the oil yield of dichloromethane was 55.50 ± 0.56%, which was greater than the oil yield of hexane of 43.76 ± 0.81% for sesame seed oil extraction by using the Soxhlet method. This was due to the fact that opening the cell wall to allow for more complete solvent extraction of the cell contents reduced the difference in surface tensions on the phase boundary, and thus promotes phase separation [25].

Table 1. Percentage yield of EOs obtained from the extraction with solvent methanol and petroleum benzine

EOs	Methanol	Petroleum Benzine
Mass of the peels used (g)	70.20	70.20
Volume of EOs obtained (mL)	7.6	1.9
Mass of EOs (g)	6.62	1.66
Percentage yield (%)	9.43	2.36

Scanning Electron Microscope (SEM)

Figures 2a-c showed the SEM images of *kaffir lime* powder before extraction, residual powder after extraction by using methanol and residual powder after extraction by using petroleum benzine, respectively. Figure 2b and Figure 2c show a few porosities as compared to Figure 2a. The cavitation bubbles produced by ultrasound during the extraction process allowed the surface of *kaffir lime* peels to undergo implosion and caused the porosity to form [30]. Meanwhile, the changing of the surface allowed the solvents entry the cellular channels of *kaffir lime* peels to extract the compounds [31]. The implosion that occurred at the plant cell wall was related to several extraction parameter conditions in terms of types of solvent used, extraction time, extraction temperature, ultrasonic power, and liquid-to-solid ratio of extraction [22].

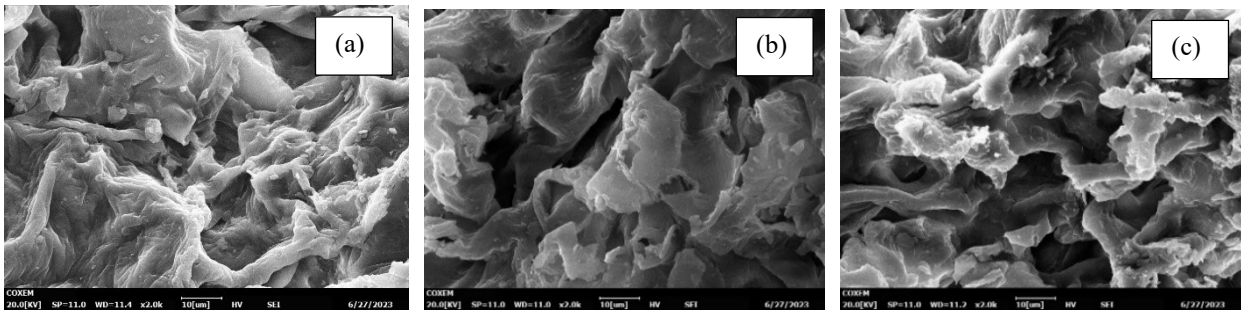

Figure 2. Photograph of SEM of (a) *kaffir lime* powder before extraction, (b) residual powder after extraction using methanol, and (c) residual powder after extraction using petroleum benzine

Phytochemical qualitative analysis

Phytochemical screening was performed to determine the secondary metabolites in the *kaffir lime* essential oils. Phytochemical qualitative analysis results are summarised in Table 2. The positive symbol (+) indicated the presence of phytochemicals while the negative symbol (-) indicated the absence of the phytochemicals in the EOs extracted by methanol and petroleum benzine. The difference in phytochemical results obtained might be due to polarity of the extraction solvent [22]. All secondary metabolites were present in the methanol extract Eos, except saponin and protein. Meanwhile, only alkaloids and terpenoids were present in the petroleum benzine extract EOs. This was because the polar solvent had a higher ability to increase cell permeability and penetrate inside the cell of a plant as compared to the non-polar solvent, and thus extract more endocellular secondary metabolites. Meanwhile, the non-polar solvent only dissolved lipophilic compounds, including terpenoids, alkaloids, alcanas, waxes, colour pigments and sterols due to the zero-polarity index; therefore, extracting fewer secondary metabolites [32].

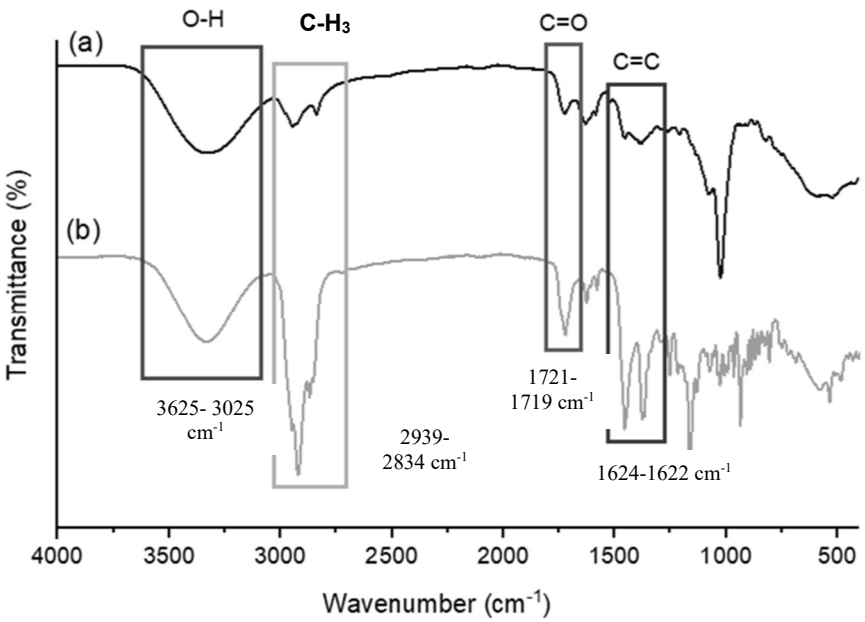
Table 2. Result of phytochemical qualitative analysis

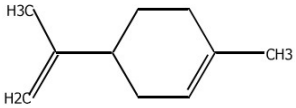
EOs	Result of Phytochemical Qualitative Analysis						
	Alkaloid	**Flavonoids**	**Terpenoids**	**Saponins**	**Tannins**	**Phenols**	**Proteins**
Methanol	+	+	+	-	+	+	-
Petroleum Benzine	+	-	+	-	-	-	-

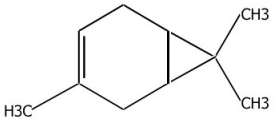
Fourier transform infrared (FTIR) spectroscopy analysis

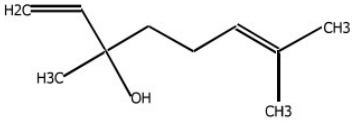
Figure 3 shows the comparison of FTIR peak configuration of EOs by using different extraction solvents: (a) methanol and (b) petroleum benzine. Similar functional groups with similar infrared absorption band intensities could be seen in both FTIR spectra. The broad peak at 3025 cm^{-1}-3625 cm^{-1} was attributable to the O-H bond stretching, indicating the existence of phenolic compounds such as terpinen-4-ol, citronellol or linalool [33]. Besides, the varied peaks at 2834 cm^{-1}-2939 cm^{-1} represented a considerable asymmetric stretching of CH_3, corresponding to an alkyl-saturated aliphatic group present in the compound [34]. The aldehyde, ester, carboxylic acid, or ketone groups were responsible for the C=O stretching at 1717 cm^{-1}-1721 cm^{-1} [34]. Furthermore, the peaks at 1622 cm^{-1}-1624 cm^{-1} contain an alkenes bond, which was a C=C stretching of aromatic rings caused by the presence of terpenes or terpenoid compounds such as D-limonene or citronellal [33]. According to Figure 3, petroleum extracts had higher intensity across all spectrum bands than methanol extracts, except O-H stretching. The solubility of a solvent might affect intensity of the peak. The polarity of functional groups in EOs can differ and the solvent of choice can have an impact on solubility and interactions of the solute and solvent. Non-polar compounds are generally more easily dissolved by non-polar solvents such as petroleum benzine [24]. It can dissolve more readily in petroleum benzine if the

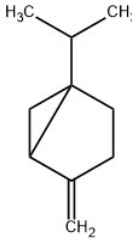
functional groups in the EOs are primarily non-polar or possess low polarity, which would result in larger intensity peaks in the FTIR spectra [35]. Comparatively, polar solvents like methanol might have a poorer affinity for non-polar functional groups, which might result in reduced solubility as well as lower oil yields [24]. Table 2 shows the fact that there were greater numbers of phytochemical groups found in methanol extracts. However, some of these compounds might not have adequate IR-active functional groups to produce strong FTIR signals. A change in dipole moment in the process of vibration will affect the infrared absorption [36]. If there is little or no change in dipole moment, the radiation only interacts with vibration, with relatively little or no absorption. The intensity of absorption increases with the shift of dipole moment [36].

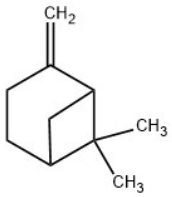


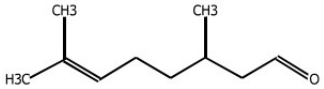


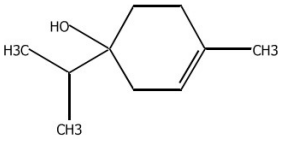


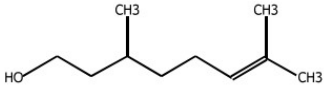


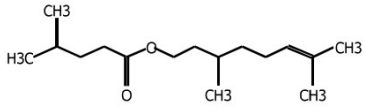


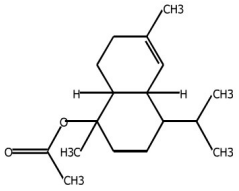


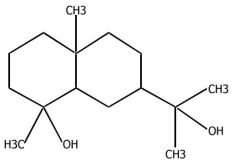












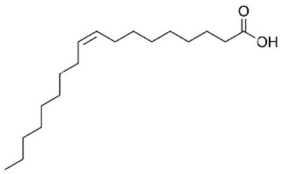


Figure 3. FTIR analysis of extraction of *kaffir Lime* essential oil using (a) methanol, and (b) petroleum benzine

Gas chromatography-mass spectrometry (GCMS) analysis

Table 3 and Figure 4 tabulate the identified chemical compounds with the different concentrations that contributed to the total EOs extracted by using methanol and petroleum benzine. Generally, the main components found from the EOs included D-limonene, β-pinene, 3-carene, linalool, citronellal, terpinen-4-ol, and citronellol. As a result, D-limonene, 3-carene, citronellol, citronellal and β-pinene were found in the EOs extracted from the *kaffir lime* peels [10]. From the result obtained, Compound 1 was a naturally occurring bicyclic monoterpene, whereas Compound 13 was a type of fatty acid. Both compounds extracted were considered non-polar compounds. However, the relative solubilities of Compound 1 and Compound 13 in both solvents might differ. Both compounds can only be solute in petroleum benzine. The terpenoid group was the majority chemical compound found in EOs. D-limonene could be considered the main component of methanol extract EOs, which provided a unique flavour, such as the smell of oranges. Previous research by [3] showed that the presence of β-pinene imparted a woody aroma to the oil, while citronellal indicated that the oil had antifungal properties and could; therefore, be used as an insect repellent.

Table 3. Chemical compounds in extracted *C. hystix* essential oil using methanol and petroleum benzine

No	Name of Compound	Structural Formula	Retention Time (min)	
			Methanol Extracts Oil	Petroleum Benzine Extracts Oil
1	Bicyclo[3.1.0]hexane, 4-methylene-1-(1-methylethyl)-		-	5.505
2	D-limonene		7.378	6.476
3	3-carene		7.690	7.005
4	Linalool		7.907	7.954
5	Sabinene		8.930	-
6	β-pinene		9.137	-
7	Citronellal		9.568	9.080
8	Terpinen-4-ol		9.879	9.646
9	Citronellol		10.548	10.595
10	Pentanoic acid, 4-methyl-,3,7-dimethyl-6-octenyl ester		12.946	12,889

11	Tau-Cadinol acetate		16.038	16.059
12	7-(2-Hydroxypropan-2-yl)-1,4a-dimethyldecahydronaphthalen-1ol		21.035	21.014
13	Oleic Acid		-	29.960

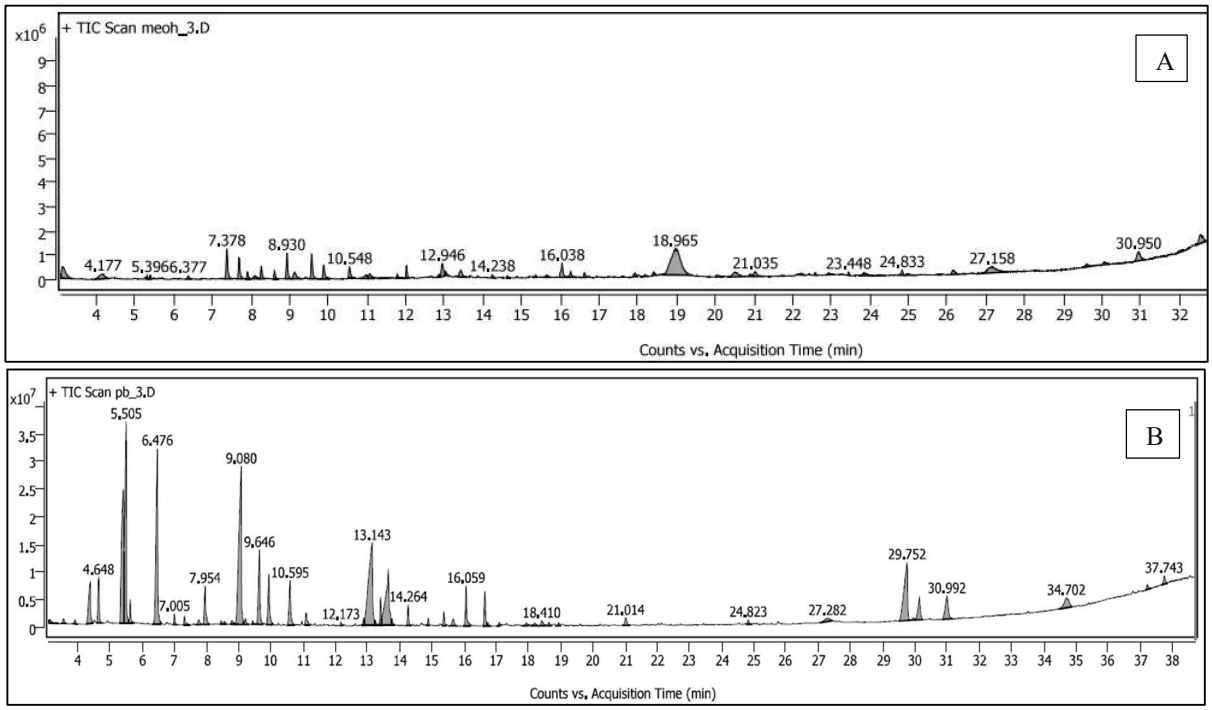

Figure 4. GCMS chromatogram of extracted *C. hystix* essential oil using (a) methanol, and (b) petroleum benzine

Conclusion

The extraction of essential Oil *C. hystrix (kaffir lime*), respectively, with methanol and petroleum benzine by using UAE was successfully studied. The percentage yield of EOs obtained for methanol extract was higher than petroleum benzine extract, which was 9.43% and 2.36%, respectively. Methanol extracted more compounds as compared to petroleum benzine due to the high polarity of solvent. Compounds that were extracted by using methanol were alkaloids, flavonoids, terpenoids, tannins and phenols while the compounds that were extracted by using petroleum benzine were only alkaloids and terpenoids. The screening phytochemical, FTIR and GCMS analyses proved that

D-limonene, β-pinene, 3-carene, linalool, citronellal, terpinen-4-ol, and citronellol were the main components found in *C. hystrix* essential oil.

Abstract

Coscinium fenestratum (Gaertn.) Colebr. (Menispermaceae) is a large woody liana found in moist deciduous to the evergreen forest at an altitude of 350–1200m. The stem and root of this species are highly medicinal valuable, and it is believed to be an endangered species in Malaysia. This study was conducted to investigate the reaction of methanol extract from *Coscinium fenestratum* with cancer cell lines, plant pathogenic bacteria, as well as DPPH scavenging and ferric reduction antioxidant power. The antibacterial activity was evaluated from disc diffusion method and microdilution method against soft rot bacteria *Erwinia chrysanthemi* and *Erwinia carotovora*. The cytotoxicity assay was performed using MCF-7 and Caco-2 cancer cell lines. The antioxidant properties of methanol extract were assessed from DPPH radical scavenging activity and ferric reducing antioxidant power (FRAP). The cytotoxicity activity revealed the methanol extract has potential to suppress the Caco-2 cell line with the percentage cell viability at 70% compared to MCF-7 cell line. The antioxidant activity from FRAP assay recorded its value of 47.8080 µg for TE/gDW and 13.8481 µg/mL for the IC_{50} from radical scavenging activity. However, the total flavonoid content (TFC) was not detected in methanol extract of *C. fenestratum*. The antibacterial assay revealed that the extract had moderately inhibited the growth of *E. chrysanthemi* and *E. carotovora* at 400 mg/mL, with inhibition zones of 11.50 mm and 11.83 mm, respectively. Therefore, the methanol extract from *C. fenestratum* has potential to act as antioxidant and anti-soft rot agent but less potential as anti-cancer agent and anti-soft rot agent.

Keywords: antibacterial, antioxidant, cytotoxicity, *Coscinium fenestratum*, plant pathogen

Abstrak

Coscinium fenestratum (Gaertn.) Colebr. (Menispermaceae), pokok liana berkayu besar yang ditemui dalam hutan daun luruh lembap hingga ke hutan malar hijau pada ketinggian 350–1200 m. Batang dan akar spesis ini sangat bernilai dalam bidang perubatan, dan ia dipercayai spesis terancam di Malaysia. Kajian ini bertujuan untuk mengkaji tindakan ekstrak metanol daripada *Coscinium fenestratum* bertindak balas dengan garisan sel kanser, bakteria patogen tumbuhan serta penghapusan DPPH dan kuasa antioksidan penurunan ferik (FRAP). Aktiviti antibakteria dinilai daripada kaedah resapan cakera dan kaedah pencairan mikro terhadap bakteria reput lembut *Erwinia chrysanthemi* dan *Erwinia carotovora*. Ujian ketoksikan sel telah diadakan menggunakan garisan sel kanser MCF-7 dan Caco-2. Sifat antioksidan ekstrak metanol dinilai daripada aktiviti penghapusan radikal DPPH dan kuasa antioksidan penurunan ferik (FRAP). Aktiviti ketoksikan sel mendedahkan ekstrak metanol berpotensi untuk menindas garisan sel Caco-2 dengan peratusan daya maju sel pada 70% berbanding garisan sel MCF-7. Aktiviti antioksidan daripada ujian kuasa antioksidan penurunan ferik mencatatkan nilainya sebanyak 47.8080 µg TE/gDW manakala 13.8481 µg/mL untuk IC_{50} daripada aktiviti penghapusan radikal. Walau bagaimanapun, jumlah kandungan flavonoid (TFC) tidak dikesan dalam ekstrak metanol *C. fenestratum*. Ujian antibakteria mendedahkan bahawa ekstrak telah menghalang pertumbuhan *E. chrysanthemi* dan *E. carotovora* secara sederhana pada 400 mg/mL dengan zon perencatan masing-masing 11.50 mm dan 11.83 mm. Oleh itu, ekstrak metanol daripada *C. fenestratum* berpotensi bertindak sebagai agen antioksida dan anti reput lembut tetapi kurang berpotensi sebagai agen anti kanser dan anti reput buah.

Kata kunci: antibakteria, antioksidan, ketoksikan sel, *Coscinium fenestratum*, patogen tumbuhan

Introduction

The cytotoxicity evaluation of plants is a vast subject in pharmaceutical studies, especially in cancer research area [1]. Methanol and methanol-water extracts of *C. fenestratum* was reported to exhibit antiproliferative activities in a concentration-dependent manner against human HT-1080 fibrosarcoma cells among the seventy-seven Vietnamese medicinal plants. The induction of apoptosis was the reason of selective activity against lung carcinoma and/or lung metastatic cell lines, A549, LLC and B16-BL6 and characteristic morphological change and DNA fragmentation that indicated the antiproliferative activity [2]. The berberine and its derivatives revealed potent anticancer activity against human fibrosarcoma cells (HT1080) using MTT assay [3]. Thai edible plant *C. fenestratum* which was extracted with 95% ethanol and tested with cytotoxic effects using Hep2 cells showed the remarkable result with high cytotoxic activity against the Hep2 cell lines at a minimum concentration of 0.05% in ethanol extract. In addition, it demonstrated the most potent cytotoxic extract based on its lowest IC50 (5 mg/mL) [4].

Previous study of antioxidant activity indicated that the berberine isolated from stem of *C. fenestratum* has higher IC_{50} value compared to its berberine derivatives contain phenolic groups which have lower IC_{50} values [3]. Recently, it was found that combinations of two or more medicinal plants extracts can effectively increase the anticancer activity of the synergistic effect between the phytochemicals, as they are found in trace amounts, whereas the attainment of a therapeutic effect requires higher doses [5].

The high berberine content in *C. fenestratum* is the main cause of its antimicrobial properties. There is a recent report on the potent antimicrobial activity of *C. fenestratum* extracts against five human pathogenic microbes [6]. Meanwhile, the aqueous extracts of *C. fenestratum* inhibited the in vitro growth of *Clostridium tetani*. Thus, it is consistent with its traditional use as a prophylactic against tetanus. Ethanolic extract of *C. fenestratum* stem has strong inhibitory effects against *Propionibacterium acnes* and *Staphylococcus epidermidis* and this was resulted from the presence of alkaloids berberine, which could be responsible for this activity. Berberine from *C. fenestratum* also showed anti-phytopathogenic fungal activity against various fungi like *Phytophthora parasitica*, *Pythium* spp., *Colletotrichum gloeosporioides, Cercospora* spp., *Fusarium oxysporum,* and *Alternaria porri* [7].

The antibacterial activity of methanol extract of *C. fenestratum* against soft rot bacteria, such as *Erwinia* species and cytotoxicity activity against Caco-2 cell line was not well documented; this is the main reason for conducting this study.

Materials and Methods

Preparation of methanolic extract from *C. fenestratum*

The preparation of methanol extract from *C. fenestratum* (CFM) has already been mentioned in a previous work [6].

Cytotoxicity study: Cancer cell line

The MCF-7 and Caco-2 cells were cultured in complete Dulbecco's Modified Eagle Media (DMEM) containing 10% fetal bovine serum (FBS) and 1% penicillin-streptomycin. The cells were maintained at 37 °C in a humidified atmosphere with 5% CO_2 atmosphere and sub-cultured every three to four days at approximately 80% to 90% of confluence.

Cell viability assay

The cell viability assay was measured using tetrazolium salt (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay according with some modifications. A total of 1.0–2.0 × 10^5 cells/mL were seeded in a 96-well plate overnight at 37°C with 5% CO_2 atmosphere. Then, the cells were treated with serial dilution concentrations of the extracts (3.125, 6.25, 12.5, 25, 50, and 100 µg/mL) in triplicate for 24 hours at 37 °C with 5% CO_2 atmosphere. Solvent (vehicle) used to dissolve the sample was used at a final concentration of < 0.1%, which does not affect the viability of cells. After 24 hours, all media were discarded and 30 µL of MTT solution (5 mg/mL MTT in PBS) was added into each well. After four hours of incubation with MTT solution, the formazan crystals were dissolved in 100 µL DMSO and left in the dark at room temperature for an additional one hour. The absorbance measured at 570 nm and 630 nm used as reference wavelength was performed using a microplate reader (TECAN infinite M200). The wells with untreated cells were taken as the control and wells with medium with 0.1% (v/v) of DMSO were used as solvent control. Results were expressed as a percentage of the average absorbance of sample treated cells with respect to untreated ones. Percentage of cell viability (%) was calculated using the following equation 1:

$$\text{Cell viability (\%)} = \frac{(\text{Absorbance of treated cell} - \text{Absorbance blank})}{(\text{Absorbance of untreated cell} - \text{Absorbance blank})} \times 100 \quad (1)$$

Statistical analysis

Data were performed in three replicates, where Microsoft Excel was used to perform graphical representation.

Antioxidant activity: Total flavonoid content (TFC)

Total flavonoid content was determined following the method described in literature. Distilled water (100 µL) was added to each of the 96 wells, followed by 10 µL of 50 g/L $NaNO_2$ and 25 µL of sample solution. After five minutes, 15 µL of 100 g/L $AlCl_3$ was added to the mixture. Six minutes later, 50 µL of 1 mol/L NaOH and 50 µL of distilled water were added. The plate was shaken for 30 s in the plate reader prior to absorbance measurement at 510 nm. The sample was measured against a mixture of DMSO instead of the extract as blank, and the absorbance was subtracted from the absorbance of 25 µl of extract and 225 µl of water. Catechin at a final concentration ranging from 2.125–100 µg/mL was used to generate a calibration curve.

DPPH radical scavenging activity

The method of radical scavenging activity assay was adapted from previous report [8]. All the extracts and standard ascorbic acid were two-fold serially diluted from 400 ug/mL to 12.5 ug/mL. The mixture of 1 mL of each extract and 3 mL of 0.004% DPPH solution was prepared and kept in a dark place for 30 min. The absorbance of all samples was measured at 517 nm using a spectrophotometer, and the percentage of scavenging activity was calculated as follows:

$$\text{Scavenging activity (\%)} = A0 - A1/A0 \times 100 \quad (2)$$

where, A_0 represents the DPPH control absorbance, and A1 represents the extracted/standard sample absorbance.

Ferric reducing antioxidant power (FRAP)

An amount of 455.30 mg of anhydrous sodium acetate was dissolved with 50 mL of distilled water. Then, 3.97 mL of glacial acetic acid was added, and finally the

mixture was diluted to 250 mL to prepare acetic acid buffer solution at a concentration of 0.30 mol/L. TPTZ weighing 156.20 mg was taken using a chemical balance, dissolved with distilled water, and 0.17 mL of concentrated hydrochloric acid was added. The solution was diluted to 100 mL to prepare TPTZ solution at a concentration of 10 mmol/L. $FeCl_3 \cdot 6H_2O$ weighing 270.03 mg was dissolved with H_2O and diluted to 50 mL. The concentration of $FeCl_3$ solution was 20 mmol/L. Acetic acid buffer, TPTZ solution, and $FeCl_3$ solution were mixed according to the ratio (10:1:1). Then, the mixture was incubated at 37°C. The working solution must be used up within 1–2 h. Next, 180.0 µl FRAP working solution was mixed with 5-µl sample in a 96-well plate. The mixture was shaken and incubated at 37°C for 15 min in the dark. The absorbance was measured at a wavelength of 593 nm. Trolox was used as the standard, while distilled water as the blank control. Trolox concentration was selected under the condition of absorbance value ranging from 0.2 to 0.8 to generate a standard curve.

Antibacterial activity against plant pathogen: Disc diffusion method

The standardized cultured bacteria, *E. chrysanthemi* and *E. carotovora*, were prepared at an optical density (OD) of 0.1. An amount of 100 µL of standardized bacteria inoculum were swabbed on the solidified agar surface to initiate bacteria growth on the agar. Then, the sterile impregnated disc of *E. spiralis* leave extracts with concentrations of 400, 200, 100, and 50 mg/mL were aseptically placed onto the inoculated agar surface and incubated at room temperature for 24 hours. The tests were conducted in triplicate for each extract and repeated with standard disc ampicillin. The effectiveness of the extracts to act as antibacterial agent was evaluated based on the diameter of the inhibition zone (mm). The greater the inhibition zone, the higher the effectiveness of the extract towards bacteria.

Microdilution method

Minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) were determined by two-fold serial dilution method as described by Mogana et al. [9]. Standardized bacteria suspension were diluted with the ratio of 1:100 in nutrient broth. An amount of 180 µL of standardized inoculum was inoculated into each well of 96 well plate, followed by 20 µL of diluted extract to give a final volume of 200 µL with final concentration in each well ranging from 50 mg/mL to 0.024 mg/mL. The plates were incubated at room temperature for 24 hours. After incubation at room temperature, 20 µL of 0.5% 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2H-tetrazolium bromide (MTT) was added into each well to indicate bacterial growth. The dark-blue color will indicate microbial growth, whereas yellow color will reveal the inhibition of microbial growth. The concentration at which the yellow color appeared in the well at the first place indicates the MIC value of the sample. The mixture in the MIC well was streaked on fresh agar plate to ensure the disappearance of bacterial growth. The MBC value was determined from the well next to the well of MIC value.

Results and Discussion

***In vitro* cytotoxicity assay**

Cytotoxicity is defined as the toxicity caused due to the action of chemotherapeutic agents (natural or synthetic drug) on living cells. A cytotoxic agent is a substance that kill cells including cancer cell and may stop the cell from dividing and growing abnormal and may shrink the tumor cell. The cell viability assay was performed using MTT on MCF-7 and Caco-2 cells to evaluate the cytotoxic effects of methanol extract of *C. fenestratum* (CFM). The cells were treated with serial dilution concentrations of the extracts at 3.125, 6.25, 12.5, 25, 50, and 100 µg/mL in triplicate for 24 hours. Table 1 shows the cell viability (%) value of the extract for each concentration and standard deviation. Results from Table 1 and Figure 1 indicate that all concentrations treated on MCF-7 cancer cell line was unable to reduce the cell proliferation until at highest concentration 100 ug/mL. However, according to Figure 2, the percentage of cell viability of Caco-2 cell line was slightly reduced to 70%, as the concentration of CFM increased. This salient information reveals CFM as a potent extract to inhibit Caco-2 cancer cell proliferation. The result against Caco-2 cancer cell line might be due to the abundant presence of phytochemical alkaloid in CFM [6], which is also antioxidative. A previous study also found terpenoid, phenolics, and saponin in CFM, where their presence may possibly contribute to the potent

cytotoxicity effect against Caco-2 cell line. Previous investigation by [10] reported the promising cytotoxicity effect of alkaloidal extract from *Peganum harmala* and the findings of the current study agree with their report, as the CFM is also an alkaloidal extract. Unfortunately, the combination of alkaloid, phenolic, terpenoid, and saponin in CFM to provide synergistic effect still cannot inhibit the MCF-7 cell proliferation well enough.

IC_{50} is recognized as the inhibition concentration of substance for 50% of cell growth. According to Table 2, CFM needed high concentration to inhibit 50% of cell growth for both MCF-7 and Caco-2 cell lines at 3381 µg/mL and 176.2 µg/mL, respectively. In comparison between both cell lines, CFM is considered a good inhibitor against the Caco-2 cell line.

Table 1. Cell viability (%) value of CFM extract

Concentration of sample (µg/mL)	**Percentage of Cell Viability for MCF-7 Cell (%) ± SD**	**Percentage of Cell Viability for Caco-2 Cell (%) ± SD**
0 (untreated cells)	100.00 ± 0.287	100.00 ± 0.903
3.125	171.475 ± 1.614	95.709 ± 0.0574
6.25	167.527 ± 7.371	93.830 ± 0.343
12.5	146.327 ± 1.341	90.513 ± 0.308
25	146.148 ± 2.112	87.333 ± 0.298
50	131.089 ± 0.473	85.170 ± 1.426
100	116.583 ± 3.005	70.014 ± 2.572

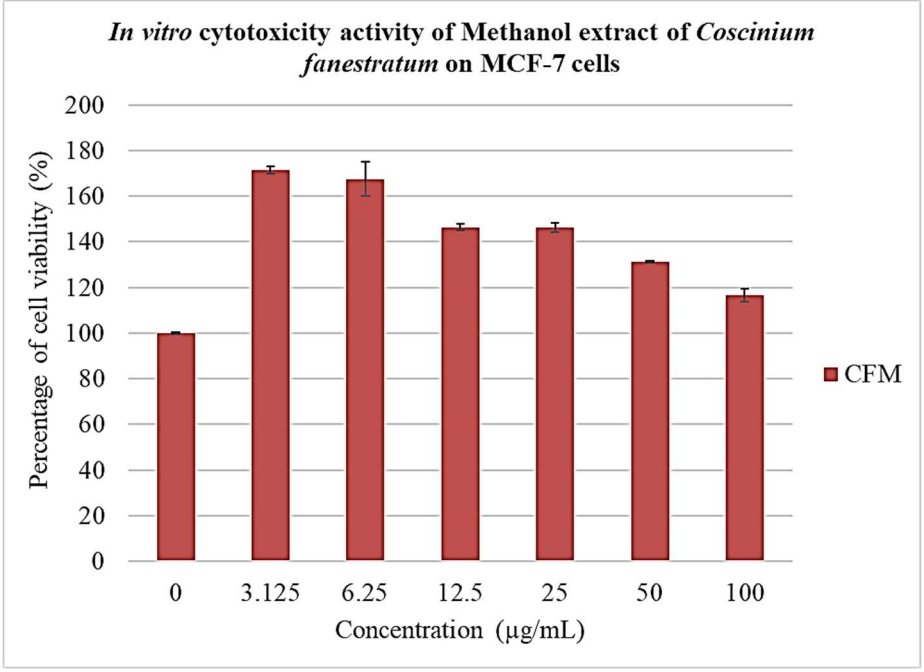

Figure 1. The percentage of cell viability of MCF-7 cells measured by MTT assay treated with CFM extract at the concentration of 3.125 to 100 µg/mL for 24 hours.

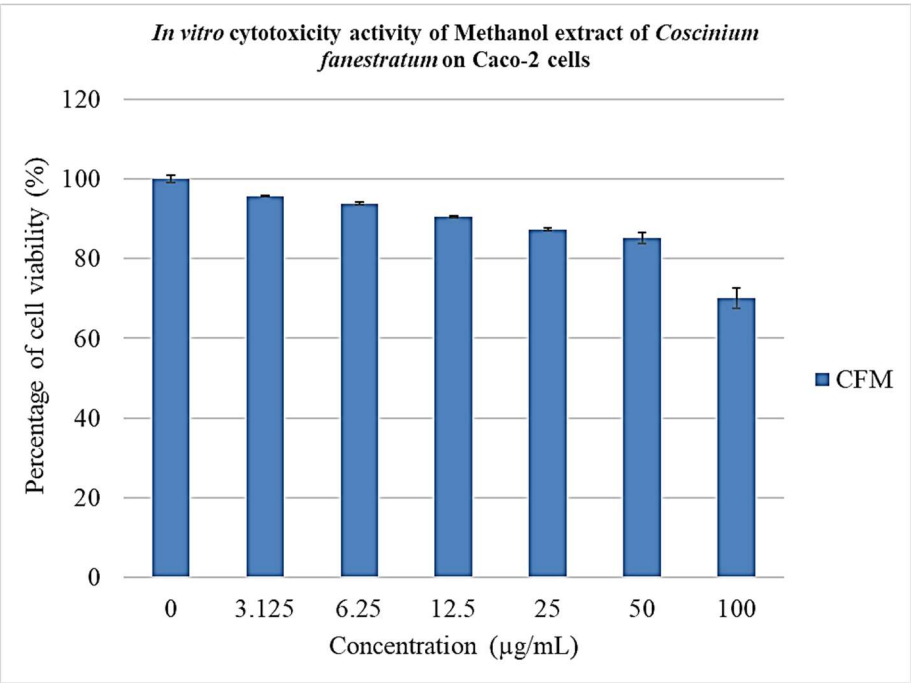

Figure 2. The percentage of cell viability of Caco-2 cell measured by MTT assay treated with CFM extract at the concentration of 3.125 to 100 µg/mL for 24 hours

Table 2. IC_{50} values of methanol crude extract of *C. fenestratum* and standard drug on MCF-7 and Caco-2 cell

Crude	IC_{50}, ug/mL (MCF-7)	IC_{50}, ug/mL (Caco-2)
CFM	338.1 ± 0	176.2 ± 0
Tamoxifen	0.4 ± 0.3	-

CFM: Methanol extract of *C. fenestratum*

Antioxidant activity

The FRAP assay is used to measure the antioxidant power based on the reduction at low pH of ferric-tripyridyltriazine (Fe^{3+}-TPTZ) to an intense blue color ferrous-tripyridyltriazine complex (Fe^{2+}-TPTZ) with an absorption maximum at wavelength 593 nm. Any changes from colorless Fe^{3+} to blue colored Fe^{2+}-tripyridyltriazine solution indicate the action of electron donating antioxidant. The FRAP value of CFM depicted in Table 3 is calculated as 47.8080 ug TE/gDW, and this value demonstrates high antioxidant power of CFM to reduce Fe^{3+} to Fe^{2+} ion. The IC_{50} value indicates the concentration of substance to scavenge 50% DPPH radical. The lower the IC_{50} value, the better the antioxidant activity is. The lower IC_{50} value of CFM at 13.8414 µg/mL revealed the remarkable potential of CFM as antioxidant agent. Moreover, this IC_{50} value is comparable with IC_{50} value of standard ascorbic acid 10.8520 µg/mL. Previous investigation [6] reported the total phenolic content (TPC) of CFM at 12.722 mg GAE/g sample, which could be one of the reasons for antioxidant properties of CFM. However, the presence of major phytochemical alkaloid and other phytochemicals, such as terpenoid and saponin [6], must not be underestimated on their contribution to antioxidant power.

Table 3. Total flavonoid content (TFC), DPPH radical scavenging activity, and ferric reduction antioxidant power (FRAP) of *Coscinium fenestratum* methanol extract

Antioxidant Activity	Methanol Extract of *C. fenestratum*	Ascorbic Acid
Total flavonoid content, (mg CE/g) (TFC)	–1.8595 ± 0.1878 (Not detected)	ND
Ferric reducing antioxidant power (ug TE/gDW)	47.8080 ± 0.4834	ND
DPPH scavenging IC50 (ug/mL)	13.8414 ± 0.1282	10.8520 ± 0.2716

Antibacterial activity

The antibacterial activity of CFM as anti-soft rot agent against two soft rot bacteria *E. chrysanthemi* and *E. carotovora* was illustrated in Table 4 and 5. This antibacterial data is the first time reported using *C. fenestratum* against *E. chrysanthemi* and *E. carotovora*. Generally, CFM extract moderately inhibited the growth of both bacteria in a concentration dependent manner (Table 4). The inhibition zone for both bacteria is not significant as the inhibition zone at 400 mg/mL is recorded as 11.5 mm and 11.83 mm. The presence of phytochemicals terpenoid and saponin [6] are believed to synergistically build the inhibitory effect on both bacteria. According to previous study [11], it was found that the growth of *E. chrysanthemi* was suppressed when using plant species, such as *E. spiralis* with inhibition zone of 16.3 mm, however the effectiveness of this plant towards *E. carotovora* was not reported. According to MIC and MBC value in Table 5, CFM is more effective to inhibit the growth of *E. carotovora* by 50% growth at MIC 15.625 µg/mL compared to *E. chrysanthemi* which is at 125 µg/mL. This means *E. carotovora* was more susceptible towards the CFM compared with *E. chrysanthemi*. The inhibitory effect was attributed with the hydroxyl group from saponin in which this group penetrated and shrunk the cell wall, and finally leading to the death of the cell [12, 13]. Previous report revealed the function of terpenoid as a plant defense to control plants from pathogen and pest and thus, prolonging the plant's lifetime [14,15].

Table 4. Antibacterial bacterial activity of methanol extract of *C. fenestratum* against *E. chrysanthemi* and *E. carotovora* from disc diffusion method

Concentration (mg/mL)	*E. chrysanthemi* inhibition zone ± SD (mm)	*E. carotovora* inhibition zone ± SD (mm)
400	11.5 ± 0.5	11.833 ± 0.29
200	6.833 ± 0.29	6.5 ± 0
100	7 ± 0	6. ± 0
50	6 ± 0	6 ± 0

Table 5. Minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) of methanol extract of *C. fenestratum* from microdilution method

Bacteria	MIC (µg/mL)	MBC (µg/mL)
E. chrysanthemi	62.5	125
E. carotovora	15.625	31.225

Conclusion

The methanol extract from *C. fenestratum* (*akar sekunyit*) is concluded to have good potential as an antioxidant source but less potential as an anti-cancer agent against breast cancer and colon carcinoma cell line, as well as an anti-soft rot agent. Regarding future work, it is recommended to use other types of antioxidant assays, such ORAC, ABTS, and CUPRAC, to establish its antioxidant power. Various anticancer cell lines, as well as plant pathogens, can be applied to evaluate its function in a broad spectrum of bioactivity. Isolation and identification of berberine alkaloid may also be conducted in the future.

Acknowledgment

The authors would like to express their gratitude to the science laboratory staff at Universiti Teknologi MARA (UiTM) Pahang and Assoc. Prof. Dr. Norazian Mohd Hassan from IIUM Kuantan for their assistance throughout this research.

Abstract

The effectiveness of the electrochemical technique to remove methylene blue (MB) from its aqueous solution was demonstrated in the current investigation. Various electrodes were used to explore the electrochemical process namely: aluminium (Al), copper (Cu) and carbon cloth (CC) as anode while the cathode was carbon cloth to select the highest removal%. Carbon cloth was selected as the best electrode due to its high efficiency for removal of MB dye compared to others. The effects of applied voltage, electrolysis time, and sodium chloride were investigated to identify the optimal conditions. Response surface approaches were used, however, to fully conceptualize how the factors interacted and get the best methylene blue dye elimination percentage using the electrochemical process. Rate constants ranged between 0.163 and 0.345 min^{-1}, demonstrating that high-rate constant accompanied pseudo first order kinetics, which was the dominating model throughout the investigation with high applied voltage and NaCl amount. Consumption energy was considered and measured; it was 0.104 Wh/mg at the maximum value applying 5 V referring that high consumption energy followed by high applied voltage. Utilizing response surface methodology (RSM), the electrochemical operating factor was optimized. The influence of NaCl addition rate, treatment time, and applied voltage were analysed using the optimum model derived from Box-Behnken Design (BBD), which was quadratic with MB removal (R^2 = 0.9447).

Keywords: methylene blue, electrochemical process, carbon cloth anode, energy consumption, pseudo first order kinetics

Abstrak

Keberkesanan teknik elektrokimia untuk mengeluarkan metilena biru (MB) daripada larutan akueusnya telah ditunjukkan di dalam kajian semasa. Pelbagai elektrod digunakan untuk meneroka proses elektrokimia iaitu: aluminium (Al), kuprum (Cu) dan kain karbon (CC) sebagai anod manakala katod adalah kain karbon untuk memilih penyingkiran tertinggi%. Kain karbon dipilih sebagai elektrod terbaik kerana kecekapannya yang tinggi untuk menanggalkan pewarna MB berbanding yang lain. Pemalar kadar berjulat antara 0.163 dan 0.345 min^{-1}, menunjukkan bahawa pemalar kadar tinggi mengiringi kinetik tertib pertama pseudo, yang merupakan model yang mendominasi bagi penyiasatan dengan penggunaan voltan tinggi dan jumlah NaCl. Penggunaan tenaga telah dipertimbangkan dan diukur; ia adalah 0.104 Wh/mg pada nilai maksimum menggunakan 5 V merujuk tenaga penggunaan tinggi diikuti dengan voltan gunaan tinggi. Dengan menggunakan kaedah permukaan tindak balas (RSM), faktor pengendalian elektrokimia telah dioptimumkan. Pengaruh kadar penambahan NaCl, masa rawatan, dan voltan gunaan dianalisis menggunakan model optimum yang diperolehi daripada Reka Bentuk Box-Behnken (BBD), iaitu kuadratik dengan penyingkiran MB (R^2 = 0.9447).

Kata kunci: metilena biru, proses elektrokimia, kain karbon anod, penggunaan tenaga

Introduction

It is very well known that harmful dyes are the main source of water contamination then it is considered as environmental issue concern [1]. Dyes in different names and applications are the dominant source for threaten water bodies as it is used in a variety of industries, including tanneries, paper mills, textile, leather, plastics, painting, food preserve, and pharmaceuticals [2-5]. Dyes are caused cancer and it is also participated to harm human health and animal. Their impact also extends to threaten aquatic life and environment [6-9].

The main constituent of textile industrial effluent is dyes, so it was characterised as high oxygen demand and resistant to biological treatment. Consequently, it requires extra treatment process which is tertiary treatment process [10]. One of these dyes is methylene blue which is water soluble, and it used in acid-base titrations and biological stains [11, 12, 9]. As seen in Figure 1, methylene blue is an organic chloride salt that contains 3,7-bis(dimethyamino)phenothiazine-5-ium.

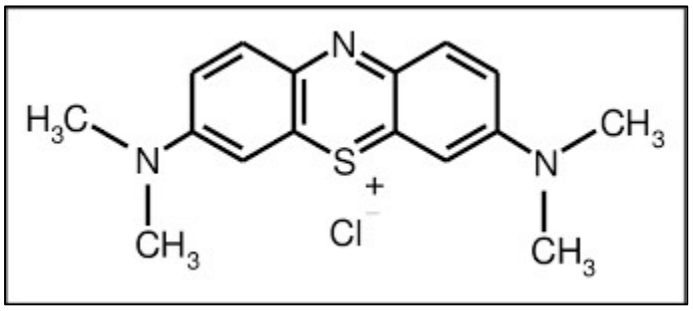

Figure 1. Chemical structure of methylene blue dye

The method most frequently employed to eliminate colour from aqueous solutions is electrochemical elimination. In contrast to other processes like photocatalysis, adsorption, membrane filtration, and reverse osmosis, the electrochemical process is simple to use, highly effective, technologically advanced, and safe. Other treatment methods like reverse osmosis, adsorption, and photocatalytic degradation were said to have certain drawbacks, such as the length of time needed for dye removal, issues with secondary pollutants, and a high cost of operation. The technologies have not shown to be particularly efficient or advantageous from an economic standpoint in eliminating colour from dye effluent [13]. However, the high prices and insufficient degradation of photocatalysis, Fenton-like processes, and ozonation processes continue to be a barrier [14]. Photocatalysis, one of the most advanced oxidation technologies, is one

of the most efficient processes because it uses an efficient semiconductor under UV/visible light irradiation and doesn't need additional chemicals or oxidants (atmospheric oxygen) to start the reaction. It is most likely among the AOPs with the highest efficiency and lowest cost [15]. The adsorption technique, on the other hand, is one of the successful methods that have been used to remove methylene blue dye due to its low cost, high efficiency, and simple operation. However, these treatment methods demand time and considerable effort to be effective [16].

The water cycle is so necessary to contaminant removal from wastewater's water system. Regarding the rigid structure of dyes, its removal from wastewater requires many steps for this purpose thus it is considered big challenge task. As we know, the main steps in wastewater treatment system are pretreatment, physical, chemical, and biological processes are reflected in the primary, secondary, and tertiary treatments, respectively according to the type of wastewater plant and target pollutants. As reported previously, conventional wastewater plants are ineffective for degradation dyes or other resistant-organic pollutants from water, resulting in other by-products more toxic than the parent compounds [17, 18]. Consequently, to avoid the issues that are linked with the conventional wastewater treatment plants, the application of advanced oxidation processes (AOPs) is the observed indication [19, 20]. These active degradation processes are able to be produced more effectively using an oxidizing agent like ozone or hydroxyl radicals to clean up the organic pollutant. After biological treatment, advanced oxidation processes can be used to get rid of the recalcitrant organic pollutants that are resistant toward the biodegradation treatment as well as to reduce the content of residual organic species.

Among the AOPs technologies such as ozonation treatment process [21], photocatalytic degradation process [22, 23], and sono-photocatalytic oxidation process [24] and electrochemical degradation process which is one of the promising technologies for its ability in remediation of organic pollutant compounds [25, 26]. Electrochemical degradation process is a promising technology due to its various benefits, which include its low cost, easy to operate, environmental compatibility and safe [20]. Anode material has interested property to assess the efficiency of electrochemical degradation method and it is considered a critical factor for this purpose [27]. However, two types of electrochemical reactions, direct and indirect electrochemical oxidation process as reported in details [28]. Electrochemical oxidation process may vary depending on the working principle. When it starts with pollutants degradation by anodic electrodes attracting the pollutants towards the anode. Following this Principle is called Direct electrochemical oxidation. On the other hand, it may be carried out by eliminating the compounds in the bulk solution concomitantly with active and strong oxidation agents like chlorine and hypochlorite [29]. Preparation of chlorine, chloride, and hypochlorite is according to the following equations:

$$2Cl^- \rightarrow Cl_2 + 2e^- \quad (1)$$

$$Cl_2 + H_2O \rightarrow H^+ + Cl^- + HOCl \quad (2)$$

$$HOCl \leftrightarrow H^+ + ClO^- \quad (3)$$

The main disadvantage in direct anode oxidation is that weaking the activity of the anode surface through fouling leading [30]. However, indirect anode oxidation is the most common for treatment of organic pollutants using boron-doped diamond (BDD) as anode [31], mixed metal oxide electrodes [32, 33] and graphite-PVC composite [34]. One of the most used electrode materials for the treatment of contaminants is BDD anode, but its high cost participates to avoid its wide application. Other materials have long-term stability issue, low degradation efficiency depending on the pollutant substrate. The most important characteristic of electrochemical oxidation process is that anodes must exhibit good evolution of oxygen to make the efficiency of electrochemical process less and the consumption of energy is high during the electrochemical process of wastewater treatment process [35].

Some process parameters were affecting electrochemical performance including electrolyte amount, applied voltage and electrolysis time. These factors were optimized conventionally by carrying a set of experiments for each factor to ensure higher

efficiency with lowest costs [36]. The literature showed that the classic optimization not effective enough to balance the optimization between the different operational factors, but treat each factor separately, but it requires a long time and effort to manually integrate between the factors [37, 38]**.** In order to facilitate the overlapping of optimal factors, a multivariable statistical technique was commonly used, which replaces the traditional methods with higher efficiency, reduces operating expenses and guarantees shorter treatment times [39]. A statistical method called response surface methodology (RSM) may be followed to study higher number of variables with lower number of experiments [40]**.** It was applied by [41] in electrocoagulation and electro-Fenton optimization for POME removal with iron and aluminium electrodes. This study aims to (i) investigate the optimum combination of electrodes (Anode – Cathode) for MB removal with electrochemical method, (ii) to optimize the most influencing factors including electrolyte amount, applied voltage and electrolysis time using response surface methodology-BBD design to achieve maximum MB dye removal efficiencies.

Materials and methods

Reagents and chemicals

Pure standards (≥98%) of methylene blue (CAS no. 61-73-4) was bought at Sigma-Aldrich (St. Louis, MO). The provider of deionized water (DIW) was EASYPure RODI (Thermo Fisher Scientific, Waltham, MA). UV-visible spectrophotometer was used for sample analysis. Copper (CAS No. 7440-50-8) sheet with 0.25 mm of thickness and 99.98% trace base metal was purchased from Merck.

Standard methylene blue dye preparation

Methylene blue stock solution (1000 mg/L) was diluted in de-ionized water and kept at 4 °C. By varying the amount of NaCl (Merck, Germany) added to MB solutions, the conductivity could be changed.

Set up of electrochemical process

A Pyrex glass vessel (100mL) was used for all analysis/A Pyrex glass electrochemical cell (reactor) was placed on top of a magnetic stirring block. Electrochemical cell setup, as shown in Figure 2.

The electrochemical cell was a glass container involved two electrodes for degradation of methylene blue at normal conditions: 1.0 atm and 20±2 ℃. The working electrode (anode) and the counter electrode (cathode) were carbon cloth in dimensions of 1cm × 1cm (1 cm^2). The gap between two electrodes was kept constant of 2 cm and both connected to the DC power supply which is working at fixed current in all electrochemical experiments. The concentration of dye was 10 mg/L in deionised water, it was prepared from the stock solution (1000 mg/L) after serial dilutions. Different concentrations of the electrolyte (NaCl) were infused into the mixture then was stirred at 500 rotation per minute under magnetic stirred device to ensure complete mixing and distribution of dye and salt in the solution. At each treated sample the corresponding current between the electrodes was recorded as well as the temperature was also monitored. The collected samples were directly analysed and the methylene blue degradation rate was measured in terms of reducing colour removal of dye at wavelength of 660 nm using UV-Visible spectrophotometry, and the range scan is between 400 to 800 nm. Three applied voltages of 2, 3 and 5 V were tested in electrochemical removing of methylene blue at fixed NaCl amount of 0.5g.

The influence of sodium chloride concentration (0.1, 0.3 and 0.5g) on the electrochemical removal of methylene blue (10 mg/L) using CC as anode at fixed 5 V was investigated. All absorbance measurements of methylene blue dye are converted into concentration using a linear calibration curve (R^2 = 0.996).

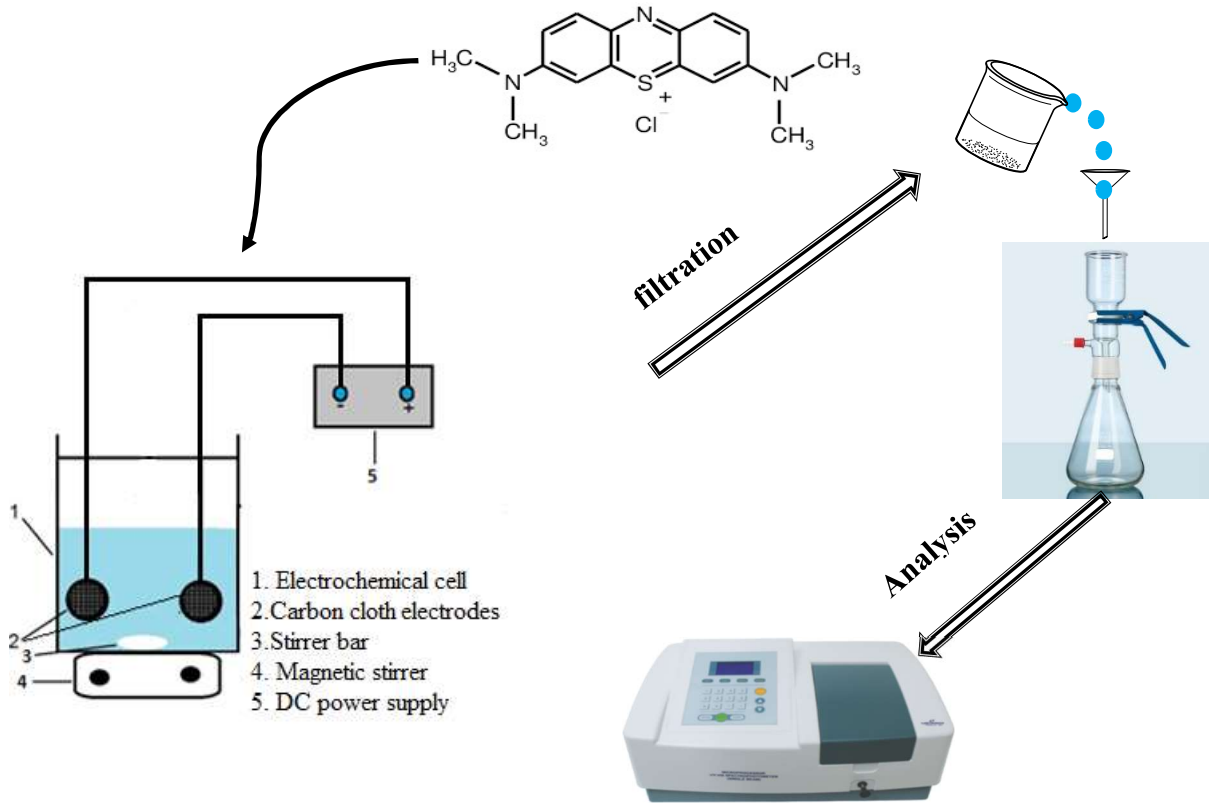

Figure 2. Electrochemical cell setup

Morphology and electrochemical characterizations of carbon cloth

The morphology and electrochemical characterizations of carbon fabric were investigated using powder X-ray diffraction (XRD, GBC MMA XRD), high-resolution transmission electron microscopy (HR-TEM, model: JEOL JEM-2011) and field emission scanning electron microscopy (FESEM, JEOL JSM-7500FA). The acceleration voltage is 15 kV and the beam current is 700 pA. All samples after treatment were analysed using U-visible spectrophotometer under maximum wavelength of 668 nm.

Box-Behnken design

Three parameters have been investigated on elimination of methylene blue dye using three-level Box-Behnken Design (BDD) namely: electrolyte amount, applied voltage and electrolysis time. Table 1 present the three parameters with their values which were processed in 45 runs and 9 centre points. The total number of experiment sets were calculated using the following equation [40]**:**

$$N = 2K(K-1) + C_0 \quad (4)$$

where C_0 is the number of a central point and K is the number of factors. The statistical studies were conducted using the Design Expert regression tool (Version MINITAB statistical software package).

Table 1. Levels and ranges of independent variables

Variable	Factors	Level		
(unit)	X	-a	0	+a
NaCl amount (g)	A	0.1	0.3	0.5
Applied voltage (V)	B	1	3	5
Electrolysis time (min)	C	4	8	12

Results and Discussion

The results presented here could introduce the efficiency of electrochemical degradation of MB via producing an active species that are strong oxidants (ClO^-). One of these active species was chloride which is presented in wastewater or added to the wastewater. Through an oxidation process at the anode electrode, these chloride ions can be converted into active chlorine (Cl_2, HOCl, and ClO). These oxidants have a long-life time to achieve the required oxidation of methylene blue dye.

Selection of electrode materials

Cu-CC, CC-CC, and Al-CC electrode material combinations were employed under the conditions of 5 volt for 20 minutes with 0.5g NaCl serving as the support electrolyte. Based on Figure 3, full elimination of MB (100%) was obtained using CC-CC electrode after 10 min; meanwhile, MB removal in terms of Cu-CC and Al-CC was 20% and 54%, respectively after 16 min. According to the statistical analysis, the electrode materials significantly affect the removal of MB (P= 0.05), according to the results. A report claims that copper anode material was an excellent option for the treatment of organic pollutants due to its antibacterial qualities, ease of ionization, high conductivity, and low toxicity [42, 43, 44].

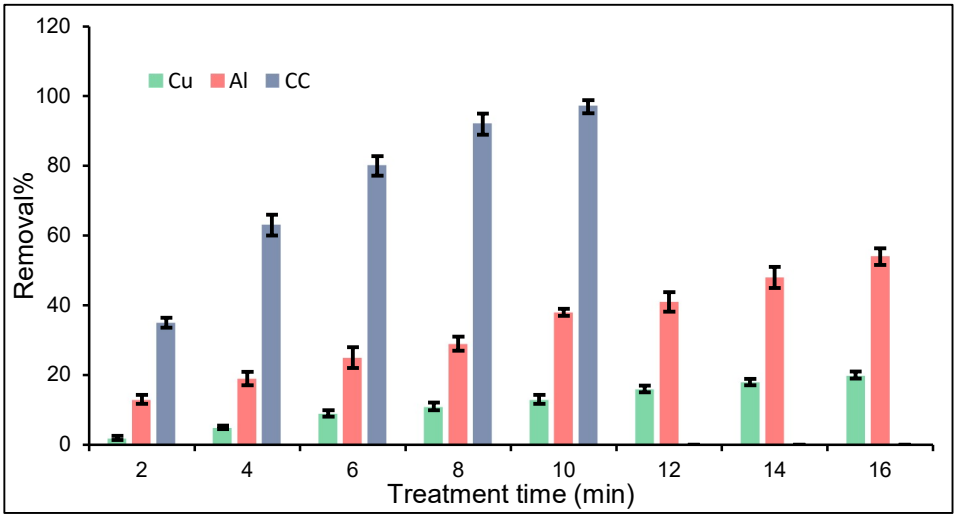

Figure 3. Selection of anode materials based on the removal% of methylene blue under these conditions: 5 V, 100 mL of solution, 5 mg/L of dye and 0.5 g NaCl

However, it was found experimentally that copper was easily corroded. In addition, the literature also showed that coper has low removal capability of MB which does not exceed (28%) [45]. As opposed to that, Al and carbon clothes were widely available with relatively low costs [46]. Furthermore, carbon clothes showed higher efficiency than Al in MB removal. The literature also supports this disadvantage of Al electrocoagulation used for POME removal with Al electrodes, the results indicated that only 42.94% of COD treated [47]. In addition, carbon clothes provide higher chemical stability, and better electrical conductivity [48]. Treatment of wastewater from poultry butcheries revealed that COD removal was 76% using graphite as anode [49]. Accordingly, the optimum electrodes combination used in this study were CC-CC based on methylene blue removal efficiency and stability of the electrolysis [50].

According to the previous report, MnO_2 based on a Pt electrode exhibited 90% removal of MB dye at the optimum conditions: pH =8, current density of 7 mA/cm^2, and supporting electrolyte of 0.05 mol/L [51]. From this point, Carbon cloth electrode exhibited a very good elimination% as shown from Figure 3.

To support the results above, characterization of carbon cloth has been investigated. The SEM image in Figure

4a, showed that the carbon cloth consists of a microstructure of embedded beam rods, this is a fictitious, two-dimensional artificial network made of organized tissue, where each fiber has a smooth surface and a constant 8.5 mm diameter. In addition, one of the characteristics of carbon cloth was that its fabric has excellent mechanical strength, flexibility, as well as high conductivity. Clear lattice fringes with 0.24 nm and 0.47 nm d-spacing, which correspond to (002) and (100) planes, are seen in Figure 4b. The pattern of electron diffraction (SAED) in the selected area, which demonstrates the crystalline nature of the porous carbon clothing, is shown in Figure 4c. However, the composition of the carbon cloth with the percentage has been included in Figure 4 d. It was observed that carbon is the major element in the sample. Consequently, the ease with which electrons and ions can approach the active surface is advantageous as it facilitates a rabid reaction producing higher power performance.

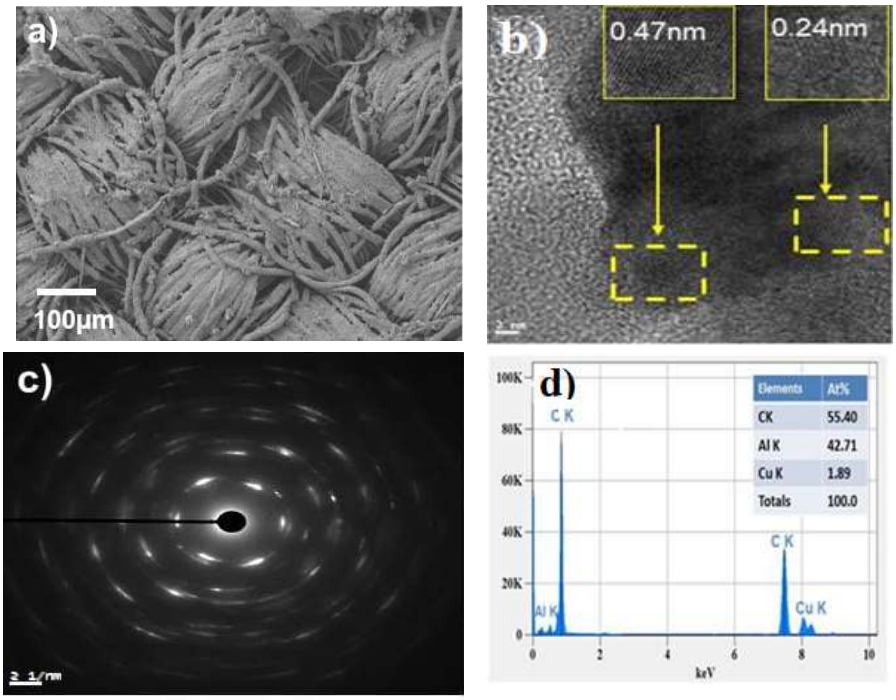

Figure 4. Characterization of carbon cloth: (a) SEM image, (b) TEM images at different magnifications of the carbon cloth (c) corresponding SAED pattern and (d) EDS analysis data for carbon cloth

The composition and phase purity of the carbon fabric were examined using the XRD pattern of the pure carbon cloth, as shown in Figure 5. The (002) and (100) planes of the carbon cloth substrate may be responsible for the acute and powerful diffraction peaks seen at 26 and 43.

Electrocoagulation modelling and optimization

Depending on the MB removal rate from the contaminated aqueous solution, the optimized operational factors of the electrochemical process were studied using three factor and three level BBD. The developed model was not much differing from the predicted values as the regression coefficient was (R^2 = 0.9447) with nine (9) center points. The experimental data for MB removal illustrated in Table 2 were then investigated and studied using analysis of variance (ANOVA). Using the values of P and F, a clear induction to the influence of an operational factor. Practical experiments have shown that using P and F values, the significance of the factors can be predicted with 95% accuracy. Higher significance obtained with a lower P (F Prob) value and a higher F value [52].

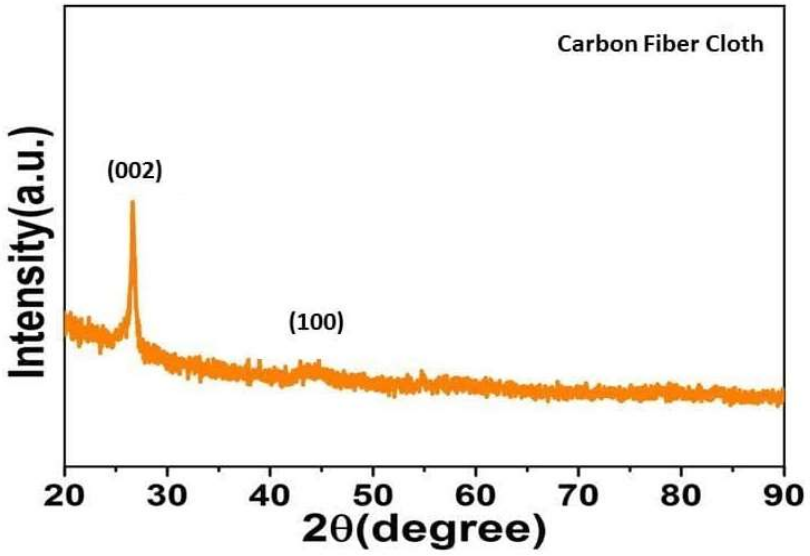

Figure 5. XRD Patterns of carbon cloth electrode

ANOVA findings showed that the F value for methylene blue dye elimination was high values, that means developed mathematical method exhibited good significance represented through preferred relationship between the response and external circumstances. Most model P values are less than 0.05, indicating that the mathematical models generated were significant. In addition, adjusted R^2 of the developed model is lower than R^2 (adjusted R^2 0.9305 < R^2 0.9447) which indicates the model has good quality. The effect of electrolyte amount (A), effect of applied voltage (B) and effect of electrolysis time (C) (p <0.05) are significant to remove MB dye.

In one reported paper, the removal of methylene blue dye was provided through a three-dimensional electrochemical process. It was observed that, through central composite design, the electrolysis time and applied voltage are the most significant factors in responses. However, initial concentration and pH factors are not significant [53].

In case of interaction factors, both interactions between (AC) and (BC) are significant meanwhile for the interaction between (AB) has no significant effect to remove MB dye. To find the relationship between each operational factor and the others, multiple regression analysis was carried out from BBD experiments. MB removal was modelled as a function of (time, electrolyte amount, and voltage) using second order polynomial equation as illustrated in (Equation 5):

$$R\% = -3.1 - 43.5\,A + 3.73\,B - 2.26\,C + 69.1A^2 + 0.108\,B^2 - 0.114\,C^2 + 6.88\,AB + 8.96 + 1.458\,BC \quad (5)$$

To evaluate the significance of each element and its relationships on treatment efficacy (%), Figure 6 shows the plot of the normal probability of the uniform effects with p = 0.05. The plot is divided into two different regions, (positive on the right side, and negative on the left side). The factors marked with red squares indicate their importance.

Table 2. The analysis of variance (ANOVA) for the second-order regression model

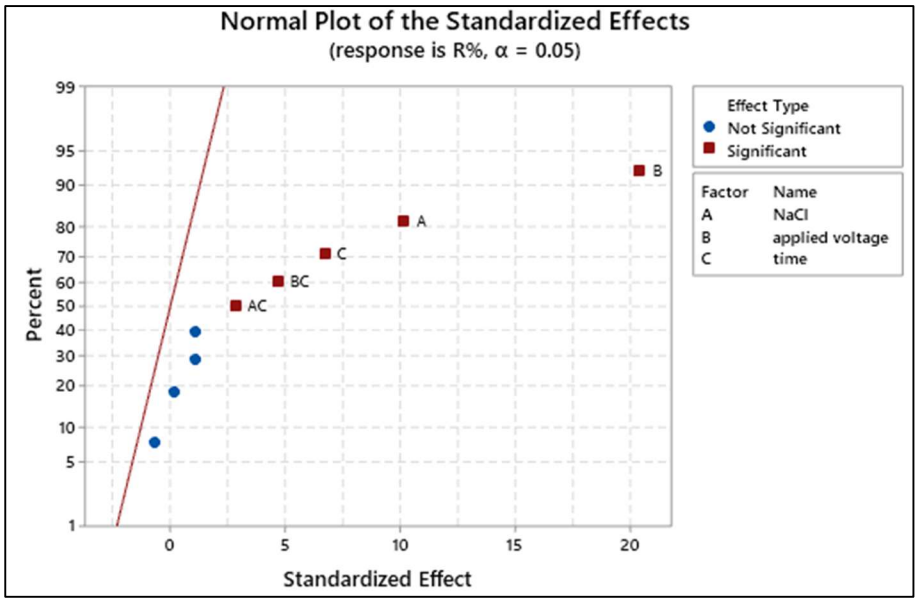

Figure 6. Plot of normalized probabilities for the impacts at p = 0.05 on removal% of MB dye

The relative importance of the individual and interaction effects was shown by the Pareto chart of the standardized effects in Figure 7. Student's t-test was used to confirm that the researched factors' impact was significantly higher than zero. The horizontal columns of a Pareto chart represented the importance of each effect. The lowest 95% confidence level statistically significant effect is shown by the vertical line (2.03) in the graph. Therefore, all values that are on the right side of the dashed line and are more than 2.03 (p = 0.05) are regarded as significant. The finding that MB removal is directly correlated with greater applied voltage, NaCl concentration, and treatment time is explained by the fact that raising these variables results in a sufficient amount of OCl^- acting as an oxidizing agent, directly assisting in the elimination of methylene blue. It is

noteworthy that the interaction between the factors (AC and BC) indicates a positive result associated with MB removal%. As a result, the effect of increasing NaCl or the applied effort relative to time leads to an increase in efficiency.

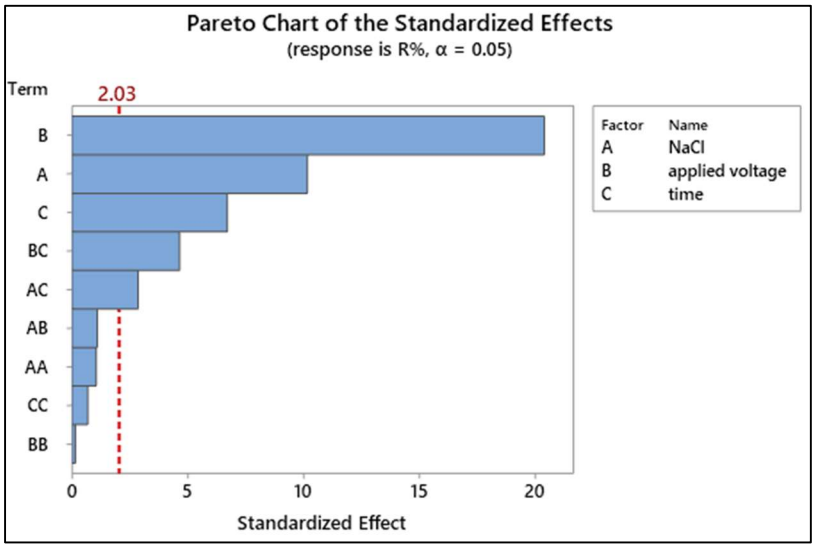

Figure 7. Chart demonstrating Pareto's standardized impacts on the percentage of removal of MB dye

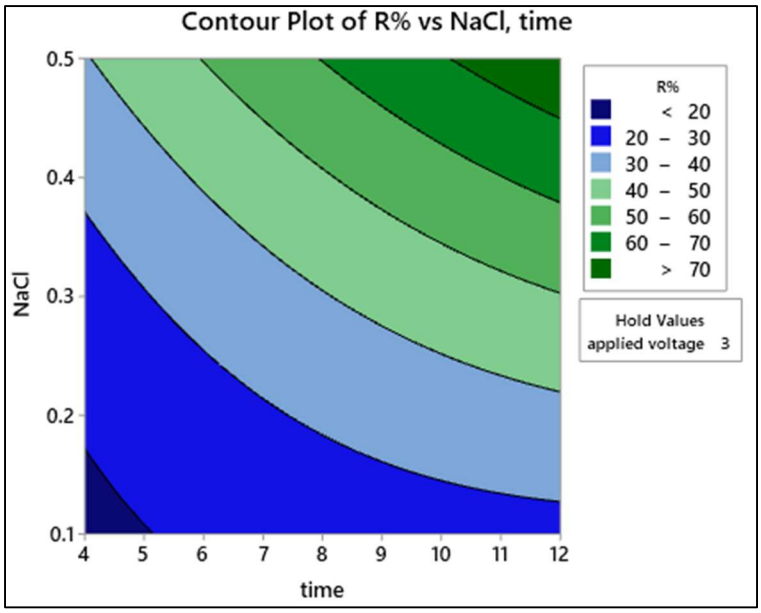

Figure 8. Contour response shows the relationship between the amount of NaCl vs electrolysis time on removal% of MB dye

It could be shown that the decolorization efficiency increases considerably with both NaCl amount and electrolysis time. In other words, increasing both NaCl amount and electrolysis time has positive impact on removal of MB dye. These results are supported by the contour plot given in Figure 8 as can be seen using 0.2-0.3g NaCl and 5-12 min of treatment time, the elimination% of MB was 20-30%. Increasing the amount of NaCl and the electrolysis time to 5 g and 10

min, respectively increases the elimination efficiency to >70%.

Figure 9 showed the efficiency of applied voltage is higher than NaCl with electrolysis time in terms of removal of MB. However, it could be noted that the elimination% raises effectively with increasing of applied voltage and time. These results are supported by the contour plot given in Figure 9 as can be seen using 3-4 V within 12 min of treatment time, the elimination% of MB was 20-40%. Increasing the applied voltage to 5 V at same period of time increases the elimination efficiency to >80%.

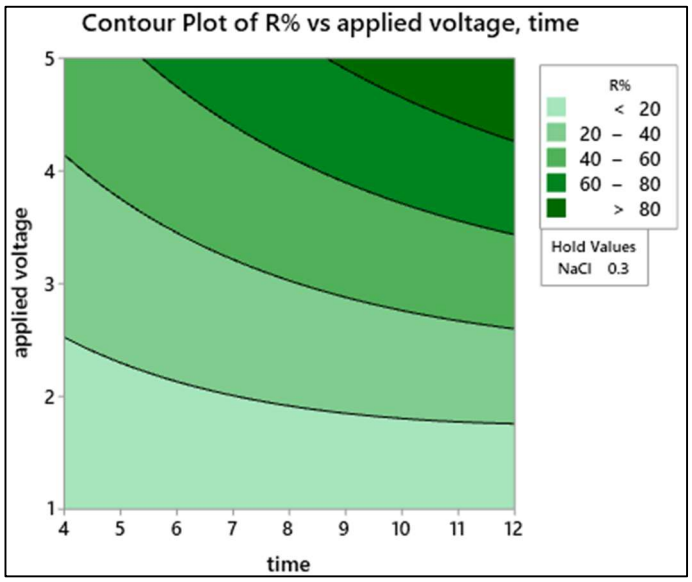

Figure 9. Contour response shows the relationship between applied voltage vs electrolysis time on removal% of MB dye

Electro-kinetics reaction

It was very well known from the results of RSM optimization that the interaction between "NaCl *vs* time" and "applied voltage *vs* time" are very significant so these two variables against time were considered in the present study. The linear time-course plot of Ln ([MB]t/[MB]0) in the elimination of MB tests in the presence of NaCl showed a pseudo-first order kinetics on the MB. The pseudo-first-order kinetic plot of MB elimination at 0.1, 0.3, and 0.5 g NaCl using 5 V is shown in an example in Figure 10. These graphs (0.988 R^2 0.99) were linear. For the experiments made possible by the applied voltage, comparable correlation coefficients were found. As a result, relative to the overall MB concentration, MB vanished at a pseudo-first-order rate for each trial. You can write the following equations:

$$-\frac{d[MB]_t}{dt} = K_{obs}[MB]_t \quad (6)$$

$$Ln\frac{[MB]_t}{[MB]_0} = -K_{obs}t \quad (7)$$

with [MB]t being the total residual concentration of MB and Kobs being the pseudo-first-order kinetic constant. Based on the slope of the linear time-course plot of Ln ([MB]t/[MB]0), Kobs was calculated for each experiment. Figure 10 displayed the profile of the methylene blue dye removal rate constant, or "Kobs," which was observed. Finding in Figure 10 showed that, under the conditions of 5 volts and 10 mg/L MB, the electrochemical elimination of MB dye followed pseudo-first order kinetics in the presence of all various NaCl concentrations. The rate range constants listed in Table 3 between 0.163 and 0.3451 min^{-1}. The rate constant that is measured at 0.3g NaCl is slightly lower than that of measured at 0.5g NaCl, the results were

0.3277 and 0.345 min^{-1}, respectively. This refers to an increase in NaCl amount would not significantly influence the MB degradation kinetics.

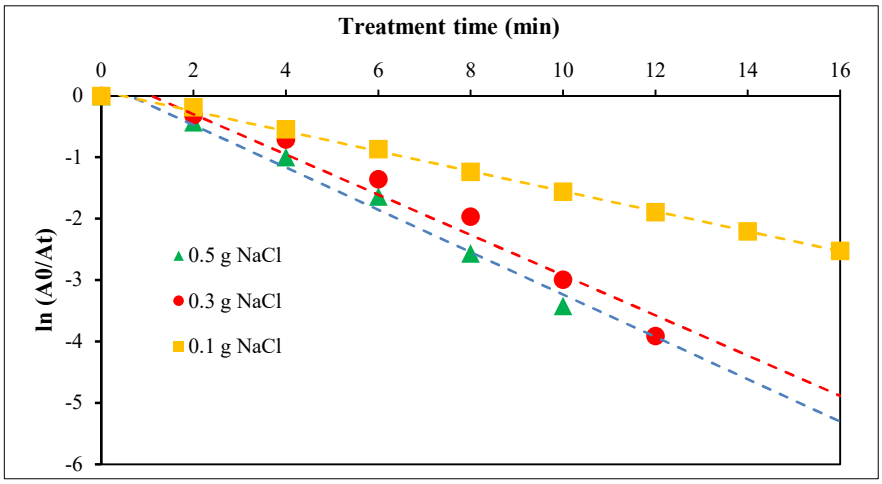

Figure 10. Impact of NaCl amount on rate constant at the following conditions: 5 volts, 10 mg/L MB, and 50 mL solution, of electrochemical degradation of MB

Table 3. Pseudo first-order rate constants for MB for various sodium chloride concentrations and voltage applications

NaCl Amount	**Effect of Sodium Chloride**		
(g)	**Equation**	**R^2**	**K_{obs} (min^{-1})**
0.1	y=0.163x+0.079	0.9981	0.163
0.3	y=-0.3277x+0.3579	0.9633	0.3277
0.5	y=-0.3451x+0.2156	0.9814	0.3451
Applied Voltage	**Effect of Applied Voltage**		
(volt)	**Equation**	**R^2**	**K_{obs} (min^{-1})**
1*	-	-	-
3	y = 0.1916 x+0.1256	0.9943	0.1916
5	y=0.3451x +0.2156	0.9814	0.3451

* There were not suitable results to be built

Kinetic study has been represented according to equations 5 and 6 so the profile plot confirmed that methylene blue dye has pseudo first-order kinetics as predominant at all applied voltage as shown in Figure 11. However, Table 4 provides a list of the reaction rate constants, K_{obs}. As we know, high applied voltage resulted quick elimination of MB dye then the rate constant could be large. On the other hand, the low applied voltage indicated that very slow removal of MB then it requires extra time to achieve the purpose. From Table 4**,** the reaction rate constants were 0.1916 and 0.3451 min^{-1} at 3 V and 5 V, respectively while it was not recorded for 1 volt as there is no significant removal.

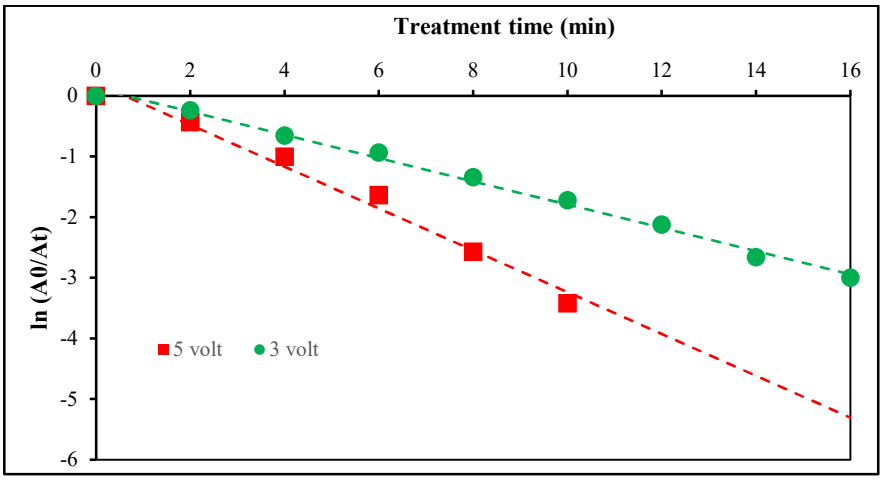

Figure 11. Impact of applied voltage on rate constant of electrochemical degradation of MB under these conditions: 0.5 g NaCl, 10 mg/L MB and 50 mL solution

Table 4. Energy consumption values of MB after electrochemical degradation process at 50 mL of 10 mg/L MB

Time	Energy consumption (Wh/mg)					
	1 V	3 V	5 V	0.1 g NaCl	0.3 g NaCl	0.5 g NaCl

14	0.0491	0.0451	-	0.0524	-	-
16	0.0561	0.0505	-	0.0579	-	-
18	0.06	-	-	-	-	-
20	0.0666	-	-	-	-	-
Average	0.0464	0.0360	0.0773	0.0428	0.0461	0.0773

Consumption energy

In electrochemical degradation process, when the removal% is high at short time then no consumption energy was observed. The energy consumption is calculated according to the equation 8:

$$EC = \frac{VI\Delta t}{\Delta\,[MB]} \qquad (8)$$

Where EC is the energy consumption in Wh/mg, I the current intensity (A), V the electrical potential (volt), t the treatment time (h) and [MB] the reduced mass of MB (mg).

However, the average consumption energy was 0.0428 Wh/mg in the presence of 0.1 g NaCl while it was 0.0773 Wh/mg in the presence of 0.5g NaCl even though it was similar to 0.3g NaCl as presented in Table 4. However, 0.3g NaCl exhibited results of 0.0461 Wh/mg which close to the results of 0.1g NaCl. As is well known, high applied voltage consumes high energy to achieve the electrochemical degradation of organic pollutants, so the present study was focused on this concept. Naturally, high applied voltage led to increased energy consumption. According to one previous study [53], greater applied voltages are linked to increased energy consumption and electrode corrosion. For this reason, in the current study, we concentrated on having the lowest energy consumption and best electrode

stability possible. All the consumption energy was calculated according to equation 7. The maximum average consumed energy was 0.0773 Wh/mg using 5 V while the lowest average consumption energy was 0.036 Wh/mg using 3 V as presented in Table 4. In light of this discovery, 5 volts was chosen as the ideal applied voltage for more research.

Conclusion

Electrochemical degradation process of methylene blue from its aqueous solution was carried out in this present work. Effect some independent variables such as amount of NaCl, applied voltage and electrolysis time was designed by using BDD software on removal% of MB. According to the mathematical method and BDD design plots, the most significant factors on removal% were NaCl amount (A), applied voltage (B) and electrolysis time (C). The interaction factors BC and AD, however, were equally important. On the other hand, unlike AB, the other interaction was not significant. The findings demonstrated that under the impact of sodium chloride and applied voltage, MB was removed in 10–20 minutes. Throughout the investigation, pseudo first order kinetics predominated. The rate constant, however, varied from 0.163 to 0.345 min^{-1}. In the current study, consumption energy was also considered; its range was 0.0366 to 0.104 Wh/mg.

Abstract

Understanding the decomposition process of different body parts is crucial in estimating the postmortem interval (PMI) and/or locating a clandestine grave. Therefore, we conducted a laboratory controlled simulated burial experiment, mimicking a burial in a shallow grave under tropical climate, to comprehensively observe the changes of soil pH and the trend of decomposition rate. Fatty flesh of commercial pigs (*Sus scrofa*) from the shoulder and rump parts was buried in sandy loam soil. Firstly, a vial was firstly half-filled with the soil. The fatty flesh was placed and covered completely with the soil, then, allowed to decompose for 150 days of burial period. The associated soils were collected at 15 designated sampling points. Soil post-experimental pH was recorded, and the remaining fatty flesh was weighed. The lipids were extracted using modified Bligh-Dyer extraction method and analyzed with a gas chromatography-flame ionization detector (GC-FID). We noted differences in the trend of pH, decomposition rate, and total lipid extract concentration. The results demonstrated that generally the soil pH of both body parts changed from acidic at the early decomposition stage, to increasingly alkaline after several days of burial, and the alkalinity decreased back towards the completion of the experiment. Besides this, the soil pH of the rump increased, and the shoulder decreased at the early butyric fermentation stage. The decomposition rate of shoulder fatty flesh was higher than that of the rump at the early decomposition process with a maximum rate at the same burial interval. At the butyric fermentation stage, the total cadaveric derived lipid of the rump was higher than that of the shoulder. The findings of this study shall provide important information on the fates of different body parts and their impact on the surrounding soil pH, which can be used in forensic investigations to locate the clandestine graves and/or to estimate the PMI of the body.

Keywords: cadaveric derived lipids, rump fatty flesh, clandestine grave, postmortem interval, sandy clay loam soil

Abstrak

Pemahaman tentang proses penguraian bahagian badan yang berbeza adalah penting dalam menganggarkan selang postmortem (PMI) dan/atau untuk mencari kubur rahsia. Oleh itu, kami menjalankan eksperimen pengebumian simulasi terkawal makmal, meniru pengebumian di dalam kubur cetek di bawah iklim tropika untuk memerhati secara menyeluruh tentang perubahan pH

tanah dan trend kadar penguraian. Daging babi komersial (*Sus scrofa*) yang berlemak dari bahagian bahu dan pinggul ditanam di dalam tanah liat berpasir. Mula-mula, sebuah vial terlebih dahulu diisi separuh dengan tanah tersebut. Kemudian, daging berlemak itu diletakkan dan ditutup sepenuhnya dengan tanah, dibiarkan mereput selama 150 hari tempoh pengebumian. Tanah yang berkaitan telah dikumpulkan di 15 titik persampelan yang ditetapkan. pH tanah selepas eksperimen direkodkan dan baki daging berlemak ditimbang. Lipid telah diekstrak menggunakan Kaedah pengekstrakan Bligh-Dyer Terubahsuai dan dianalisis dengan gas kromatografi- pengesan nyalaan pengionan (GC-FID). Kami mencatatkan perbezaan dalam trend pH, kadar penguraian dan jumlah kepekatan ekstrak lipid. Keputusan menunjukkan bahawa secara amnya pH tanah kedua-dua bahagian badan berubah daripada berasid pada peringkat penguraian awal, meningkat kepada beralkali selepas beberapa hari pengebumian dan menurun kembali menghampiri selesai eksperimen. Selain itu, pH tanah bagi pinggul meningkat dan bahu menurun pada peringkat pembusukan hitam. Kadar penguraian daging lemak bahu adalah lebih tinggi daripada pinggul pada proses penguraian awal dengan kadar maksimum pada selang pengebumian yang sama. Pada peringkat penapaian butirik, jumlah lipid kadaver yang diperolehi adalah lebih tinggi daripada bahu. Penemuan ini memberikan maklumat penting tentang nasib bahagian badan yang berbeza dan kesannya terhadap pH tanah sekeliling yang boleh digunakan dalam penyiasatan forensik untuk mengesan kubur rahsia dan/atau untuk menganggarkan PMI mayat.

Introduction

Decomposition is defined as a process in which the tissue of dead organisms is degraded through the chemical and biological degradation of the tissue to simpler forms of matter and the physical removal of soft tissue by arthropods and scavengers [1-3]. It is a complicated process primarily dependent on a number of biotic and abiotic factors such as temperature, pH and moisture of the soil, the presence of microbial communities, burial environment and cadaver condition [3-6]. Several physical, chemical and climatic factors may delay and accelerate the decomposition process [2, 3]. Due to these factors, the decomposition rate of a buried body has been found to be much lower than that of a body on the soil surface [7, 8]. The decomposition process, which involves two principal processes of autolysis and putrefaction, can be described in a series of decay stages based on physicochemical changes [2, 7, 9, 10]. For this study, the decomposition stages were described as initial decay (0- 3 days), putrefaction (4-10 days), black putrefaction (10-20 days), butyric fermentation (20-50 days) and dry decay (> 50 days), each stage having its duration (burial interval) and characteristics [11]. The stages shall ease the documentation of physical and chemical changes that may be observed throughout the decomposition process. Furthermore, the progress of the decomposition can be measured, in particular, to evaluate the extent of tissue degradation, and subsequently, to estimate the postmortem interval (PMI).

The recovery of a clandestine grave or body and estimation of PMI are crucial in forensic investigation to give a closure to the cases. The PMI indicates the time of a person's death, potentially assisting in the identification of the deceased and reducing the number of suspects in homicide investigations [12-14]. There are a number of methods that have been used to estimate PMI, including the potassium levels of vitreous humor, analysis of body temperature or algor, livor and rigor mortis, ages of insects in immature stages that feed on a corpse, and DNA degradation [15]. However, the estimation of PMI becomes more difficult and less accurate with the longer time of death [16]. This is because at the more advanced stage of the decomposition process, the uncertainty and errors in estimating PMI will be significantly increased [15]. With this, the identification of the deceased will be more difficult, especially for a buried body, where DNA identification may not be possible as the DNA may have vanished due to the chemical reactions in the soil [17].

This paper details a simulated burial experiment in sandy clay loam soil, where the aim is to investigate the decomposition rate of different body parts, the changes in soil pH, and the concentration of cadaveric derived lipids that may be introduced into the surrounding soil. The fatty flesh of the domestic pig (*Sus scrofa*) was used to replace human tissues due to ethical issues. Pigs are known to have similar anatomical structures and functions, such as skin, body hair, cardiovascular and urinary system, and fatty acid distributions as humans

[2, 18, 19]. This simulated burial experiment was conducted with the ultimate aim to establish an alternative approach using cadaveric derived lipids to locate the clandestine graves and/or to estimate the PMI.

Lipids are one of the products that are liberated from a decomposed human body [8, 20-22]. The lipids are known to have the characteristics of chemical stability, ubiquity, diagenetic, and extreme diversity in the structures [23-24]. Hence, lipids have higher persistent characteristics and preserve longer within soil. The soil lipids have also been recognized to contain several diagnostic markers of soil environmental conditions, where the simple lipids such as fatty acids and alcohol have been considered to be good markers of origin and evolutions of lipid material in soils [25-27]. Hence, together with the unique properties of soil, the decomposition rate of different body parts, the changes in the soil pH and distribution of the extractable lipids were measured in order to investigate the extent of the decomposition process, and subsequently, elucidate the potential of cadaveric derived lipids as decomposition biomarkers. The documented lipid patterns and other decomposition information for every stage of decomposition event would yield valuable insights about the duration elapsed since death. Besides, a comparative analysis of the quantity of cadaveric lipids extracted from the soil at a particular place would prove the existence of a body in the past and, consequently, the location of a clandestine grave.

Materials and Methods

Simulated burial experiment: Sandy clay loam soil

Sandy clay loam soil was the soil of interest for this study, which is known to consist mainly of sand and silt, with a low amount of clay [28]. Sandy loam soil, with a composition of 60% sand, 30% silt, and 10% clay, was collected from a rubber plantation which is located at Bukit Payong, Marang, Terengganu (5.2248°N, 103.1075° E), to mimic the burial of one of the common body disposal sites which used to be encountered in forensic investigations.

Particle size analyzer (PSA 1190) was used to identify the mixture composition of the soil. 5-10g of oven dried soil sample was sieved to remove the small branches, and tiny stones. The sieved sample have to tumble slowly to prevent the brazil-nut-effect during the analysis. Glucagon (0.1%) was used to help the soil rich with organic matters to disperse completely to obtain the result in soil triangle graph with the composition percentage.

Experimental design

A laboratory controlled simulated burial experiment was conducted to investigate and compare the decomposition process of a different part of cadaver, i.e., shoulder and rump that was buried in sandy loam soil, under tropical climate. First, the soil was collected from approximately one meter depth, i.e., the depth of graves that are commonly encountered in forensic investigations. The soil was used to bury about 20g of pig (*Sus scrofa*) fatty flesh for each, shoulder and rump body parts in vials, mimicking a burial in a shallow grave. The accurate mass of fatty flesh at each sampling point was measured and recorded. The vials were labeled and allowed to be exposed to the ambient environment. Then, the fatty flesh was allowed to decompose for a number of designated sampling points, corresponding to the decomposition stages, with specific burial intervals. The gaps between adjacent samplings were two days for the first ten days of sampling points, representing the initial decay and putrefaction stages, and three days for the black putrefaction stage. The stages have been known as active decay stages, which was postulated to be accompanied with massive introduction of cadaveric derived materials. The soil moisture was checked consistently. At each sampling point, the remaining fatty flesh was removed from the soils and weighed. The difference of mass was used for the calculation of decomposition rate. The formula of decomposition rate is as shown below. The associated soils were stored in a freezer before being freeze-dried and subjected to further subsequent analyses. The soil was then freeze dried prior to lipid extraction.

$$Decomposition\ rate = \frac{Initial\ mass\ of\ fatty\ flesh - Final\ mass\ of\ flatty\ flesh}{Sampling\ Time\ Period} \quad (1)$$

Soil post-experimental pH

The pH of control and experimental soils was measured using a calibrated pH meter. Distilled water was added to dried soil samples in disposable culture tubes in a ratio of 1:5 of soil: water. The mixture was then mixed well and the soil was allowed to settle for at least 5 minutes. After that, the pH of the soil was measured by completely immersing the pH probe into the solution. The probe was ensured to avoid contact with the soil that had settled at the bottom of the tube. The pH reading was allowed to stabilize before recording the value. All pH measurements for every sample were repeated three times and recorded.

Total lipid extraction

Modified Bligh-Dyer extraction method was used to extract the lipids from the associated soils. Approximately 3 g of dry soil was transferred into a Pyrex culture tube. Then, 3 mL of 2:1 DCM/methanol (2:1, v/v) and 100 µL of internal standard of tetratriacontane (C-34) were added into the sample. The sample was sonicated for 15 minutes at 30°C, and this was followed by centrifuging it for 5 minutes (~3000 rpm). The supernatant was then transferred into a clean vial and the process was repeated three more times using 2 mL of DCM/methanol (2:1, v/v). After being treated with 3 mL Bligh-Dyer solvent the soil sample was sonicated for 15 minutes and centrifuged for 5 minutes (~3000 rpm). The obtained supernatant was transferred into the same vial. The Bligh Dyer solution was prepared by mixing buffered water, chloroform and methanol in a ratio of 4:5:10 [29]. The extraction was repeated three times with 2 mL Bligh-Dyer solvent. To break the organic phase, 2 mL of each buffered water and chloroform were added to the supernatant, and the mixture was centrifuged for 5 minutes. The organic layer at the bottom was transferred to a new clean vial. The process was repeated three times with 2mL chloroform. The excessive solvent was then evaporated using a mild nitrogen flow. The total lipid extract (TLE) was weighed using the following formula equation 2 and stored in the freezer prior to subsequent analyses.

$$\text{Total Lipid Extract} = \text{Final mass of vial} - \text{Initial Mass of vial} \quad (2)$$

Where, initial mass of vial = mass of empty vial, and final mass of vial = mass of vial with the extracts

Instrumental analysis

A Gas Chromatography – Flame Ionization Detector (GC-FID) (GC-6890N, Agilent) was used to analyze the samples. The GC-FID was equipped with a column of HP-5 5% phenyl methyl siloxane column, with helium as the carrier gas. After injection at 50 °C, the oven temperature was held for 2 minutes, followed by an increase in temperature to 300 °C at 10°C min^{-1}, which was held for 20 minutes. The peaks were selected by comparing the retention times with the external standard, prepared by the mixing of several lipid components, including palmitic and stearic acids, cholesterol, tetratriacontane, and triacylglycerides.

Results and Discussion

Post experimental soil pH

The breakdown of the adipose tissue in the rump and shoulder showed a similar pattern to that of previous investigations. The pH of the soil often rises in the early stages for buried corpses, then becomes more alkaline before acidifying in the later stages [30-32]. Furthermore, a similar trend in the pH changes was observed for the associated soils of the decomposing shoulder and rump fatty flesh. The post experimental soil pH increased at the early decomposition stages and decreased towards the end of the burial interval (Figure 1). The pH was acidic at the beginning of the decomposition event, then increased to become alkaline before acidifying again towards the completion of 150 days of the burial event.

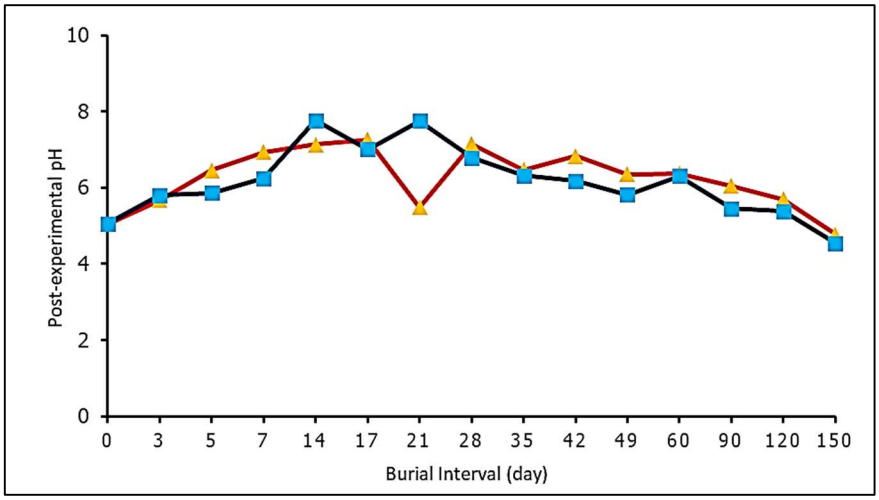

Figure 1. The changes in post experimental soil pH associated with the decomposition of pig fatty flesh of rump (blue line) and shoulder (red line) for 150 days of burial interval

The pH change was literally variable in response and slightly differed between the rump and shoulder body parts. However, the overall trend in pH changes for both body parts was similar throughout the 150 days of burial period. The pH increased between day 0 and day 14 of the burial period, corresponding to the initial and putrefaction stages of the decomposition process. The highest pH for the burial of rump and shoulder parts was observable after day 14 and day 17 of the burial period with a pH 7.77 and pH 7.26, respectively. Interestingly, on day 21 of the burial period, the soil pH of the shoulder body part increased while that of the rump fell, indicating a distinct trend in the soil pH during the early butyric fermentation stage. After 21 days of burial period, the decrease in the soil pH of decomposing rump and shoulder fatty flesh was observed, and thereafter, it continued to decline towards the completion of 150 days of burial period, with minor fluctuations. The lowest soil pH for shoulder (pH 4.78) and rump (pH 4.54) was recorded on day 150, corresponding to the dry decay stage.

The increasing in post-experimental soil pH at the first two decomposition stages, i.e., initial and putrefaction stages, may be due to the increase in the concentration of nitrogen-containing compounds, such as ammonium ions in the soil, resulting from the degradation of body macromolecules [30, 33]. After these stages, the decrease in the soil pH could be due to several reasons. Mineralization of protein and other organic nitrogen occurs via ammonification followed by nitrification of ammonia, NH_4^+, which may reduce the concentration of these nitrogen-containing compounds that are responsible for the increase in soil pH. The conversion of NH_4^+ to NO_3^- liberates protons, causing the soils to become more acidic [30, 32, 34, 35]. Besides, the continual degradation of fatty flesh may also produce non-mineralized decomposition by-products, such as acetic acid and phenolic compounds, and these may be deposited into the soil system. Organic components have been known to lower the pH and potentially inhibit subsequent decomposition events and microbial activities [34, 36]. These activities in the soil may also explain the fluctuations in the soil pH between day 17 and day 28 of the burial period for both rump and shoulder parts. These days correspond to the putrefaction and black putrefaction stages.

The decrease in the post-experimental soil pH after 21 days of burial period, continued towards the completion of the 150 days, a finding that is similar to a previous study by Haslam and Tibbett [35], which found that the soil pH became acidic when the decomposition process entered the butyric fermentation and dry decay stages. This decrease in the soil pH may also be explained by the presence of the decomposition acidic by-products as the increase in the amount of nitrate through the nitrification process has been known to result in a

decrease of soil pH [21, 35]. Moreover, the leaching of decomposition fluid which contains acidic by-products, such as volatile and long-chain fatty acids, also contributes to the decrease of soil pH (31, 38-40).

Decomposition rate

In general, the fatty flesh of both body parts demonstrated a similar trend in the decomposition rate. The decomposition rates of a cadaver for both shoulder and rump parts were high at the early stages of the process, and slowed down towards the end of the 150 days of burial interval (Figure 2). However, the trend was found to be slightly different than that commonly observed for buried cadavers [8]. Furthermore, the decomposition rate of shoulder fatty flesh was higher than that of the rump fatty flesh. This observation may indicate that the shoulder fatty flesh decomposes much faster than the rump fatty flesh.

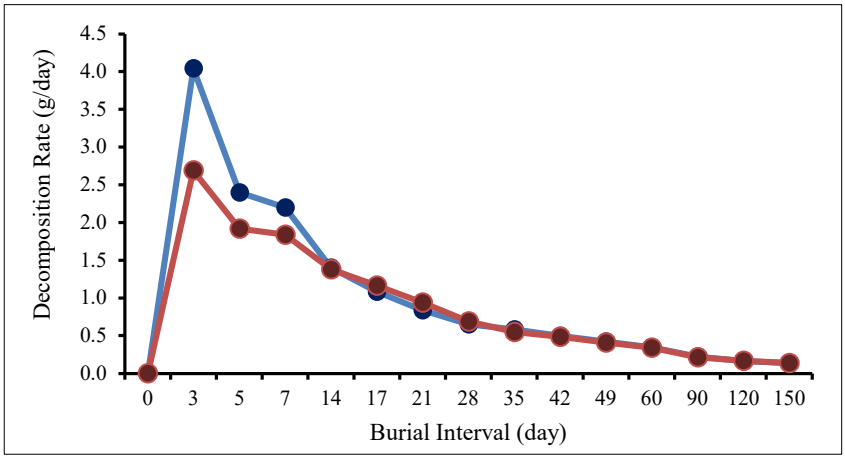

Figure 2. Graph of rate of decomposition of the burial fatty flesh of shoulder (blue line) and rump (orange line) for 150 days of burial period

The decomposition rate rapidly increased between day 0 and day 3 of the burial interval, reaching a maximum after 3 days of burial period, with magnitudes of 4.044 g/day and 2.690 g/day for the fatty flesh of shoulder and rump body parts, respectively. These days correspond to the initial decay stage. After this point, the decomposition rate decreased sharply and continued to decrease towards the end of the burial interval, reaching the lowest in the decomposition rate of shoulder and rump fatty flesh on day 150 of burial period. The lowest decomposition rates were recorded as 0.137 g/ day and 0.135 g/day for the fatty flesh of the shoulder and rump, respectively. This observation may indicate the completion of the decomposition process where most of the fatty flesh has disintegrated.

The biotic and abiotic factors of below ground are different compared to those above ground, which may reduce the activity of the decomposers [8, 34, 41]. Fiedler and Graw [42] stated that the decomposition of buried bodies depended mainly on scavenger activity, insect colonization, and temperature. Burial depth has also been identified to decrease the decomposition rate of a buried cadaver to lower the in-soil temperature, less decomposer activity, and grave moisture content [41, 43]. Considering the burial environmental factors for both rump and shoulder body parts, it has been hypothesized that the main body components of fat and muscular protein would contribute to the differences in their decomposition rates. The observation may be due to the autolysis process that took place during these days. This process has been known to involve the highest and most active degradation activity by microorganisms [4, 20, 34, 36]. The maximum decomposition rate may also be due to the higher rate of redox potential of tissues which contributed to the growth of bacteria at the end stage of autolysis during the decomposition of the fatty flesh [16, 17, 45]. Furthermore, the maximum soil microbial activity had also been observed within the first ten days of burial [44

– 46].

Total lipid extracts (TLEs)

The TLE mass recovered from the associated soils of both decomposing body parts exhibited a similar trend, i.e., increased at the beginning of the experiment, then decreased towards the completion of 150 days of the burial period. The TLE mass from both associated soils was found to slightly increase between day 0 and day 7 of the burial period, corresponding to the initial stage, and decreased towards the completion of the 150 days of the burial process. However, the mass of TLEs extracted from the associated soil of decomposing shoulder fatty flesh was lower than that of the rump fatty flesh. The mass of TLEs extracted from the soils of shoulder fatty flesh ranged from 0.0025 g to 0.0301 g/g soil dry weight, whilst, the mass of TLEs recovered from the soils of rump fatty flesh ranged between 0.0005 g/g and 0.5720 g/g soil dry weight. The lowest and the highest masses of soil TLEs of shoulder fatty flesh were recorded on day 7 (0.0025 g/g soil dry weight) and day 3 (0.0301 g/g soil dry weight), respectively. These days correspond to the initial decay (day 3) and putrefaction (day 7) stages.

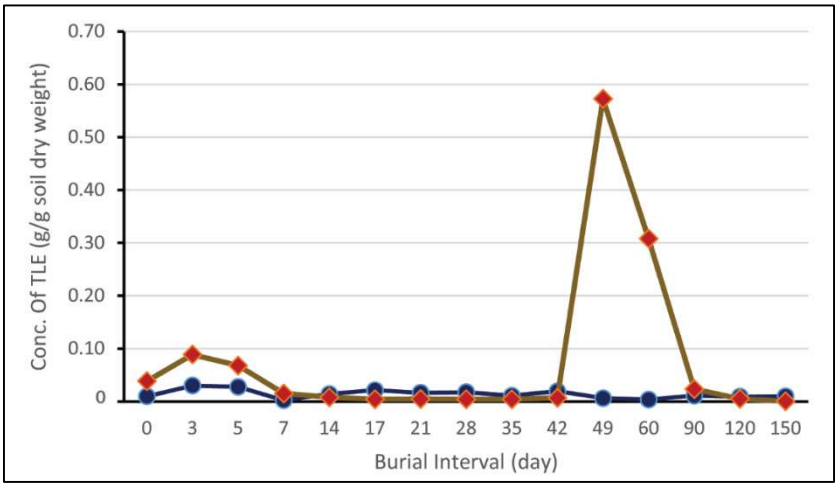

Figure 3. Total Lipid Extracts (TLEs) recovered from the soils associated with the decomposition of fatty flesh of rump (brown line) and shoulder (black line) parts for 150 days of burial interval

The trend of TLE mass of the rump fatty flesh was slightly different compared to that of the shoulder fatty flesh. Similar to that of the shoulder body part, the TLE mass increased between day 0 and day 3, corresponding to the initial decay stage. Then, the TLE mass decreased from day 5 until day 42 of the burial period, corresponding to the stages of putrefaction, black putrefaction, and butyric fermentation. After these points, the mass of TLE increased rapidly and reached the highest mass of TLE on day 49, i.e., 0.572 g/g soil dry weight. The TLE mass then decreased sharply after day 49 and this continued to the end of the burial period, reaching the lowest TLE mass on day 150, i.e. 0.0005 g/g soil dry weight.

The increase in the TLE mass that is observed at a number of burial days may potentially be the result from the leaching of cadaveric materials from the decomposing fatty flesh into the surrounding soil environment. The slight increase in the TLE mass during the initial decay and putrefaction stages agreed with the previous findings which described these first two stages as active decomposition stages [16, 47]. The decrease in the TLE mass after day 7 of burial period may explain a rapid mineralization of the introduced cadaveric materials to the simpler lipid components, such as carbon dioxide and water, as lipids are known to be vulnerable to the decomposition process when exposed to suitable conditions [48, 49]. Remarkably, the decrease in the TLE mass after this point can directly correlate with the decline in the decomposition rate of fatty flesh of both body parts.

The noticeable rapid increase in the TLE mass for rump that took place after 42 days of burial period potentially indicated a massive deposition of the cadaveric materials from the remaining fatty flesh into the surrounding soil system even though the decomposition rate started to slow down. This observation may also be a sign of slow mineralization of the cadaveric derived lipids, which may be due to the shifting in the microbial communities that were responsible for the decomposition process [45, 46, 50, 51]. The decomposition products have been suggested to impose a significant impact on the microbial communities that are responsible for the process, where they are known to either speed up or inhibit the disintegration of the fatty flesh [4, 45, 46]. It has been known that the fast-high rate of decomposition at the beginning of the experiment will be accompanied by a massive indication of the introduction of cadaveric substances into the surrounding burial soil [11, 18, 21, 31]. The mass of TLE was high at the beginning of the experiment. The potential explanation for this observation may be due to the rapid mineralization of the bigger compounds to simpler compounds. For example, the hydrolysis of triglycerides to free fatty acids and carbon dioxide. This explanation can be supported by the concentration of fatty acids detected by the GC-FID. The concentration of fatty acids was low at the beginning of the experiment, although the rate of decomposition was high.

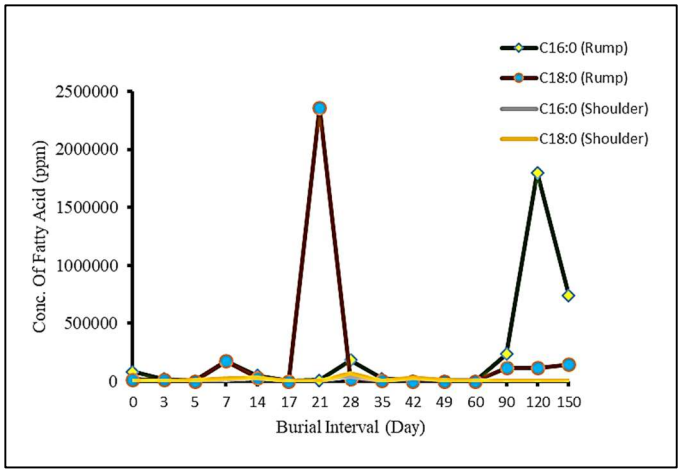

Figure 4. The concentrations of palmitic and stearic acids extracted from the soils associated with the decomposition of fatty flesh of rump and shoulder body parts

A gas chromatography–flame ionization detection (GC–FID) method was used for direct quantitative analysis of fatty acids. The analyses of cadaveric derived lipids, such as fatty acids, recovered from the associated soil was carried out to determine their potential usage for estimating the PMI. The lipid components detected were palmitic (C16:0) and stearic (C18:0) acids, together with cholesterol. Figure 4 shows the concentrations of fatty acids and cholesterol detected at different sampling points for 150 days of the burial interval. During the decomposition process, fatty acids are released from adipose tissues. The adipose tissues are made up from 60-85% lipids by weight, and 90-99% triglycerides, which would be further hydrolyzed into glycerin and free fatty acids [8]. Bull et al. [21] suggested an approximate 500-fold difference in the concentrations of palmitic (C16:0) and stearic (C18:0) acids extracted from the soils with decomposing cadaver or fatty flesh compared to that of control soils. Therefore, the presence of fatty acids in soil extracts at concentrations greater than that of the control soil can be interpreted as them having derived from anthropologically introduced organic matter such as pig adipose tissue. Furthermore, the remarkable changes in soil lipid compositions can help to confirm the prior presence of a cadaver in the suspected area. Janaway et al. [17] identified that the postmortem lipid components, such as palmitic, stearic, and oleic acids, were found as soon as 8 hours after

death, and that the most abundant lipid components in human body are oleic (C18:1), linoleic (C18:2), and palmitoleic (C16:1) acids. According to Dent et al. [8], these unsaturated fatty acids will be turned into simpler fatty acids shortly after death through hydrolysis and oxidation processes.

The majority of soil extracts showed a significant level of cholesterol along with the dominance of stearic (C18:0) and palmitic (C16:0) acids. Interestingly, the soils of both body parts had more palmitic (C16:0) acid than stearic (C18:0) acid. Furthermore, the soil of rump had greater fatty acid contents of C16:0 and C18:0 components than that of the shoulder. The total C16:0 and C18:0 concentrations of rump were determined to be 3315843.7 ppm and 2998265 ppm, respectively. The total values of C16:0 and C18:0 for the shoulder were 2108658.1 ppm and 1132487.0 ppm, respectively. There was 3840.1 ppm and 3466.9 ppm of cholesterol in the rump and shoulder, respectively.

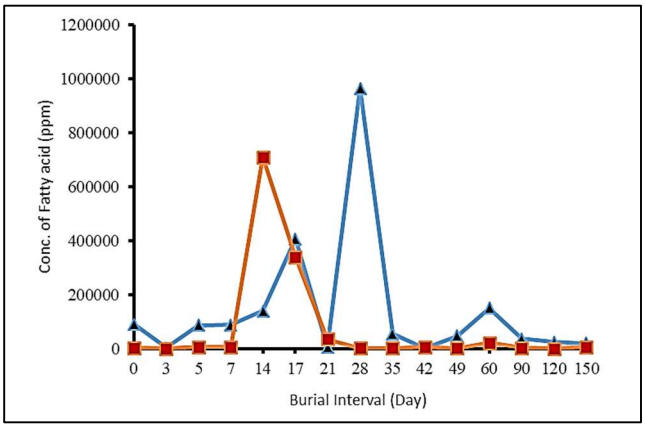

Figure 5. The concentrations of fatty acids of C16:0 and C18:0 components extracted from the soils associated with the decomposition of shoulder fatty flesh. The blue and orange lines represent the concentrations of C16:0 and C18:0 fatty acids, respectively

For the soils of the shoulder, the concentration of fatty acids generally increased between day 7 and day 21 of the burial interval, with minor fluctuations (Figure 5). These days correspond to the first three active decomposition stages of initial decay, putrefaction and black putrefaction. With a sharp increment between day 7 and day 14, the stearic acid reached maximum concentration (709127.6 ppm) on day 14, and then, the concentration of stearic (C18:0) acid decreased rapidly after this point and continued to decrease towards the completion of 150 days of the burial period. On the other hand, the palmitic acid demonstrated a first sharp increase in concentration after 17 days of the burial period, with a concentration of 138899.6 ppm, followed by a sharp decrease in the concentration of this fatty acid. The second dramatic increment in the concentration of this C16:0 component was observed after 21 days, where it reached a maximum concentration (964554.7 ppm) on day 28 of burial period. The possible explanation for this fluctuation is the introduction of different cadaveric substances during decomposition, which caused the shifting in microbial communities. Besides, there was also a slight increase in pH from day 21 to 28, which may impose an impact of the microbial community that is involved in the decomposition process. It is well known that soil microbial community has a strong correlation with soil pH [42]. The soil pH might facilitate succession of certain microbial species and induce the breakdown of lipids. The concentrations of palmitic (C16:0) and stearic (C18:0) acids decreased towards the end of the experiment. This observation was in line with the decomposition rate of the shoulder fatty flesh.

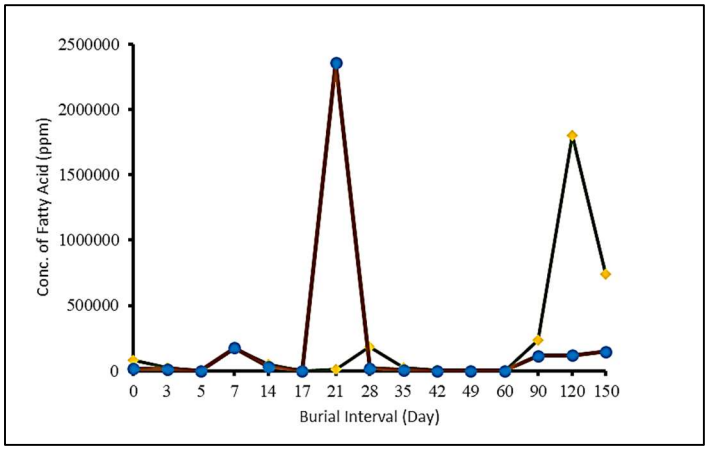

Figure 6. The concentrations of C16:0 and C18:0 extracted from the soils associated with the decomposition of rump fatty flesh. The green and brown lines represent the concentrations of C16:0 and C18:0 fatty acids, respectively.

The concentrations of palmitic and stearic acids extracted from the soils associated with the decomposition of rump fatty flesh demonstrated significantly different trends than that of the shoulder fatty flesh. Remarkably, the total concentration of C16:0 acid was higher than that of C18:0 acid. Furthermore, the concentration of palmitic acid was low at the early decomposition process before a rapid incline after 90 days of the burial event, with minor fluctuations between day 0 and day 35. The concentration of this fatty acid rapidly increased and reached a maximum (1798832.3 ppm) on day 120, corresponding to the dry decay stage. Then, the concentration of palmitic acid sharply declined after this point. The concentration of the stearic acid increased sharply after 17 days of the burial period and reached a maximum concentration (2359151 ppm) on day 21, corresponding to the black putrefaction stage. After this point, the concentration of this acid sharply declined to a much lower concentration which continued to decrease towards the completion of 150 days of the burial interval.

A higher abundance of palmitic and stearic acids extracted from the associated soils may be an indication of hydrogenation process of unsaturated acids and triacylglycerols during the decomposition of the fatty flesh of both rump and shoulder body parts. It is known that the hydrolysis of triacylglycerols is followed further by hydrogenation to form saturated components, yielding palmitic and stearic acids [8]. Moreover, the increase and decrease of the concentrations of palmitic and stearic acid may be due to the shifting of microbial communities due to the introduction of cadaveric components into the soil. The increment of fatty acid levels might be due to the initial growth and feeding stage of maggots, whereas the decrement of fatty acid might be due to the pupation period [40]. This also suggested that the activity of insects played a role in the amounts of fatty acids detected in the soil. The high concentrations of these short chain fatty acids may be explained by the observation that short-chain fatty acids had degraded faster than long-chain fatty acids [33]. This statement may also explain the low concentrations of cholesterol, and long-chain lipids extracted from the soils associated with the decomposition of both rump and shoulder body parts (Figure 7).

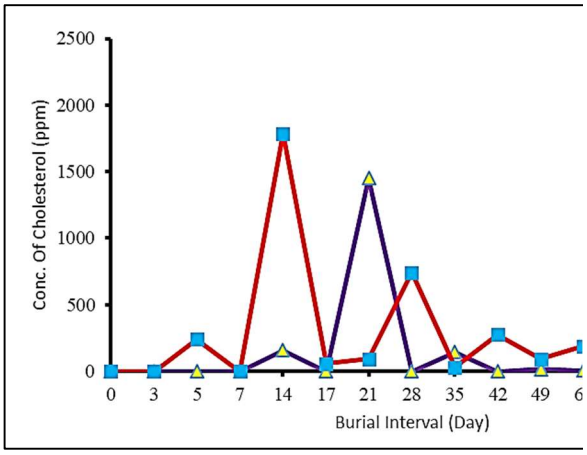

Figure 7. The concentrations of cholesterol extracted from soils associated with the decomposition of rump (purple line) and shoulder (red line).

Conclusion

This study was conducted to investigate the potential of cadaveric lipids to be developed as burial biomarkers that may aid in locating clandestine graves and/or to determine the PMI. The distribution of the cadaveric derived lipids was documented to further confirm their potential to provide useful information to aid forensic investigators as their concentrations may differ significantly, which can act as fingerprints for each of the decomposition stages. The fatty flesh of shoulder and rump demonstrated similar trends in the post experimental soil pH and decomposition rate. The post experimental soil pH was acidic at the early decomposition stages, then became alkaline, and then acidic again towards the completion of 150 days of the burial interval. The decomposition rate was found to be high at the initial stage and had reached the maximum after 3 days of the burial interval. Then, the decomposition rate then eventually decreased after this point and continuously decreased towards the completion of the process. Even though, both the body parts exhibited similar trends, the decomposition rate of fatty flesh of the shoulder was higher than that of the rump. A similar trend was also observed for their extractable derived lipids throughout the burial period. The concentrations of lipids slightly increased at beginning of experiment and decreased towards the end of experiment with minor fluctuations, which may due to the activity of the microbial community that is responsible for the decomposition process. However, the concentration of the extractable cadaveric lipids of the rump was higher than that of the shoulder. Moreover, the concentration of cadaveric lipids of the rump rapidly increased after 42 days of the burial period and decreased thereafter. The concentrations of cadaveric derived fatty acids and cholesterol extracted from the soils of both rump and shoulder were also different in their trends throughout the 150 days of the burial period. Hence, these findings may indicate that the analysis of soil cadaveric lipids can be developed as an alternative forensic tool to locate a clandestine grave and to estimate the PMI and/or to identify the victim and the criminal. It is recommended to investigate the breakdown of other body components in order to provide more evidence that different body parts break down at various rates. More information about the destiny of various body parts can therefore be obtained.

Abstract

Catalytic oxidative desulfurization (Cat-ODS) is utilized to remove the sulfur content in diesel fuel. Bimetallic catalysts are introduced in the desulfurization process of model diesel fuel, which includes components like n-octane, thiophene (Th), dibenzothiophene (DBT), and 4,6-dimethyldibenzothiophene (4,6-DMDBT). The presence of dopants was confirmed by atomic absorption spectroscopy (AAS) and X-ray fluorescence (XRF). It was found that the addition dopants toward Fe/Al_2O_3 catalyst significantly increased the selectivity of catalytic performance. Using the optimized condition, 98% sulfur removal was achieved. The catalyst's reproducibility test demonstrated that it could be utilized repeatedly for up to five cycles. In addition, mechanism pathways of bimetallic catalysts, both with and without the presence of catalyst have been thoroughly optimized using density functional theory (DFT).

Keywords: desulfurization, catalyst, density functional theory, diesel model, sulfur

Abstrak

Penyahsulfuran oksida bermangkin (Cat-ODS) digunakan untuk menyingkir kandungan sulfur dalam bahan api diesel. Mangkin dwilogam diperkenalkan dalam proses penyahsulfuran bahan api diesel model, yang merangkumi komponen seperti n-oktana, thiofen (Th), dibenzothiofen (DBT), dan 4,6-dimetildibenzothiofen (4,6-DMDBT). Kehadiran dopan telah disahkan oleh spektroskopi penyerapan atom (AAS) dan analisis sinar-X pendaflour (XRF). Didapati bahawa penambahan dopan ke arah mangkin Fe/Al_2O_3 meningkatkan selektiviti prestasi mangkin dengan ketara. Menggunakan keadaan optimum, 98% penyingkiran sulfur telah dicapai. Ujian kebolehulangan mangkin menunjukkan bahawa ia boleh digunakan berulang kali sehingga lima kitaran. Di samping itu, laluan mekanisma mangkin dwilogam, dengan penggunaan mangkin dan tanpa mangkin telah dioptimumkan secara menyeluruh menggunakan teori ketumpatan fungsi (DFT).

Kata kunci: penyahsulfuran, mangkin, teori ketumpatan fungsi, model diesel, sulfur

Introduction

Acid gas combustion produced by the combustion of diesel fuel which released sulfur dioxides compounds to the atmosphere either from industries or transportation can harm the environment and endanger human health [1]. Consequently, the sulfur content in fuels has grown more restricted over the world to overcome these environmental norms and more stringent sulfur control in diesel has been implemented to lower the sulfur content up to 10 parts per million (ppm), known as ultralow-sulfur diesel, wishing to achieve soot-free Euro VI emission standards [2].

Current conventional method in the removal of sulfur, hydrodesulfurization (HDS), is less effective in the removal of aromatic sulfur compounds such as dibenzothiophene (DBT), sulfur compound that mainly exists in fuel oils, and their alkylated derivatives [3, 4]. This technology is restricted since it requires expensive process due to high operational cost, and high operational temperature in the hydrogen gas atmosphere [5]. In order to ensure that the sulfur level of diesel fuels matches the rules, many efforts have been made in searching for a prompt and efficient desulfurization system to overcome the abundance of organosulfur in diesel fuel such as extraction desulfurization (EDS), adsorptive desulfurization (ADS), and oxidative desulfurization (ODS). Among them, catalytic oxidative desulfurization (Cat-ODS) is economically feasible for large scales utilization. When compared to the traditional HDS methods, it needs less capital and has lower running expenses. ODS technology has received a lot of interest since it is useful for creating ultra-low sulfur fuels under moderate circumstances. It can operate under mild conditions due to low temperature and no need for hydrogen gas [6].

Essentially, oxidative desulfurization is divided into two major steps: the first step is the oxidation of compounds consisting of sulfur converted to sulfoxides and sulfones using a selected oxidant. Secondly is the extraction of sulfoxide and sulfone from diesel via extraction, adsorption, and distillation [7, 8]. The efficiency of ODS is greatly dependent on the proper oxidant-catalyst combination. Several oxidants, including tert-butyl hydroperoxide (TBHP), sodium hypochlorite (NaClO), and hydrogen peroxide (H_2O_2), appear to be the best competitors due to their strong oxidizing capacity [3]. Some low-cost metals features, Fe, Zn, and Mo have been discovered to be quite successful in the desulfurization of fuel oils due to their physiochemical properties [9]. According to Bakar et al. [10] pure Fe-Al_2O_3 has a modest oxidative activity and was chosen as a viable option for desulfurization as it requires minimal cost and simple recycling [11].

It has been proven that bimetallic catalysts show higher catalytic activity in the ODS process [12]. Naseri et. al. [13] synthesized bimetallic catalysts composed of molybdenum and zinc. It showed maximal removal of DBT molecules in ODS reaction using the bimetallic catalyst. The same result was observed in the study by Luna et. al. [14] where the bimetallic catalyst using tungsten and vanadium exhibited highest ODS activity. Cobalt is widely known as a catalyst in oxidation processes and hydrodesulfurization [15]. In a previous work, Sampanthar et al. [16] have shown that Mn and Co catalysts were highly active in oxidation of refractory sulfur compounds in diesel using molecular oxygen. The fabricated catalyst can improve the contact surface of the catalyst with sulfur compound. Metal doping would introduce the defects on metal oxides, which in turn plays a significant role in the desulfurization performance. Herein, low valance of Co^{2+} was substituted to the higher valance of Fe^{3+} by the lattice defects [17].

In this study, cobalt was used as a dopant to form bimetallic catalysts. The effect of dopant dosage on catalytic activity was investigated. The mechanistic pathway was postulated and verified by computational study. Co/Fe-Al_2O_3 catalyst was tested for five successive cycles under the optimized condition to ensure the accuracy of the catalytic performance. The fresh Co/Fe- Al_2O_3 catalysts were characterized by atomic absorption spectroscopy (AAS) and X-ray fluorescence (XRF).

Materials and Methods

Materials

The catalyst support used was alpha alumina Al_2O_3 beads with diameter of 3-5 mm were obtained from

Sigma-Aldrich. The dopant iron (III) nitrate nonahydrate $Fe(NO_3)_3$ and cobalt (II) nitrate $Co(NO_3)_2$ were used as dopant to synthesize bimetallic catalysts. These dopants were obtained from QRëc. Hydrogen peroxide (H_2O_2) 30% in water (QRëc) and tertbutyl hydroperoxide (TBHP) (70 wt.%) were obtained from QRëc and Across Organics. They were employed as oxidizing agent during ODS process. *N*-octane (99%) was utilized as the solvent for the model diesel fuel, which included thiophene (Th, 99%), dibenzothiophene (DBT, 97%), and 4,6-dimethyldibenzothiophene (4,6-DMDBT, 95%). *N,N*- dimethylformamide (DMF) from MERCK was used as extraction solvent to remove sulfur impurities.

Catalysts preparation

Bimetallic catalysts based with different Fe and Co metal loadings were prepared by incipient impregnation method on Al_2O_3 beads. 4g of alumina support was immersed into the 2g of $Fe(NO_3)_3$ solution until complete absorption occurred on the surface. The mixture was put onto the glass wool and dried in an oven at 100 °C for 24 hours. The furnace was set up at the temperature of 400 °C and the catalysts was heated for 5 hours to ensure all the metal counter ions and water molecule are removed. The cobalt-iron supported on alumina catalyst was prepared by doping with $Co(NO_3)_2$ after the successful impregnation with iron using the same impregnation method. A series of bimetallic catalysts with different Co salt loading was synthesized (10, 20, and 30 wt.%). The developed catalysts were designated as follows Co/Fe-Al_2O_3 (10:90), Co/Fe-Al_2O_3 (20:80), and Co/Fe-Al_2O_3 (30:70). Based on AAS analysis, it shows that there are slightly differences in active species concentration compared to theoretical calculation this might because AAS analysis fully characterized the elemental composition of the material [18]

Oxidative desulfurization and characterisation

The 500-ppm model diesel fuel was formulated with three model sulfur compounds: thiophene (Th), dibenzothiophene (DBT), and 4,6-dimethyldibenzothiophene (4,6-DMDBT) in *n*-octane solvent. Model diesel fuel (10 mL) was added to the round bottom flask, together with catalyst (0.1g) and TBHP oxidant (O/S= 3).

The ratio of S molar ratio and TBHP is (1:3) (m/v). The mixture was refluxed for 30 min with intense stirring. The resulting mixture was cooled and filtered. The oxidized diesel fuel was extracted by solvent extraction (DMF) in a 1:1 diesel-to-solvent ratio (v/v). The extraction process was rapidly agitated at room temperature for 30 minutes before the diesel and solvent phases separated. Gas chromatography (Agilent 7890A) with a flame ionisation detector (GC-FID) together with equity 5 column were used to measure the sulfur content. The synthesized catalysts were further characterised using atomic absorption spectroscopy (AAS) and X-ray fluorescence (XRF) to analyse the elements presence in the catalyst. The textural properties of the catalyst and support were analyzed by nitrogen physisorption isotherms. N_2 adsorption-desorption isotherm was performed on Micromeritics ASAP 20120 adsorption analyzer at -196 °C. The equilibrium geometries and energy of the intermediates in the hypothesised process were calculated using density functional theory (DFT). All the energy calculations in this paper were done with the Gaussian 09/Gaussian 16 programme.

Result and Discussion

Atomic absorption analysis (AAS) was performed using the direct approach to assess the total metal content in Co/Fe-Al_2O_3 catalyst. The analysis of AAS in (Table 1) confirmed the presence of Fe and Co elements for all the catalysts. The Fe and Co metal content of the bimetallic catalyst were found to be in the targeted range. The trend for Co loading is an agreement with XRF analysis.

The large quantities of weight percentages of all elements were determined using XRF analysis in comparison to the nominal weight percentage introduced to the system, and the results were illustrated in Table 2. From XRF data measurement, the actual weight percentages for the elements in Co/Fe(10:90)/Al_2O_3, which was calculated for the preparation of Co and Fe were 15.8 wt.% and 84.2 wt.%, respectively. The percentages detected were found to be lower for iron species in Co/Fe(10:90)/Al_2O_3 due to the presence of other elements in the sample matrix and affecting the accuracy of the analysis. These matrix

effects can lead to a lower measured percentage for the target [19]. Even though there was a variation in AAS and XRF measurements, the data remained compatible with results acquired with more precision [20] From the XRF data, the amount of every element calculated was approximately similar to theoretical calculation. Thus, it evidenced that all the elements were present and dispersed well on the catalyst support. From our previous publication, XRD analysis proved the presence of oxide phase of Fe_3O_4 and Co_3O_4 in the catalyst [21].

Table 1. The concentration of metal element in Co/Fe-Al_2O_3 catalyst

Catalyst	Calcination Temperature (°C)	Concentration (ppm)	
		Fe	Co
Co/Fe-Al_2O_3 (10:90)	400	0.055	0.025
Co/Fe-Al_2O_3 (20:80)	400	0.030	0.057
Co/Fe-Al_2O_3 (30:70)	400	0.026	0.061

Table 2. Composition of metal element in Co/Fe- Al_2O_3 catalyst

Catalyst	Element (wt.%)	
	Fe	Co
Co/Fe-Al_2O_3 (10:90)	84.2	15.8
Co/Fe-Al_2O_3 (20:80)	80.6	19.4
Co/Fe-Al_2O_3 (30:70)	70.0	30.0

Effect of dopant ratio

The study was carried out to investigate the removal of sulfur compounds from model diesel fuel over Co/Fe-Al_2O_3 catalyst by using different dopant ratios of Co and Fe, calcined at 400 °C in a range of 10:90, 20:80, 30:70, and the results are presented in (Figure 1). The Co/Fe ratio of 10:90 gave the highest conversion of DBT (100%), 4,6-DMDBT (79%), and thiophene (93%). The variability in reactivity of sulfur compounds is mostly due to differences in electron densities on the sulfur atom and the sulfur compound's steric hindrance. Th, DBT, and 4,6-DMDBT contain electron density on the sulfur atom of 5.696, 5.758, and 5.760, respectively [22]. The removal of 4,6-DMDBT is the lowest compared to Th and DBT, since there is a methyl group presence on 4,6-DMDBT that acts as an obstruction for sulfur atom to take an approach to the catalyst's active core. An excess of cobalt concentration may form a cluster of active species on the catalyst's surface and reduced its surface area. The high amount of cobalt also prevented the Fe active sites from being equitably distributed across the supported catalyst surface, causing the catalyst's activity to become distorted [23]. Previous research had shown that Co loading can result in variable active surface site [24], and the catalytic characteristics were shown to be reliant on the dispersion and engagement of the Co with the support [25].

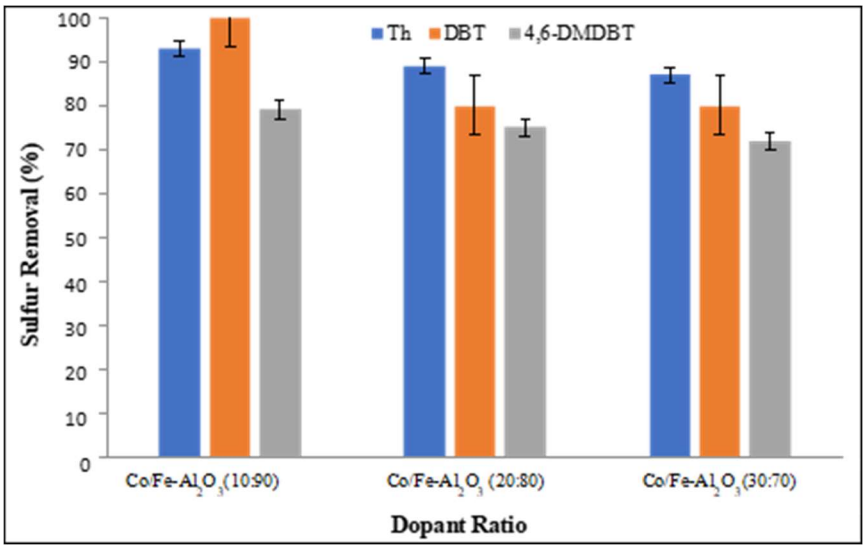

Figure 1. The impact of catalyst doses (Reaction conditions: Oxidant = TBHP, T = 50°C, time = 30 min, solvent = DMF)

Repeatability test

The repeatability investigation was performed three times to ensure accuracy. The catalytic activity of these catalysts was studied under similar preparation and experimental conditions. The outcome of three repetitions of Co/Fe(10:90)-Al_2O_3 catalyst repeatability testing as illustrated in (Figure 2). The observation showed there were not much difference in the repeatability test for the model diesel sample, indicating the accuracy of the analysis performed.

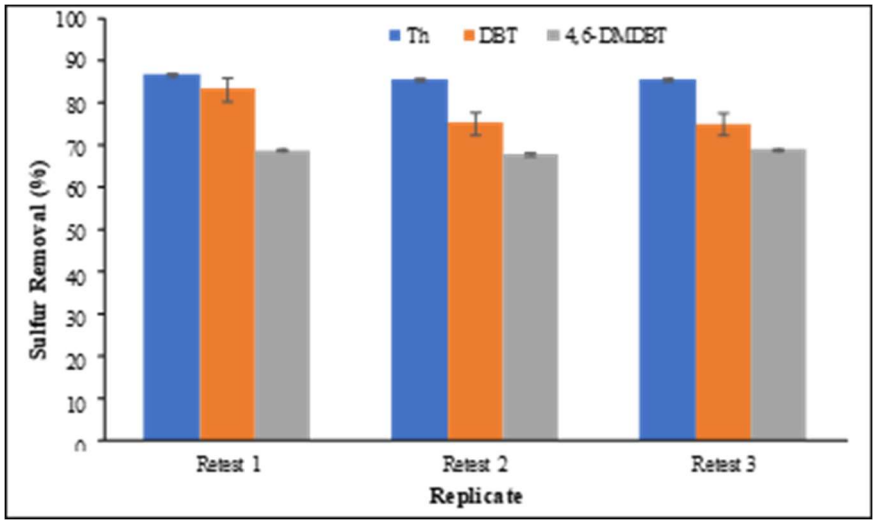

Figure 2. Repeatability test of Co/Fe- Al_2O_3 catalyst calcined at 400°C (Reaction conditions: Oxidant = TBHP, T = 50 °C, time = 30 min, solvent = DMF).

Catalyst recycling performance

The capacity of a catalyst to be recycled is crucial from an economic perspective [4]. Hence, 0.1g of Co/Fe-Al_2O_3 in the ratio of 10:90 catalyst calcined at 400 °C was tested for five consecutive cycles under similar conditions. The catalyst was retrieved, rinsed with methanol to reduce the adsorbed sulfur compound, and dried in an oven at 80 °C-100 °C for 12 hours and tested

in the next cycle. It was found that there is no significant decline in activity even after three recycling runs as shown in (Figure 3). After the fourth and fifth cycle of the reaction, a decrease in the desulfurization activity of the catalyst were observed. This may relate to the washing or activation of some active catalyst spots during the oxidation or recycling process of the catalyst. A slight decrease in sulfur removal after the fourth cycle indicates that the active site was maintained during the reaction. In addition, the surface area of the used Co/Fe-Al_2O_3 catalyst (216 m^2/g) was very close to those of the fresh one (226 m^2/g) [21]. As a result, it was discovered that the Co/Fe-Al_2O_3 catalyst had a high catalytic activity for the Cat-ODS of diesel as well as a strong resistance to sulfur.

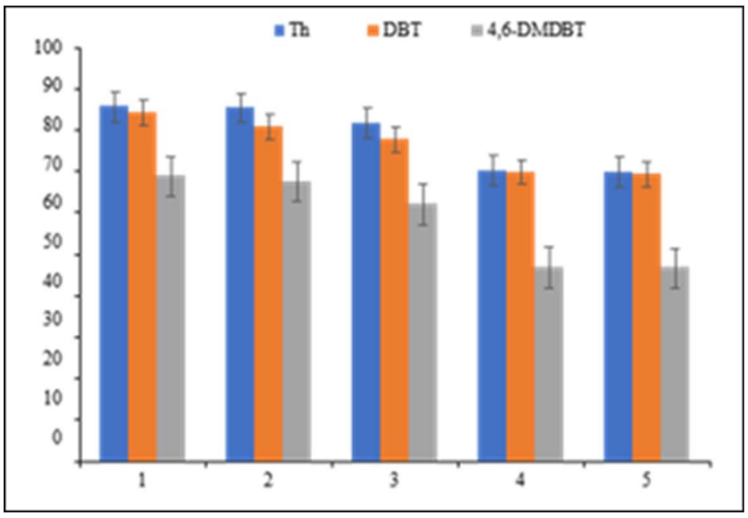

Figure 3. Catalyst cycling test of Co/Fe- Al_2O_3 catalyst calcined at 400 °C for 5 hours (Reaction conditions: Oxidant = TBHP, T = 50°C, time = 30 min, solvent = DMF)

Mechanistic study by computational

The mechanism of oxidative desulfurization with Co/Fe-Al_2O_3 catalyst in TBHP system was proposed in (Figure 4). Early research suggested that Fe^{3+}, O, and OH groups of iron oxides might engage with the thiophene ring, leading to adsorption through a variety of methodologies [26, 27]. The mechanism of the Co/Fe-Al_2O_3 catalyst include the formation of an intermediate product (1), as a consequence of the nucleophilic attack by TBHP on Co/Fe-Al_2O_3 surface when there is a reaction between TBHP and element Co or Fe. The electrophilic properties of peroxidic oxygen start to increase, made it more reactive because the electrons are extracted from the peroxyl moiety. DBT sulfoxide (3) is formed when DBT (2) is oxidised when responded to the nucleophilic attacks of sulfur in the DBT molecule (2) on the positively charged intermediate species (1). Following that, the DBT sulfoxide (3) was further oxidised to produce DBT sulfone (4) and tert-butanol (5) as by-products.

The energy level diagram for the oxidation of DBT and 4,6-DMDBT by TBHP in the presence of catalyst was displayed in (Figure 5). Several significant features were observed from the profile energy. Based on Table 3, the first oxidation of 4,6-DMDBT, -20.2 eV energy was released, higher than oxidation energy released by DBT which is -7.67 eV for the first step. Next, the second step of 4,6-DMDBT by adding oxygen to positively charge S atom demonstrated the releasing energy of about -1.65 eV. The energy required to form 4,6-DMDBT sulfoxide is 3.2 eV, which shown that is more energy required than DBT sulfoxide due to the presence of methyl group in the structure. The overall interaction energy between 4,6 DMDBT and catalyst is -23.19 eV which was less exothermic than DBT, -40.78 eV. The exothermic reactions indicate that sulfoxide and sulfone are persistent compounds. Based on the barrier heights in the reaction profile, we can see that the oxidation phase for sulfone synthesis was simpler than that of sulfoxide,

and thus the sulfone product yield is expected to be greater than sulfoxide.

The bond length for Fe-O in 4,6-DMBT is 1.81 A˚, a bit longer than the bond length in DBT (1.80 A˚). Seeing as the methyl group was qualified to donate the aromatic ring the electrons, this suggests that the methyl group would impair the S-C strength qualities. Longer bond lengths on the scission of the S-C in ODS reaction may be easier in 4,6-DMDBT [28]. However, C-S bond cleavage was difficult to occur due to the steric hindrance effect of 4,6-DMDBT. On the contrary, according to conducted experiment, the ODS response in this reaction is simpler in DBT based on total energy. This is most likely due to the fact that DBT with access to the S-atom would result in a lower barrier height than the more sterically hindered S-containing 4,6-DMDBT molecule. Prove that methyl group steric hindrance was a key factor in the ODS system's selectivity.

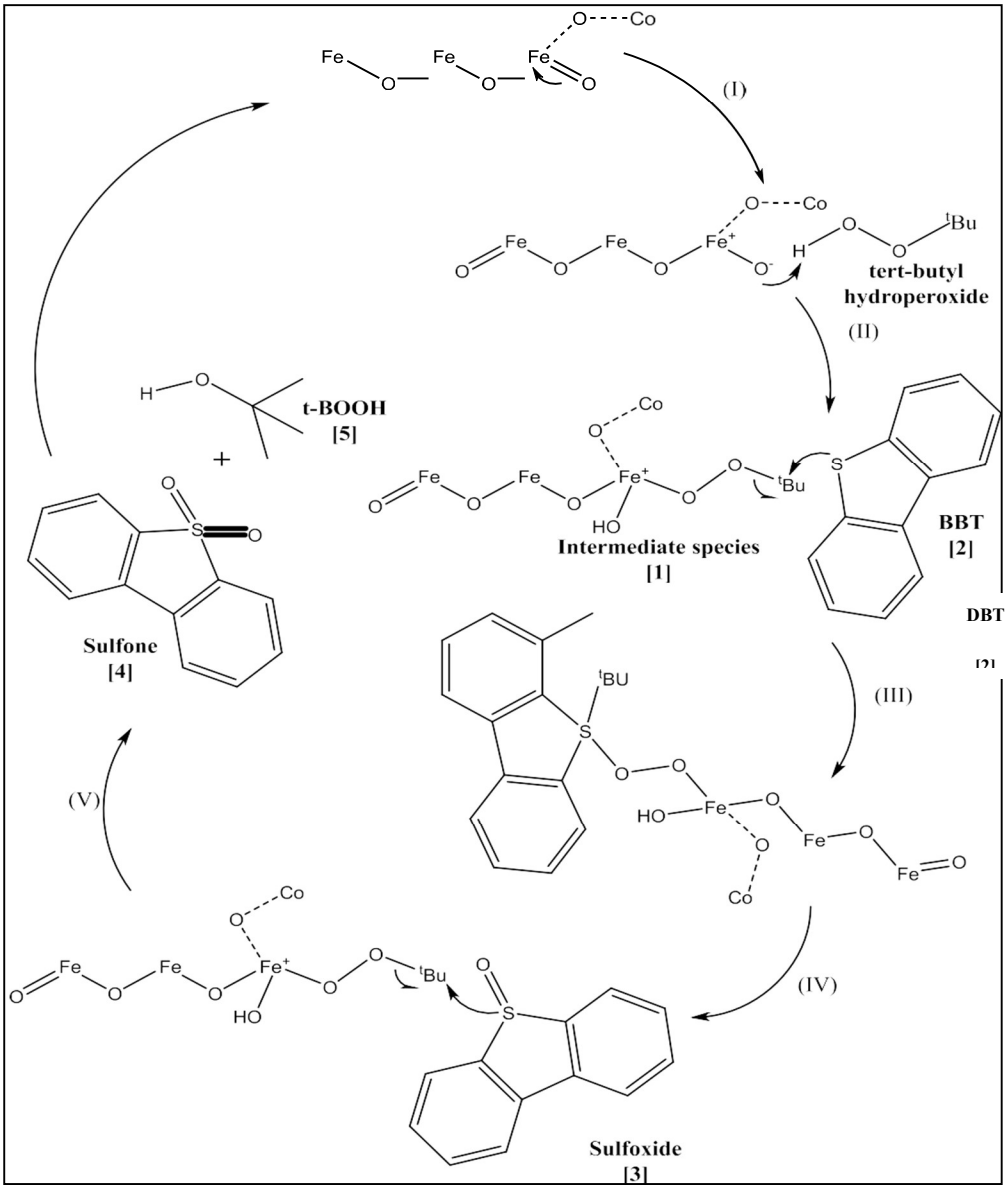

Figure 4. A proposed oxidation chemical route of dibenzothiophene by TBHP in the presence Co/Fe-Al_2O_3 catalyst

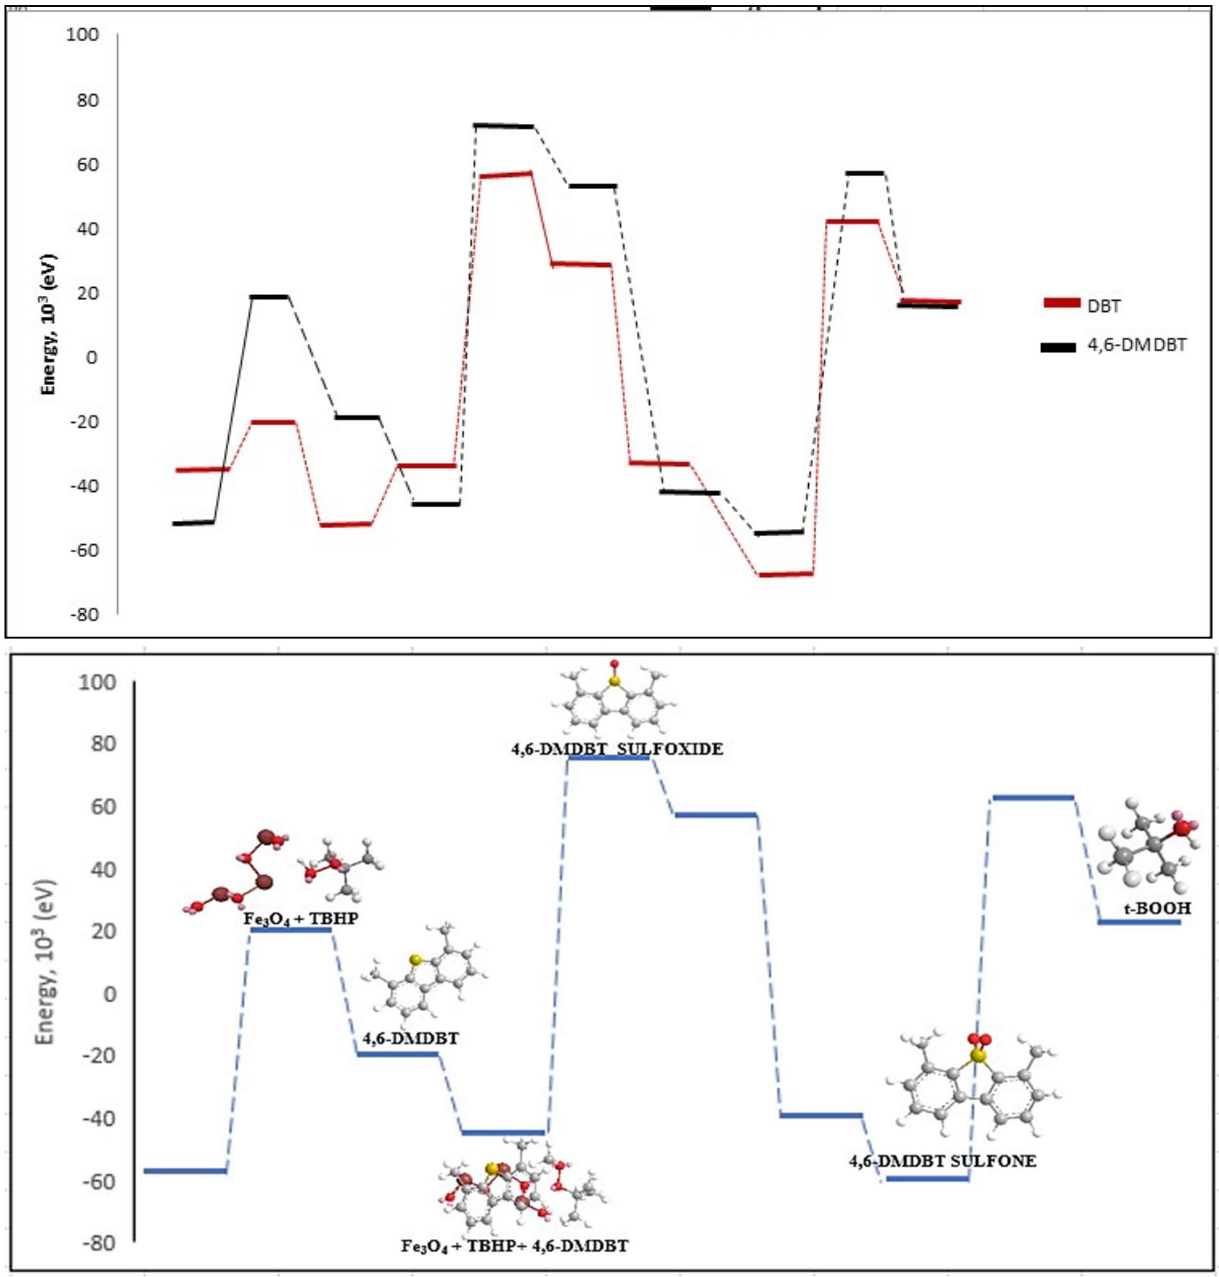

Figure 5. Energy level diagram for the oxidation of DBT and 4,6-DMDBT by TBHP in the presence of Co/Fe-Al_2O_3 catalyst

In order to determine the role of catalysts in oxidative desulfurization, an experiment was carried out in which the desulfurization process was examined without the use of a catalyst, as shown in (Figure 6). The first oxidation of DBT took place by nucleophilic attack of sulfur in DBT to oxygen in TBHP to form intermediate species. The energy required for the oxidation of DBT is 11.45 eV. This result showed that more energy was required to break the bond of reactant compared with oxidation of DBT in the presence of a catalyst. Next, the negatively charged oxygen in TBHP attacked hydrogen in intermediate to form tert-butanol and sulfoxide and the energy is released to -3.10 eV. Further reaction takes place by sulfoxide with TBHP to form sulfone and tert-

butanol. The overall activation energy of the oxidation of DBT and TBHP without the presence of a catalyst is -4.01 eV.

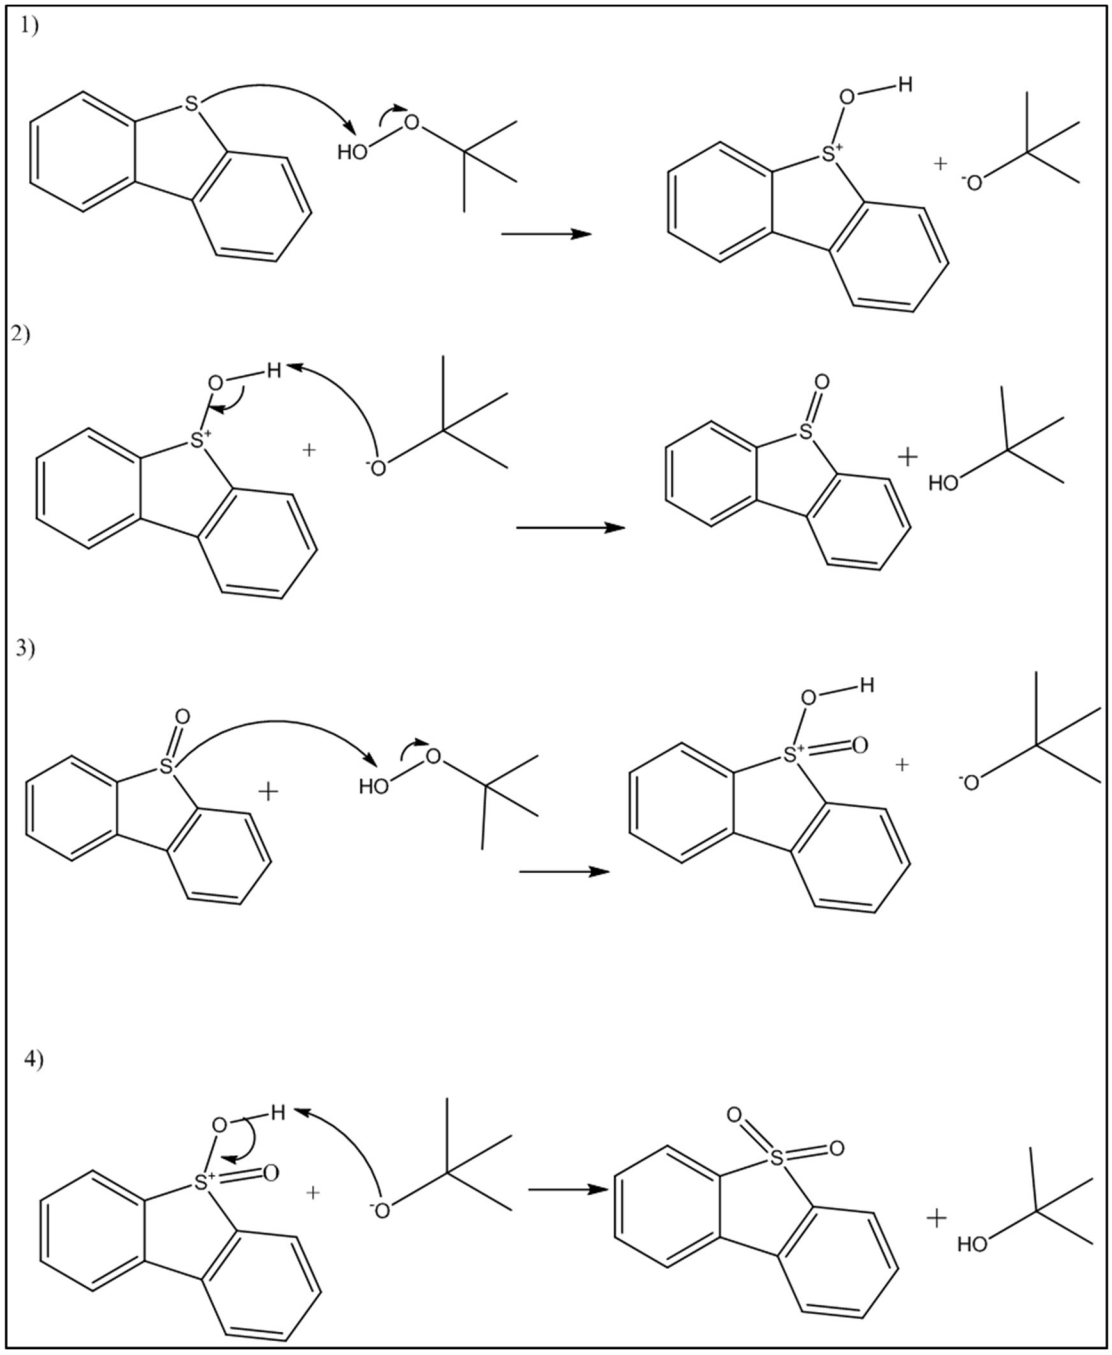

Figure 6. A proposed reaction for the oxidation of dibenzothiophene by TBHP

The activation energy in (Table 3), observed that the oxidation of DBT with catalyst released more energy than without a catalyst which is -40.78 eV and -4.01 eV. The energy profile demonstrated that all three reactions are exothermic. It shows that catalytic oxidation of DBT released more energy than uncatalyzed oxidation which

is -40.78 eV and -4.01 eV, respectively. This result revealed that catalysts can have a major influence on ODS, which is consistent with the experimental studies.

Table 3. Reaction energy for the oxidation of DBT and 4.6-DMDBT by TBHP

Steps	Ea(eV), x10^3		
	DBT		4,6-DMDBT
	Without Catalyst	With Catalyst	With Catalyst
I	11.45	-7.67	-20.2
II	-3.10	0.83	-1.65
III	-3.26	-3.83	5.69
IV	-9.10	-12.03	3.2
V		-17.81	-10.23
Overall	-4.01	-40.78	-23.19

Conclusion

Co/Fe in the ratio of 10:90 catalyst calcined at 400°C showed the highest conversion of DBT at 100%, 4,6-DMDBT (79%), and thiophene (93%). Meanwhile, Co/Fe-Al_2O_3 catalyst could retrieve its catalytic recycling performance up to five cycles. The mechanism of 4,6-DMDBT by the proposed pathway was also investigated and found that higher activation energy -23.19 eV compared to DBT, and this agreed with the catalytic activity, where DBT is easy to remove compared to 4,6-DMDBT. Furthermore, the mechanism without the catalyst of DBT released lower energy, -4.01 eV respectively. In conclusion, the presence of the catalyst can speed up the reaction in removing sulfur compounds.

Abstract

The Zika virus (ZIKV) is a mosquito-borne virus spread by the bite of *Aedes aegypti* and *Aedes albopictus* mosquitoes. The outbreak of the virus resulted in the 2015-2016 ZIKV epidemic, in which later Public Health Emergency of International Concern was declared by the World Health Organization (WHO). Despite the complications following the infection of ZIKV, clinically approved therapeutic agents and vaccines are still unavailable for the treatment of ZIKV. Schiff base vanillin derivatives, derived from vanillin and primary amines, were reported for their potential antiviral activity against a several viruses, including influenza virus and SARS coronaviruses. Therefore, they were aimed to be tested for their *in silico* antiviral activity against ZIKV NS2B-NS3 protease. In this research, ligand-based pharmacophore modelling was employed to analyse the antiviral activity of Schiff base vanillin derivatives. They were imported as test sets in the pharmacophore model generated from a list of training sets, which are reported drugs against ZIKV. Furthermore, structure-based molecular docking was also performed to analyse the docking performances of the Schiff base vanillin derivatives in the crystal structure of ZIKV NS2B-NS3 protease in a complex with a boronate inhibitor (PDB: 5LC0). The analyses were based on pharmacophore scores, binding affinities and matching interactions in comparison with the 5LC0 ligand in the active site. Based on the findings *via* ligand-based pharmacophore modelling and structure-based molecular docking, it was discovered that a number of Schiff base vanillin derivatives showed potential antiviral activity against ZIKV, thus being promising drug candidates and bringing futuristic *in vitro* and *in vivo* tests.

Keywords: Zika virus, Schiff base vanillin derivatives, pharmacophore modelling, molecular docking, computer-aided drug design

Abstrak

Virus Zika (ZIKV) adalah virus bawaan nyamuk yang disebarkan melalui gigitan nyamuk *Aedes aegypti* dan *Aedes albopictus*. Wabak virus ini menyebabkan epidemik ZIKV 2015-2016, di mana kemudian Darurat Kesihatan Awam Keprihatinan Antarabangsa telah diisytiharkan oleh Pertubuhan Kesihatan Sedunia (WHO). Walaupun komplikasi setelah jangkitan ZIKV, agen terapeutik dan vaksin yang diluluskan secara klinikal masih belum tersedia untuk rawatan ZIKV. Terbitan vanillin bes-Schiff, yang diperolehi daripada vanilin dan amina primer, telah dilaporkan aktiviti antiviral berpotensi terhadap beberapa virus, termasuk virus influenza dan koronavirus SARS. Oleh itu, mereka akan diuji untuk aktiviti antiviral secara *in silico* terhadap protease NS2B-NS3

ZIKV. Dalam penyelidikan ini, pemodelan farmakofor berasaskan ligan digunakan untuk menganalisis aktiviti antiviral terbitan vanillin bes-Schiff. Mereka diimport sebagai set ujian terhadap model farmakofor yang dihasilkan daripada senarai set latihan, iaitu ubat-ubatan dilaporkan terhadap ZIKV. Selain itu, dok molekul berasaskan struktur juga dilakukan untuk menganalisis prestasi dok terbitan vanillin bes-Schiff di dalam struktur kristal ZIKV NS2B-NS3 protease dalam kompleks dengan perencat boronat (PDB: 5LC0). Analisis dijalankan berdasarkan skor farmakofor, afiniti dok, dan interaksi yang sepadan dengan ligan 5LC0 di tapak aktif. Berdasarkan hasil pemodelan farmakofor berasaskan ligan dan dok molekul berasaskan struktur, adalah didapati bahawa beberapa terbitan vanillin bes-Schiff menunjukkan aktiviti antiviral yang berpotensi terhadap ZIKV, oleh itu menjadi calon ubat yang menjanjikan dan mampu membawa ujian *in vitro* dan *in vivo* pada masa depan.

Introduction

The Zika virus (ZIKV) is a mosquito-borne viral disease spread by the bite of *Aedes aegypti* and *Aedes albopictus* mosquitoes, which belongs to the *Flaviviridae* virus family (Figure 1). The virus belongs to the Flavivirus genus, which is the same genus as dengue, yellow fever, Japanese encephalitis, and West Nile viruses [1]. ZIKV was first discovered in 1947 in the Ziika forest of Uganda, which was identified in a Rhesus macaque monkey [2]. Infections among humans have since been detected in Africa and Asia from the 60s to 80s, which then relentlessly spread over the Western hemisphere in the past decade [2]. Major outbreaks were recorded in 2007 in Africa, which was in the Yap Islands, Micronesia [3], and later in 2013 in French Polynesia [4]. In 2015 in Brazil, ZIKV infection was detected in association with microcephaly, a condition where the size of head is smaller than the normal size [2]. Consequently, the World Health Organization (WHO) declared a Public Health Emergency of International Concern (PHEIC) from February to November 2016 [2].

ZIKV is highly infectious among pregnant women, not only it can lead to microcephaly among infants, but as well as congenital malformations, such as limb contractures, high muscle tone, eye abnormalities and hearing loss, also known as congenital Zika syndrome [2]. Other than that, other complications such as preterm birth and miscarriage might follow as well [5]. On top of that, Zika infections may also increase the risk of developing a rare autoimmune disorder, known as the Guillain–Barré syndrome [5]. The virus is not only transmitted by the bite of *Aedes aegypti* and *Aedes albopictus* mosquitoes, as well as mother-to-fetus virus transmission, sexual transmission, transfusion of blood and organ transplantation [2]. Despite numerous complications, licensed and approved drugs and vaccines are still unavailable from the treatment of Zika infections [2], which resulted in great deal of active research in different fields in search of drugs and vaccines for the medication of Zika infections.

ZIKV is a small enveloped, positive-sense single-stranded RNA virus [6]. The opening frame (ORF) encodes one polyprotein made up of 3419 amino acids, which is cleaved by the host of viral proteins into 3 structural proteins and 7 non-structural proteins [7]. The structural proteins consist of activating capsid, membrane, and envelope, while the non-structural proteins consist of NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5 proteins [8] (Figure 2). Among all non-structural proteins, NS2B-NS3 protease serves a very crucial role in replication of virus and maturation of non-structural viral proteins, hence activating the virus [7]. NS3 protease belongs to the trypsin/chymotrypsin protease superfamily, whereby the protease domain is found at the N-terminus, and the RNA helicase domain is found at the C-terminus [9]. The NS3 helicase, which plays an imperative role in the replication and capping of RNA, is encoded by the NS3 C-terminal 440 residue region [10]. However, in order for the activation of NS3 protease, NS2B protease must be present in complex with NS3 protease [11]. Thus, the transmembrane NS2B protease combines with the N-terminal 170-residues of NS3 to form NS2B-NS3 protease, which has excellent proteolytic activity, making it an attractive and promising target for the design and development of drugs to inhibit the viral activity of NS2B-NS3 protease, which in turn to search for the medication of Zika infection [12].

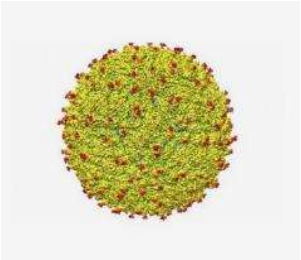

Figure 1. Representation of the surface of ZIKV [13]

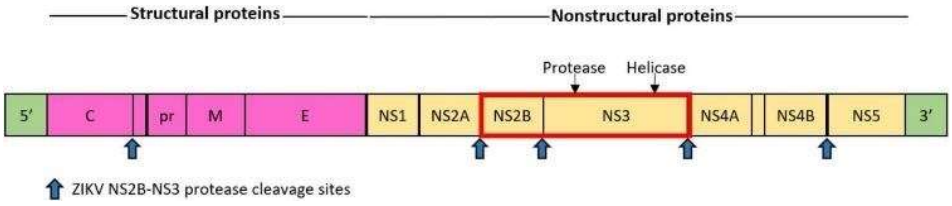

Figure 2. Representation of ZIKV genome [12]

Heretofore, clinically approved therapeutic agents and vaccines are still unavailable not only for Zika infection, but for most of the viral infections. Affected patient from ZIKV are only prescribed pain and fever reliever such as paracetamol and acetaminophen, and recommended staying hydrated, as well as getting enough rest. However, the complications as elaborated above might still follow, which describes the severity of the condition and the necessity to search for the clinically approved and licensed drugs and medications. Nevertheless, the design and discovery of drugs, medicines or novel compounds as inhibitors of viral proteases has always been a very complicated and challenging field among researchers. Not only being expensive, laborious and time-intensive, it was reported that in the past, but the process of drug discovery was also done based on serendipitous discovery from the isolation of crude extracts from different natural products, such as *Aphloia theiformis*, an edible endemic plant from Indian Ocean islands [14]. On top of that, these crude extracts and chemicals were only tested for their biological activity but not based on the biological target [15]. Fortunately, following the advance of modern technology, computer-aided drug design (CADD) allows the process of drugs discovery to be more efficient and time-saving at the cost of minimum expense. On top of that, in combination with laboratory processes, the mechanism of drug against the biological target, and the design of novel drugs or inhibitors based on the active sites of biological target can be illustrated well. Therefore, a great deal of research and efforts have been performed *via* CADD which resulted in the disclosure of numerous compounds possessing great potential as inhibitors of NS2B-NS3 protease of ZIKV (Figures 3-5).

Myriad studies shed light on the analysis of protein-ligand interaction. 2 drugs approved by Food and Drug Administration (FDA), which are asunaprevir and simeprevir, were discovered as potential NS2B-NS3 inhibitors *via* structure-based molecular docking of CADD, therefore possess potent anti-ZIKV activity [16]. Similarly, Meewan et al. reported their work in analysing 7 million compounds against the NS2B-NS3 protease through virtual screening, whereby out of all, 6 of the compounds which contain phenylquinoline and aminobenzamide groups showed positive docking result in the active site of the protease, therefore exhibiting potential antiviral activity to suppress the viral replication [12]. Furthermore, in another reported research of virtual screening of 1861 FDA approved drugs in Drug Bank against the crystal structure of NS2B-NS3 protease, antihistaminic chlorcyclizine displayed the most important interaction with the active site, thus suggesting itself for being a promising drug against ZIKV [17]. Moreover, a few clinically approved drugs showed great binding affinity in the active site of ZIKV, which includes sofosbuvir, hydroxychloroquine, azithromycin and novobiocin [9].

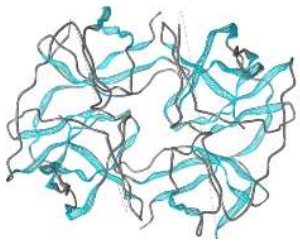

Figure 3. Crystal structure of ZIKV NS2B-NS3 Protease Shown in Structure-Based Perspective of LigandScout 4.4 [18]

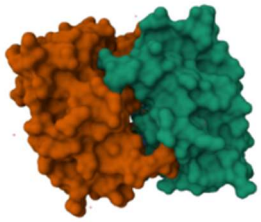

Figure 4. Crystal structure of ZIKV NS2B-NS3 Protease in Complex with Boronate Inhibitor [18]

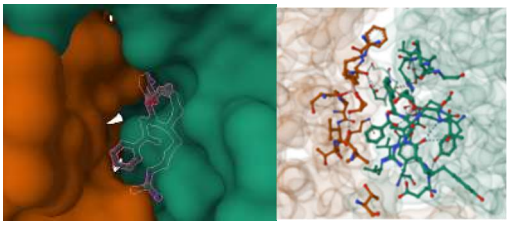

Figure 5. The boronate inhibitor in the active site of 5LC0 [18]

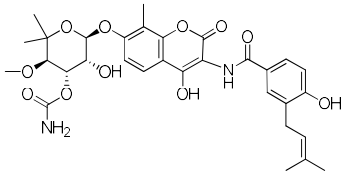
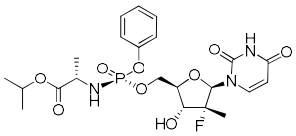
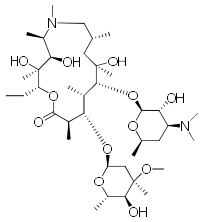
Among all the significant efforts of researchers, one of the class of compounds which potentially spike an interest in the Schiff base vanillin derivatives. Schiff base vanillin derivatives, which are synthesised from the Schiff base reaction between vanillin and primary amines, were reported for their potential antiviral activity against distinct types of viruses. In an earlier *in silico* research, the vanillin derivatives were reported to be able to inhibit the neuraminidase protease of influenza virus, which was later proven again by the performance of 2′-(4-Methylumbelliferyl)-*α*-*D*-*N*-acetylneuraminic acid (MUNANA) assay [19]. Similarly, the vanillin derivatives were also reported to show inhibitory activity against the main protease of severe acute respiratory syndrome coronavirus-2 (SARS-CoV 2) by the performance of both ligand-based pharmacophore modelling and structure-based molecular docking [20]. For having great interest and significant potential as antiviral compounds, but being limited in terms of the amount of research simultaneously, the present study focuses on the analysis and development of Schiff base vanillin derivatives as ZIKV NS2B-NS3 inhibitors *via in silico* methods, which are structure-based molecular docking and ligand-based pharmacophore modelling by using LigandScout 4.4.

Materials and Methods







Ligand-based pharmacophore modelling was performed by using LigandScout 4.4 software. Chemical structures of training sets were downloaded from ChemSpider in the MDL-mol format, while all the chemical structures of Schiff base vanillin derivatives were drawn by using ChemDraw Ultra 12.0 and downloaded in MDL-mol format as well. Structure-based molecular docking was performed by both LigandScout 4.4 and Autodock Vina. All Schiff base vanillin derivatives were converted from the MDL-mol format to the MDL-sdf format by using

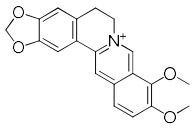
Open Babel GUI.

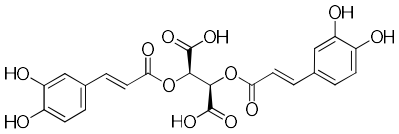
Ligand-based pharmacophore modelling

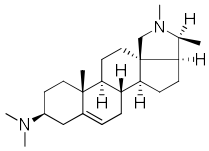
3 drugs which were reported in previous research for their inhibitory activity against ZIKV NS2B-NS3 protease were selected as training sets. The 3 training sets novobiocin [21], sofosbuvir [22] and azithromycin [23] were selected due to the depiction of a lot of common pharmacophore features by their molecular structures, hence being able to generate a model with as many pharmacophore features as possible. Their chemical structures are shown in Table 1 below:

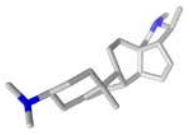
Table 1. 2D and 3D chemical structures of training sets: novobiocin [21], sofosbuvir [22] and azithromycin [23]

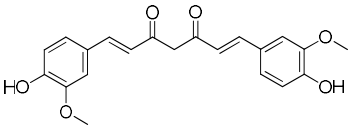
Training Sets	2D Chemical Structure	3D Chemical Structure
Novobiocin		
Sofosbuvir		
Azithromycin		

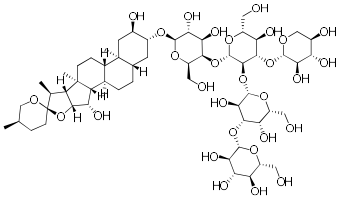


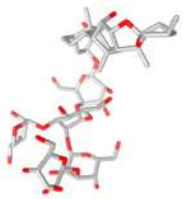


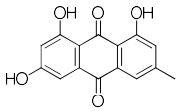


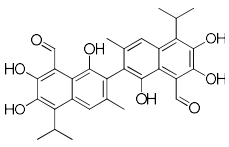


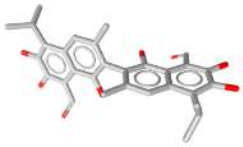




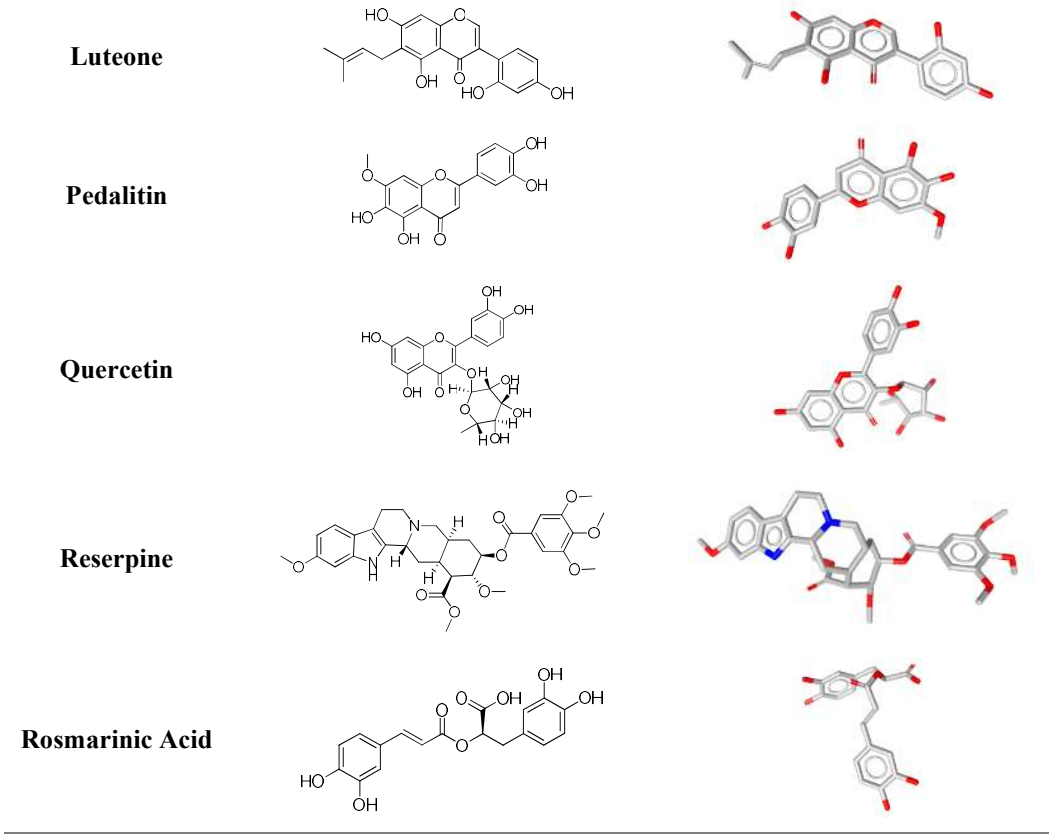








The chemical structures of the training sets were downloaded from ChemSpider in the MDF-mol format and imported into the ligand-based perspective of LigandScout 4.4 to generate the pharmacophore model based on common feature hypotheses. Test sets played imperative role in validating the reliability of the generated pharmacophore model. Hence, chemical compounds from natural products that were reported in previous literatures to possess inhibitory activity against NS2B-NS3 protease were selected as test sets to evaluate and validate the reliability of the pharmacophore model. A total of 12 chemical compounds from natural products include berberine [24], chicoric acid [25], conessine [26], curcumin [26], digitonin [26], emodin [24], gossypol [26], luteone [25], pedalitin [27], quercetin [27], reserpine [25] and rosmarinic acid [25]. These chemical compounds were downloaded from ChemSpider and imported as test sets in the ligand-based perspective of LigandScout 4.4 in the MDF-mol format (Table 2).



After the import of training sets and test sets, all the MMFF94 energies of the chemical structures were first minimised to ensure closest local minimum and maximum stability. Conformations of ligand sets were generated, clustered based on pharmacophore RDF-code similarity and average cluster distance calculation, and ligand-based pharmacophore modelling was performed based on pharmacophore fit. The 3 training sets generated a pharmacophore model, in which evaluations and analyses were based on the test sets' matching pharmacophore features and pharmacophore fit values in the generated pharmacophore model. The selection of test sets was based on compounds from natural products with wide difference of chemical structures and functional groups. The greater the difference in the chemical structures of the test sets, the higher the accuracy of these test sets to validate the

reliability of the pharmacophore model. If test sets were able to show pharmacophore fit values similar to or greater than the values of the training sets, as well as depicting as many matching pharmacophore features as possible, the pharmacophore model is said to be reliable for the assessment of the Schiff base vanillin derivatives as ZIKV NS2B-NS3 protease inhibitors.

The chemical structures of Schiff base vanillin derivatives were drawn and downloaded in the MDL-mol format by using ChemDraw Ultra 12.0. The Schiff base synthesis mechanism was generally as shown in Figure 6:

Table 2. 2D and 3D chemical structures of test sets from natural product

Test Sets	2D Chemical Structure	3D Chemical Structure

Gossypol		

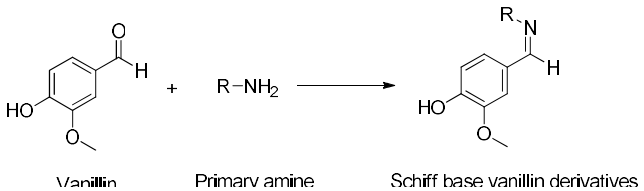

Figure 6. Schiff base synthesis mechanism

Schiff base vanillin derivatives were drawn based on the general mechanism between vanillin and primary amines, in which the list of primary amines was as follow:

(1) 1-piperidinecarboxamide
(2) 4-dinitrophenylhydrazine
(3) 2,6-dibromo-4-nitroaniline
(4) 2-amino-3-bromo-5-methylbenzoic acid

After all Schiff base vanillin derivatives were drawn and downloaded, they were imported as test sets into the ligand-perspective of LigandScout 4.4, together with novobiocin, sofosbuvir and azithromycin as training sets. Similarly, MMFF94 energies were minimised, conformations of all ligands were generated and clustered, and ligand-based pharmacophore modelling was run. The results were also obtained based on the vanillin derivatives' matching pharmacophore features with the features of the generated pharmacophore model, as well as their pharmacophore fit values in the model. Schiff base vanillin derivatives that displayed satisfied pharmacophore fit values and matching features were recorded and brought forward to the analyses in structure-based molecular docking.

Structure-based molecular docking

Crystal structure of Zika virus NS2B-NS3 protease in complex with a boronate inhibitor (PDB code: 5LC0) was retrieved from Protein Data Bank (PDB) and imported in the structure-based perspective of LigandScout 4.4, as shown in Figures 7 and 8.

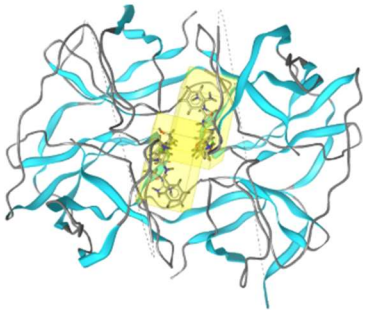

Figure 7. Crystal structure of Zika virus NS2B-NS3 protease in complex with a boronate inhibitor (PDB code: 5LC0) [18]

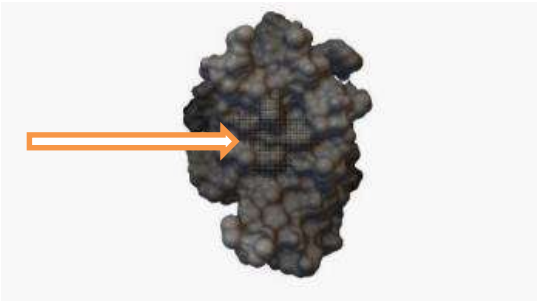

Figure 8. 3D cloud structure of Zika virus NS2B-NS3 protease in complex with a boronate inhibitor (PDB code: 5LC0) viewed by Autodock Vina

The boronate inhibitor, which is the ligand in the active site of 5LC0, shows inhibitory activity against the NS2B-NS3 protease of ZIKV (Figure 9). Therefore, evaluations and analysis were based on the alignments of the Schiff base vanillin derivatives with the pharmacophore model of the ligand to show their matched and aligned interactions with the active sites. Furthermore, the Schiff base vanillin derivatives were docked into the active sites of 5LC0 to evaluate their pharmacophore scores and binding affinities. The ligand was first selected, and the pharmacophore model of the ligand was generated. The ligand and generated pharmacophore model were then copied to the alignment perspective. The first Schiff base vanillin derivative, which is vanillin + 2-Amino-3-bromo-5-methylbenzoic acid was inserted as a single compound in the MDL-sdf format into the structure-based perspective. Again, all ligands and pharmacophore model were copied into the alignment perspective (Figure 10).

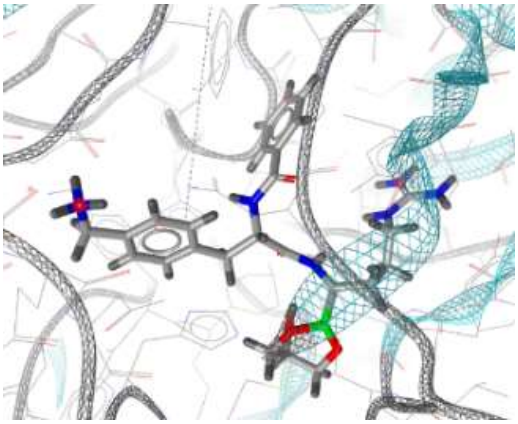

Figure 9. The boronate inhibitor in the active site of 5LC0 [18]

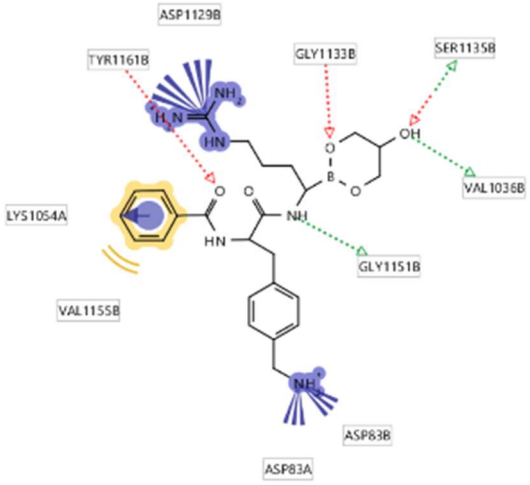

Figure 10. The protein-ligand interactions of boronate inhibitor against the NS2B-NS3 protease [18]

In the alignment perspective, the MMFF94 energy of the first Schiff base vanillin derivative was first minimized to represent minimum energy and maximum stability of the conformation. Alignment was then performed between the boronate inhibitor, and the Schiff base vanillin derivative based on common pharmacophore feature. The yellow spheres, blue features, green and red arrows were the pharmacophore features of boronate inhibitor, while the orange spots showed the common pharmacophore feature shared between the two ligands as depicted in Figure 11.

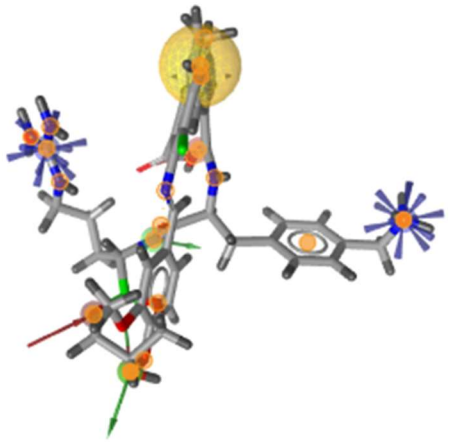

Figure 11. Alignment between pharmacophore model of boronate inhibitor and Schiff base vanillin derivative

Shared pharmacophore model was then generated, followed by merging the pharmacophores and interpolating the overlapping features. The result was as displayed in Figure 12 below.

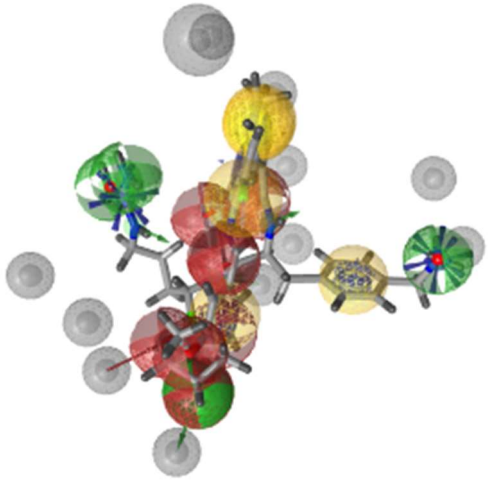

Figure 12. Shared pharmacophore featured, merged pharmacophores and interpolated overlapping features

The ligand was then injected back into the active site of 5LC0 to show the interactions of Schiff base vanillin derivatives inside the active site of NS2B-NS3 protease. From here, the interactions shown by Schiff base vanillin derivatives in compared to those depicted by boronate inhibitor in the active site of 5LC0 is analysed as portrayed in Figure 13 below.

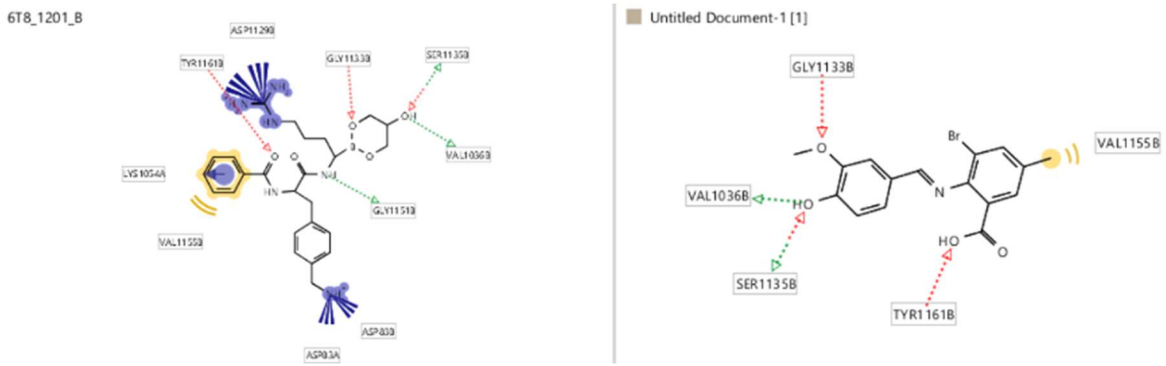

Figure 13. Protein-ligand interactions of Vanillin + 2-Amino-3-bromo-5-methylbenzoic acid, in which out of 10 interactions by boronate inhibitor, the vanillin derivative successfully matched 5 interactions

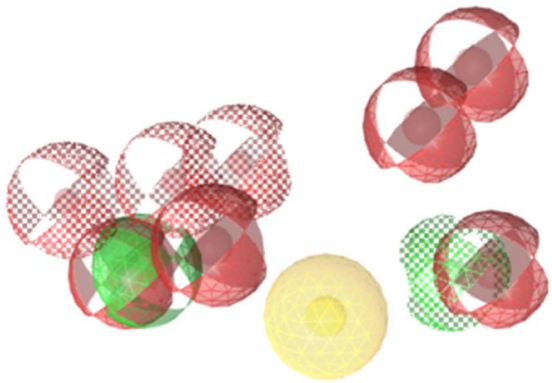
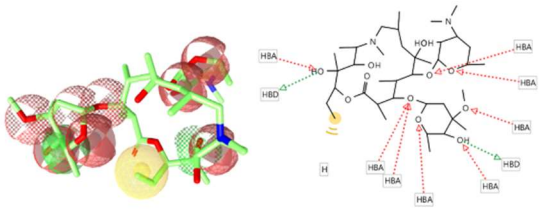
After the evaluation of interactions between the Schiff base vanillin derivative and the active sites of NS2B-NS3 protease, the vanillin derivative was then docked into the active site of the protease by using AutoDock Vina. 9 conformations of the vanillin derivatives with the best docking result obtained, and from here, the conformation with the best pharmacophore score and binding affinity was analysed. All the above steps are repeated for all drawn Schiff base vanillin derivatives, whereby the derivatives that showed the best results together with ligand-based pharmacophore modelling were recorded, evaluated and discussed.

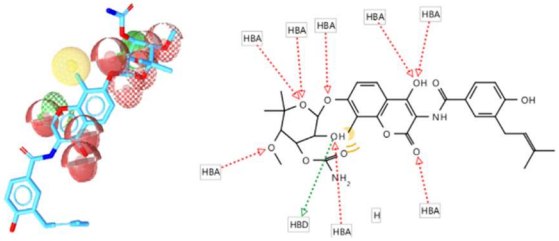
Results and Discussion

Ligand-based pharmacophore modelling

A pharmacophore model is successfully generated from the training sets, which were novobiocin, sofosbuvir and azithromycin. The model (Figure 14) was composed of 11 pharmacophore features, which are 8 hydrogen bond acceptors (HBA), 2 hydrogen bond donors (HBD) and 1 hydrophobic interaction (HI).







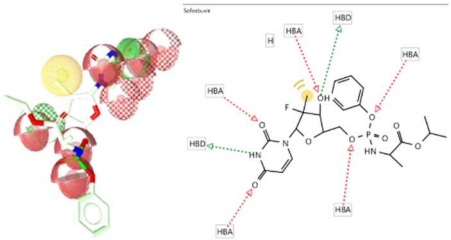


Figure 14. Generated pharmacophore model with 11 pharmacophore features

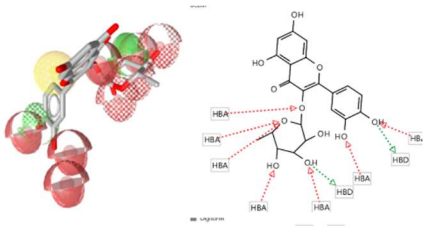

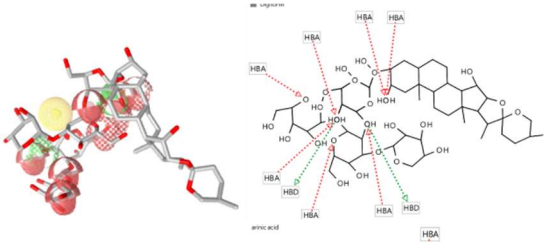

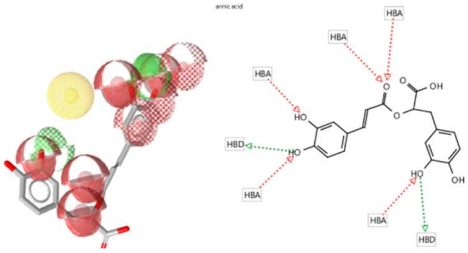

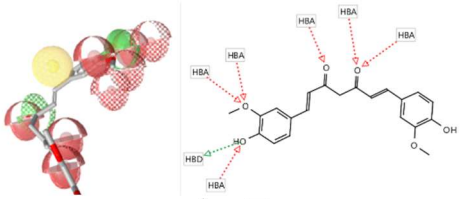

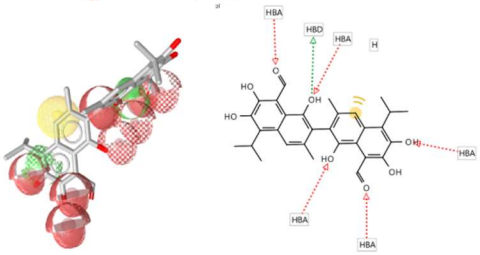

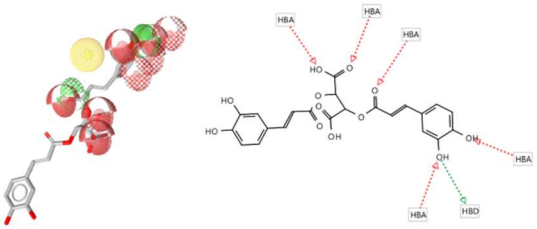

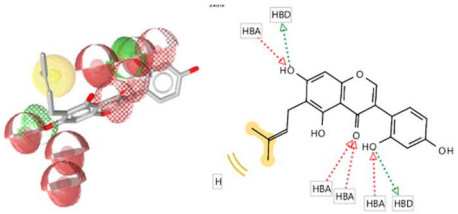

Out of 12 test sets, which were the chemical compounds from natural products for the validation of pharmacophore model, 11 test sets were able to illustrate 4 to 11 matching pharmacophore features, as well as good pharmacophore fit values. 2 test sets, which were quercetin and digitonin, showed higher fitting values than the training set. Thus, the pharmacophore model is justified for its reliability in evaluating the inhibitory activity of Schiff base vanillin derivatives against ZIKV NS2B-NS3 protease. Table 3 shows the pharmacophore fit values and matching features of test sets in the pharmacophore model, and Table 4 shows their matching features with the pharmacophore features depicted by the model.

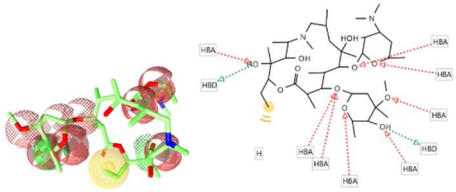
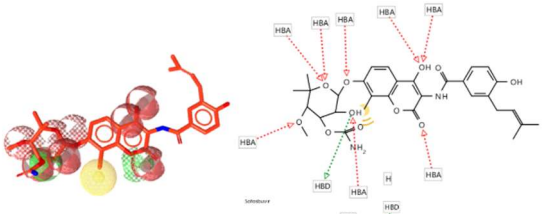
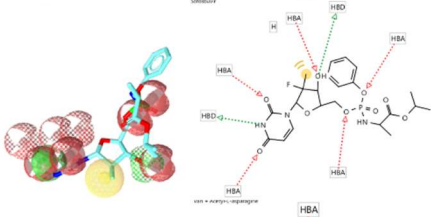
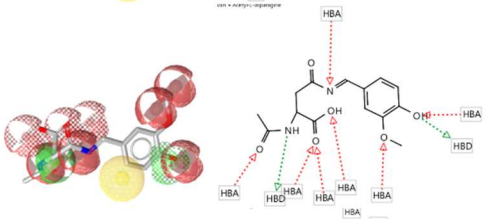
(21) Thiobenzamide

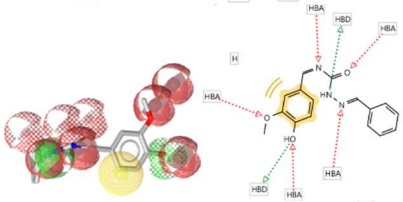


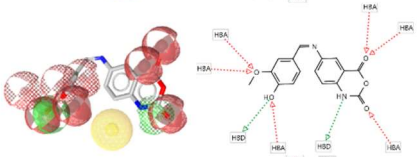
Similarly, the training sets generated a pharmacophore model with 11 features, which are 8 hydrogen bond acceptors (HBA), 2 hydrogen bond donors (HBD) and 1 hydrophobic interaction (HI). Out of 21 vanillin derivatives, a total of 19 compounds showed good pharmacophore fit values and 6 to 9 matching

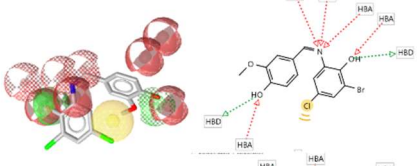


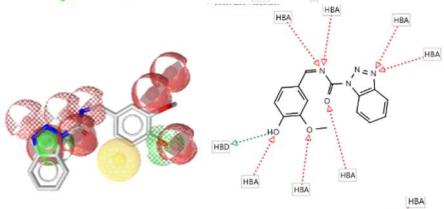


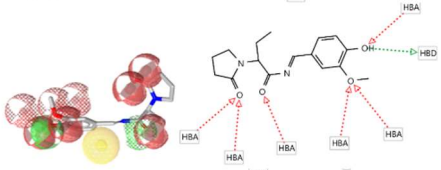


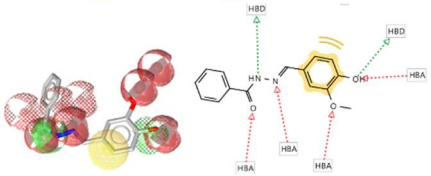












pharmacophore features out of the 11 features from the model. On top of that, compound (9) showed a fit value higher than the training set and the majority number of matching features, depicting immense potential as ZIKV NS2B-NS3 inhibitor. Nonetheless, (1) and (11) are unable to depict good matching features and pharmacophore fit values. The results of ligand-based pharmacophore modelling of Schiff base vanillin derivatives in the generated pharmacophore model were shown in Table 6, while Table 7 displayed their matching features with the pharmacophore features of the model.

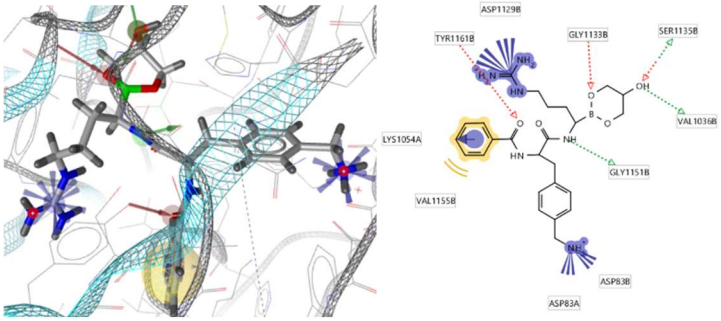
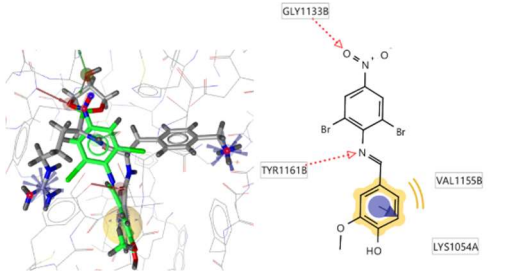
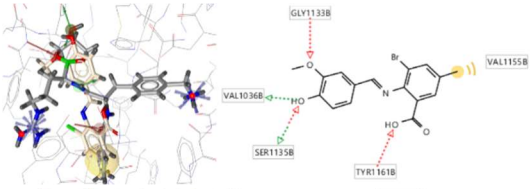
Based on Table 8, HBA and HBD were found mostly in both hydroxyl group, OH and ether group, C-O-C of vanillin part. Similarly, HI interaction was mostly found in the benzene ring of vanillin. This depicted the importance of vanillin in showing matching interactions with the generated pharmacophore model, hence showing vanillin's potential as ZIKV NS2B-NS3 inhibitors as the training sets. On top of that, HBA and HBD were also discovered in the imine linkage, C=N of Schiff base vanillin derivatives. Hence, this explains the importance and capability of Schiff base vanillin derivatives to show similar and matching interactions with the training sets as ZIKV NS2B-NS3 inhibitors. For the primary amine part, most HBA was shown by O atom in carbonyl, C=O groups, hydroxyl, OH groups and even nitro, NO_2 group, as well as depicted by N atoms. Due to the great amount of HBA and HBD involved, the selection of primary amines in reaction with vanillin to form Schiff base vanillin derivatives should consider most of the O and N atoms. This explains why compound (9) can show exceedingly high pharmacophore fit values, even higher than one of the training sets. The primary amine of (9), which is acetyl-L-aspargine, consists of 1 OH group, 3 O of C=O and 1 N group. Therefore, in combination with the OH and C-O-C of vanillin part, (9) depicted most of the pharmacophore features by the model, as well as having suitable molecular orientation. In some of the Schiff base vanillin derivatives, HI interaction was discovered in Br and Cl atoms. Thus, due to the presence of HI interaction in the model, primary amines with group 17 atoms or aromatic rings are preferably selected. The primary amines of compound (1) and (11) lack of the required functional groups to be aligned with the pharmacophore model. 1- piperidinecarboxamide in (1) has only 1 C=O and N group, while aniline in (11) has only 1 N group and 1 benzene ring. Due to the shortage of common pharmacophore features as well as suitable alignment orientation in the pharmacophore model, (1) and (11) are unable to display good fitting results in the model. Based on the results and explanations, all 19 Schiff base vanillin derivatives possessed potential inhibitory activity against ZIKV NS2B-NS3 protease, just as the interactions shown by the training sets. Therefore, all are subjected to structure-based molecular docking for further evaluation as ZIKV NS2B-NS3 inhibitors.

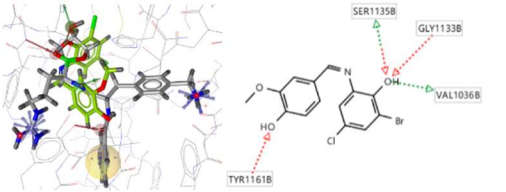
Structure-based molecular docking

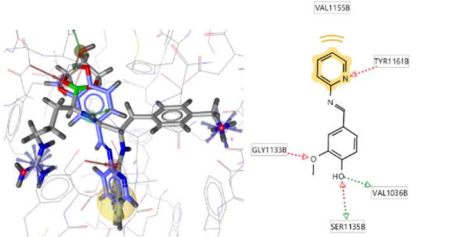
Based on the downloaded PDB crystal structure, the pharmacophore model and interactions of boronate inhibitor with the active sites of NS2B-NS3 protease were shown in Figure 15 below. The inhibitor showed 11 interactions, which were 3 HBA, 3 HBD, 3 positive ionisable area (PI), 1 aromatic ring (AR) and 1 HI.

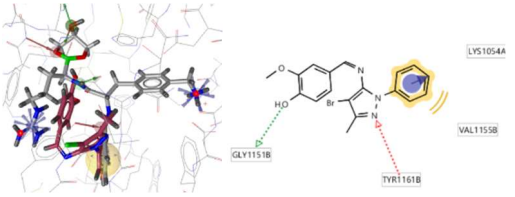












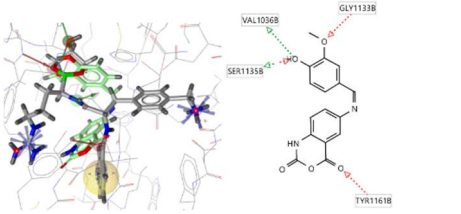


Figure 15. Pharmacophore model and interactions of boronate inhibitor with the active sites of 5LC0

Upon alignment and docking of the 19 Schiff base vanillin derivatives from ligand-based pharmacophore modelling results, 17 of them can depict 4 to 7 matching interactions with the active sites of 5LC0. On top of that, they are also able to show good pharmacophore scores and binding affinity values, hence having great inhibitory potential against NS2B-NS3 protease. Nevertheless, (1), (2), (9) and (11) were unable to show enough matching features in interaction with ZIKV NS2B-NS3 protease. This is due to the lack of enough common pharmacophore features to be aligned with the boronate inhibitor, as well as in the active site of 5LC0. Table 8 showed the pharmacophore scores and binding affinity values of the Schiff base vanillin derivatives upon docking *via* AutoDock Vina in the active site of ZIKV NS2B-NS3 protease, whereby the shaded columns, which were derivative (14), (15) and (19) showed the highest pharmacophore scores. Table 9 depicts their aligned interactions with the boronate inhibitor in the active site of ZIKV NS2B-NS3 protease.

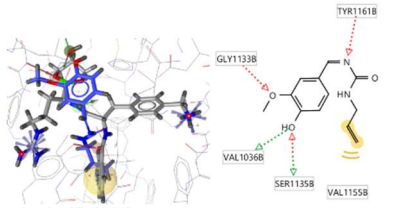

Table 8. Pharmacophore scores and binding affinity values (kcal mol^{-1}) of Schiff base vanillin derivatives upon docking by AutoDock Vina in the active site of ZIKV NS2B-NS3 protease

The 17 Schiff base vanillin derivatives were able to depict at least 4 matching interactions with satisfying pharmacophore scores, hence showing their potential inhibitory activity against NS2B-NS3 protease. Other than that, the molecular docking results of the Schiff base vanillin derivatives were also expressed based on their binding affinity values, which is a function of Gibbs free energy [28]. Binding affinity refers to the strength of binding interaction between a protein molecule to its ligand, which is between the 5LC0 protease with the Schiff base vanillin derivatives in this study. Being represented by the equilibrium dissociation constant, the more negative the binding affinity values, the greater the binding interaction and affinity [29]. Since binding affinity values are a function of Gibbs free energy, therefore affinity values less than -6.0 kcal mol^{-1} are considered active molecules, while affinity values greater than -6.0 kcal mol^{-1} are considered inactive molecules [29]. Based on the obtained results, the Schiff base vanillin derivatives showed binding affinity values less than -6.0 kcal mol^{-1}, ranging from -6.20 kcal mol^{-1} to -8.90 kcal mol^{-1}, indicating their property as active cluster molecules.

The interactions of the boronate inhibitor with the active sites of NS2B-NS3 protease are HBA towards TYR161B, GLY133B and SER135B, HBD towards SER135B, VAL36B and GLY151B, PI towards ASP129B, ASP83A and ASP83B, AR towards LYS54A, as well as HI towards VAL155B. The Schiff base vanillin derivatives mostly depict HBA towards TYR161B, GLY133B and SER135B, HBD towards SER135B and VAL36B, AR towards LYS54A and HI towards VAL155B. Most of the HBA and HBD were found to be depicted by the hydroxyl and ether group of the vanillin part, showing that vanillin itself plays an

imperative role in interactions with the active sites of ZIKV NS2B-NS3 protease. Moreover, the Schiff base vanillin derivatives displayed their inhibitory action against LYS54A and VAL155B, which are AR and HI through the benzene and pyridine rings of the primary amine part. This shows the potential of aromatic primary amines as NS2B-NS3 protease inhibitors, to be utilised as a starting product for the synthesis of Schiff base vanillin derivatives to inhibit NS2B-NS3 protease. This may explain the lack of potential of (9), as the primary amine of (9) is an aliphatic primary amine. Even though compound (2) shows reliable results in ligand-based pharmacophore modelling, due to the lack of enough pharmacophore features, as well as unable to depict suitable orientation in the active site of 5LC0, compound (2) is unable to align with boronate inhibitor. In another crystal structure of ZIKV NS3 protease in complex with peptidomimetic inhibitor, which is 4-guanidinomethyl-phenylacetyl-Arg-Arg-Arg-4-amidinobenzylamide, the inhibitor also showed HBA against TYR161B, GLY133B and SER135B, thus depicting the importance of interactions with these active sites [30]. Similarly, the crystal structure of ZIKV NS2B-NS3 protease with compound MI2219 (PDB code: 7VLH), and the crystal structure of Zika NS2B-NS3 protease with compound MI2220 (PDB code: 7VLI) showed HBA and HBD interaction with TYR161B, showing the imperative role of interaction with TYR161B in inhibition activity against the NS2B-NS3 protease [31], which is depicted by 16 out of 17 of the Schiff base vanillin derivatives. Compounds (1) and (11) have been shown to lack HBA and HBD interactions in ligand-based pharmacophore modelling due to the lack of required functional groups, hence they are unable to depict any interaction with these important active sites, especially TYR161B, GLY133B and SER135B. In conjunction with the results obtained from ligand-based pharmacophore modelling, all the 17 Schiff base vanillin derivatives above showed a great deal of potential as ZIKV NS2B-NS3 protease inhibitors *via in silico*, being promising drug candidates and bringing futuristic *in vitro* and *in vivo* tests to confirm the inhibitory activities.

Lipinski's rule of 5

Lipinski's rule of 5 or known as RO5 is a guideline rule which analyse and evaluate the drug likeness, and pharmacological and biological activity of chemical compounds as orally active drug for human consumption. The rule described the molecular properties crucial for a drug's pharmacokinetics in humans, known as 'ADME': absorption, distribution, metabolism, and excretion. RO5 states that for a chemical compound to be an orally active drug, the chemical compound should have:

- Not more than 5 hydrogen bond donors (HBD) (nitrogen-hydrogen and oxygen-hydrogen bonds)
- Not more than 10 hydrogen bond acceptors (HBA) (nitrogen and oxygen atoms)
- Molecular weight less than 500 g/mol
- Partition coefficient log P not greater than 5 [32]

Based on RO5, all 17 Schiff base vanillin derivatives that showed potential inhibitory activity against ZIKV NS2B-NS3 protease fulfilled all rules, having less than 5 HBD, less than 10 HBA, molecular weight less than 500 g/mol and partition coefficient log P less than 5. Therefore, they are considered to possess drug likeness as potential orally active drugs, thus supporting their role as potential NS2B-NS3 inhibitors. Table 10 summarised the RO5 results of the Schiff base vanillin derivatives.

Conclusion

From ligand-based pharmacophore modelling to structure-based molecular docking, a total of 21 Schiff base vanillin derivatives were evaluated for the ZIKV NS2B-NS3 protease inhibitory activity. Out of 21 derivatives, 17 showed potential results as NS2B-NS3 inhibitors. In ligand-based pharmacophore modelling, 19 of them showed good pharmacophore fit values, and 6 to 9 matched pharmacophore features out of 11 features depicted by pharmacophore model of training sets. In structure-based molecular docking, 17 of them showed 4 to 7 matching interactions with the 11 interactions shown by boronate inhibitor ligand in the active site of 5LC0, as well as good fit values and binding affinity values upon docking. As a result, the Schiff base vanillin derivatives that passed both ligand-based pharmacophore modelling and structure-based molecular docking are **(3), (4), (5), (6), (7), (8), (10), (12), (13), (14), (15), (16), (17), (18), (19), (20)** and **(21)**. The 17 Schiff base vanillin derivatives also fulfilled Lipinski's Rule of 5, depicting their drug likeness

properties and being potential orally active drugs. Being proven as promising drug candidates through *in silico* study, further analysis and research *in vivo* and *in vitro* becomes interesting and potential research in future to ensure the safety and lethality of these derivatives, and to bring more opportunities to more research in the study of ZIKV NS2B-NS3 inhibitors.

Abstract

A critical global environmental crisis has emerged due to the use of synthetic organic pollutants in industry, which resulted in the pollution of water. Recently, photocatalysis has attracted much attention for its potential to effectively, economically, and environmentally friendly remove organic pollutants from wastewater. ZnO is known as a potential photocatalyst for the degradation of wastewater in the UV region. However, ZnO has limited light absorption within the UV region and exhibits fast recombination of electron-hole pairs, which reduces its efficiency. To overcome this issue, a g-C_3N_4/ZnO photocatalyst for organic pollutant degradation in wastewater was developed to extend the light absorption towards the visible region. This research aims to investigate the performance of g-C_3N_4/ZnO nanocomposites in the degradation of ofloxacin (OFL). The ZnO was prepared using the sol-gel method, while the g-C_3N_4 was prepared using thermal decomposition. The composite catalyst of g-C_3N_4/ZnO was prepared by mixing g-C_3N_4 and ZnO. The prepared catalysts were characterized using X-ray diffraction (XRD), field emission scanning electron microscopy (FESEM), UV-Vis NIR spectrophotometer, high-resolution transmission electron microscopy (HRTEM), and Brunauer Emmet Teller (BET). As a result of the composite photocatalyst combining ZnO and g-C_3N_4, the band gap decreased from 3.30 eV to 2.92 eV. The degradation of OFL using g-C_3N_4/ZnO nanocomposite is 11 times higher than that of pristine ZnO and double than that of pristine g-C_3N_4.

Abstrak

Krisis alam sekitar global yang kritikal telah muncul akibat penggunaan bahan pencemar organik sintetik di dalam industri, mengakibatkan pencemaran air. Baru-baru ini, fotokatalisis telah menarik banyak perhatian kerana potensinya untuk merawat bahan organik daripada air sisa tercemar secara berkesan, ekonomikal dan mesra alam. ZnO dikenali sebagai fotomangkin berpotensi untuk degradasi air sisa tercemar di kawasan UV. Walau bagaimanapun, ZnO mempunyai penyerapan cahaya yang terhad dalam kawasan UV hanya disebabkan oleh tenaga jurang jalur yang besar (3.37 eV) dan mempamerkan penggabungan semula pantas pasangan lubang elektron, yang mengurangkan kecekapannya. Untuk mengatasi isu ini, fotomangkin g-C_3N_4/ZnO untuk degradasi bahan organik dalam rawatan air sisa telah dihasilkan untuk meningkatkan penyerapan cahaya ke arah cahaya tampak. Matlamat penyelidikan ini adalah untuk menyiasat prestasi nanokomposit g-C_3N_4/ZnO dalam degradasi ofloksasin (OFL). ZnO disediakan menggunakan kaedah sol-gel, manakala g-C_3N_4 disediakan menggunakan penguraian terma. Mangkin komposit g-C_3N_4/ZnO disediakan dengan mencampurkan g-C_3N_4 dan ZnO. Pemangkin yang disediakan telah dicirikan menggunakan pembelauan sinar-X-(XRD), mikroskopi imbasan elektron pancaran medan (FESEM), spektrofotometer UV-Vis NIR, mikroskopi transmisi elektron resolusi tinggi (HRTEM), dan Brunauer Emmet Teller (BET). Hasil daripada fotomangkin komposit yang menggabungkan ZnO dan g-C_3N_4, jurang jalur menurun daripada 3.30 eV kepada 2.92 eV. Degradasi ofloksasin menggunakan nanokomposit g-C_3N_4/ZnO adalah 11 kali lebih tinggi daripada ZnO dan 2 kali lebih tinggi daripada g-C_3N_4 tulen.

Kata kunci: g-C_3N_4/ZnO, ofloksasin, degradasi, fotokatalisis, rawatan air tercemar

Introduction

The increasing use of pharmaceuticals in recent years has attracted researchers' attention due to their harmful impact on the environment. They have been identified as the most common organic pollutants found in wastewater from various sources, such as hospitals, households, industries, and agricultural waste. Antibiotics contribute to a large proportion of the numerous pharmaceutical products consumed due to their widespread use in veterinary and human medicine for the treatment or prevention of bacterial diseases [1, 2]. Ofloxacin (OFL) is a quinolone antibiotic known as an antibacterial agent used for the treatment of bacterial infections in body parts including the skin, kidney, soft tissue, respiratory tract, and urine tract [3]. OFL is a third-generation fluoroquinolone antibiotic and cannot be completely metabolized by the human body, in which 20-80% of the indigested agent is excreted in pharmacologically active form. It has been reported that low concentrations of OFL can accumulate in water for prolonged periods of time. The fluoroquinolones that are present in wastewater can lead to the proliferation of drug resistant bacteria through induction and selection. It can be harmful to human health and can potentially reduce the ability of human immune system to fight those bacteria strains [4–9].

OFL has been detected in water environments such as in hospital wastewater (35 µg/L), urban wastewater treatment plants (1.8 µg/L), sewage water (0.89-31.73 µg/L) and surface water (0.5-35 µg/L) [10,11]. Various methods have been extensively explored for the removal of OFL such as adsorption, biodegradation, chlorination, precipitation, coagulation etc. [6, 12-15]. However, most of the methods are unable to remove the organic pollutant completely and effectively. In recent years, photocatalysis has attracted attention for antibiotic degradation due to its high efficiency, excellent stability, and eco-friendliness compare to the conventional methods [5, 16, 17].

ZnO is a metal oxide semiconductor that has good electron transfer ability, exhibits photostability and can generate holes for strong oxidation. Despite its numerous advantages, ZnO has certain limitation of poor photocatalytic response to visible light due to having a wide band gap (3.37 eV) and fast recombination of photogenerated electron-hole pairs [18, 19]. Various approaches have been attempted to overcome this limitation, which include making suitable composites such as ZnO/CdS, ZnO/Sn_3O_4, CuO/ZnO, ZnO/TiO_2, ZnO-CoO_x-CeO_2 and etc. [20-24].

Graphitic carbon nitride (g-C_3N_4) is the most stable allotrope of carbon nitrides at ambient temperature and has received a lot of attention in recent years. The g-C_3N_4 is a metal-free n-type semiconductor polymer with a two-dimensional structure similar to graphite. In

the visible spectral range, g-C_3N_4 has a band gap of 2.7 eV, corresponding to an optical wavelength of 460 nm, making it an excellent photocatalyst. In addition to being safe and non-toxic, g-C_3N_4 is highly stable and has a strong reduction ability, as well as being light active. [25-29]. However, g-C_3N_4 also has disadvantages of photogenerated electron and holes pairs that easily recombine, which greatly reduces the performance of the photocatalyst. Since g-C_3N_4 has a large resistance, it blocks the transfer of photoexcited electrons.

The combination of g-C_3N_4/ZnO could improve the photocatalytic performance due to the complementary properties of both g-C_3N_4 and ZnO. The ability of g-C_3N_4 to absorb visible light is well known, whereas ZnO can absorb only UV light. This combination can extend the light absorption with a broader spectrum of light that can enhance the photocatalytic performance. The g-C_3N_4/ZnO composite exhibits synergistic effects, resulting in a more efficient and effective photocatalyst than either material alone. This synergy has the potential to improve electron-hole pair generation and separation which can improve the photocatalytic performance [30-33]. The formation of g-C_3N_4 and ZnO to form a heterojunction can significantly reduce the recombination rate of electron holes by modifying the charge carrier pathway at the interface. Hybrid structures can facilitate interfacial charge transfer, enabling electrons and holes to be simultaneously available for selective redox reactions [34]. In summary, heterojunction of g-C_3N_4 and ZnO provides several advantages, including improved charge separation, extended light absorption range, increased photocatalytic activity, and improved stability. Due to these characteristics, g-C_3N_4/ZnO heterojunctions are attractive for a variety of environmental and energy applications.

In the present work, g-C_3N_4/ZnO nanocomposite has been synthesized using sol-gel, thermal decomposition method followed by wet impregnation method. The photocatalytic activity was evaluated based on the degradation of OFL. It has been observed that the photocatalytic activity of the composite has improved significantly compared to the pristine.

Materials and Methods

Materials

Melamine ($C_3H_6N_6$,>99%) was used as the precursor for g-C_3N_4, Zinc acetate $Zn(CH_3COO)_2$ was used for the preparation of ZnO. The ammonium hydroxide (NH_4OH) and absolute ethanol were used as the solvent, and analytical grade of OFL (Sigma-Aldrich) was used as the organic pollutant in this study.

Preparation of the g-C_3N_4/ZnO photocatalysts

The synthesis method that was used for the preparation of ZnO catalyst is the sol-gel method. This method involves the dissolution of the starting material, $Zn(CH_3COO)_2$, in absolute ethanol. The solution was then stirred using a magnetic stirrer for an hour to make sure the solution completely dissolved and obtained a homogenous mixture. The NH_4OH, was then added to the solution to obtain pH 9. The mixture was then dried to obtain the ZnO precursor. The ZnO precursor was then annealed at 300 °C for 24 hours. The g-C_3N_4 was prepared using thermal decomposition by directly heating the melamine using a crucible and covering it with a lid at 550 °C for 3 hours. The preparation of a composite catalyst of g-C_3N_4/ZnO was done by using wet impregnation, which involved mixing g-C_3N_4 and ZnO in a 1:1 mass ratio. The solid mixture was then dissolved in deionized water and stirred for 1 hour to obtain a homogenous solution. The mixture solution was then filtered, washed with deionized water, and dried in an oven at 200 °C for 5 hours. The dry powder was then ground into a very fine powder to obtain the final products, which were ready for other characterizations.

Characterization of the g-C_3N_4/ZnO photocatalysts

The phase studies of the catalyst were performed by the XRD PANalytical X'Pert Pro MPD Diffractometer using the Bragg Brentano optical configuration under ambient conditions. The morphology and crystallite size of the photocatalysts were examined using field emission scanning electron microscopy (FESEM, JEOL JSM-7600F) equipped with energy dispersive X-ray spectroscopy (EDX) to give quantitative elemental mapping. The light absorption properties were studied using the Perkin Elmer Lambda 950 UV-Vis NIR in

reflectance mode. The surface area, pore volume, and pore diameter were determined using the N_2 adsorption-desorption isotherm by the BELJAPAN BELSORP-mini porosity analyzer.

Degradation of OFL by g-C_3N_4/ZnO

The photocatalytic activity of ZnO, g-C_3N_4, and g-C_3N_4/ZnO photocatalyst was evaluated by the determination of OFL degradation at each interval using UV-Vis NIR spectrophotometer. The photocatalytic reactor is equipped with a 150-watt LED visible lamp as the light source to carry out the photocatalytic activity (under standard temperature and pressure). The amount of 0.25 g of photocatalyst was added to 150 mL of 10 ppm OFL solution. Then, the solution was stirred for about 30 minutes in a dark condition for equilibrium adsorption, and then the light source was applied until the reaction was completed. The solution was extracted at intervals of 15 minutes. The photocatalytic analysis was performed using UV-Vis NIR spectrophotometer in absorbance mode. The photocatalytic performance of the photocatalyst was evaluated through the degradation of OFL using the following equation [1]:

$$Degradation\ (\%) = \frac{Co - Ct}{Co} \times 100\% \qquad (1)$$

where C_0 is the initial concentration of pollutant and C_t is the concentration of OFL at time (min).

Results and Discussion

Figure 1 represents the XRD patterns of pure ZnO, g-C_3N_4, and composite g-C_3N_4/ZnO. The phase structure was analyzed by the XRD Xpert Highscore Plus software. The 2θ values that correspond to the diffraction peak of the ZnO sample are 31.7°, 34.4°, 36.2°, 47.3°, 56.5°, 62.7°, 66.4°, 67.9°, and 69.0°, corresponding to (100), (002), (101), (102), (110), (103), (200), (112), (201), (004), (202), and (104) planes, which prove that the sample is pure and belongs to the hexagonal wurtzite crystalline phase of ZnO (ICDD No. 01-079-2205). The XRD pattern of g-C_3N_4 shows two peaks at 13.1° and 27.4°, which correspond to the ICDD pattern of g-C_3N_4 (ICDD No. 01-087-1526). The 13.1° peak that corresponds to the (100) plane indicates the periodic arrangement of the structural units in the layer that is graphite-like phase carbon nitride. The intensive peak at 27.4° belongs to the (002) plane and corresponds to the interlayer stacking of the conjugated carbocyclic plane [33]. The position of these two diffraction peaks is consistent with the previous report on g-C_3N_4 [35]. The XRD pattern of composite materials shows the appearance of ZnO and g-C_3N_4 peaks, which indicate the success of the composite materials.

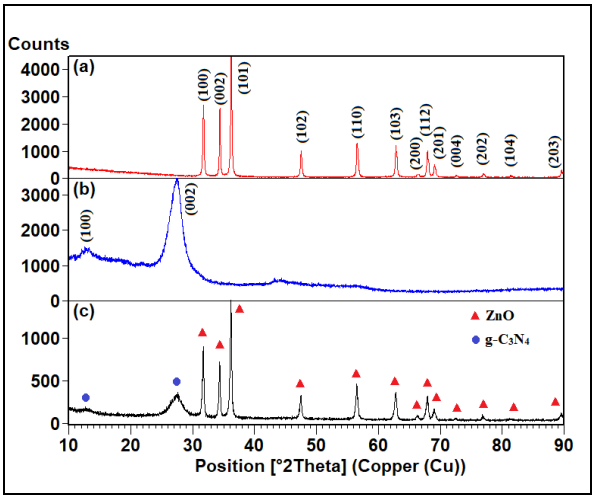

Figure 1. XRD patterns of (a) ZnO (b) g-C_3N_4 (c) g-C_3N_4/ZnO

Figure 2 represents the FESEM micrograph of pristine g-C_3N_4, pristine ZnO, and composite g-C_3N_4/ZnO at 50 k magnification. The composition of g-C_3N_4/ZnO was investigated by elemental mapping, as shown in Figure

3. (a)–(e) that confirms the uniform distribution of elements. The elements present in the material were determined using EDX analysis, as demonstrated in Figure 3 (f). The existence of Zn, O, C, and N elements can be clearly visualized in the EDX spectrum of the g-C_3N_4/ZnO, and no other elements were detected, which confirms its purity. Figure 4 (a) indicates the TEM image of g-C_3N_4/ZnO, which shows a nanospherical shape with an average crystallite size of 35 nm. The high-resolution and SAED images of g-C_3N_4/ZnO are shown in Figure 4 (b), which indicates the interplanar spacing of about 0.281 nm at the (100) plane of ZnO that is estimated from the intensity profile image.

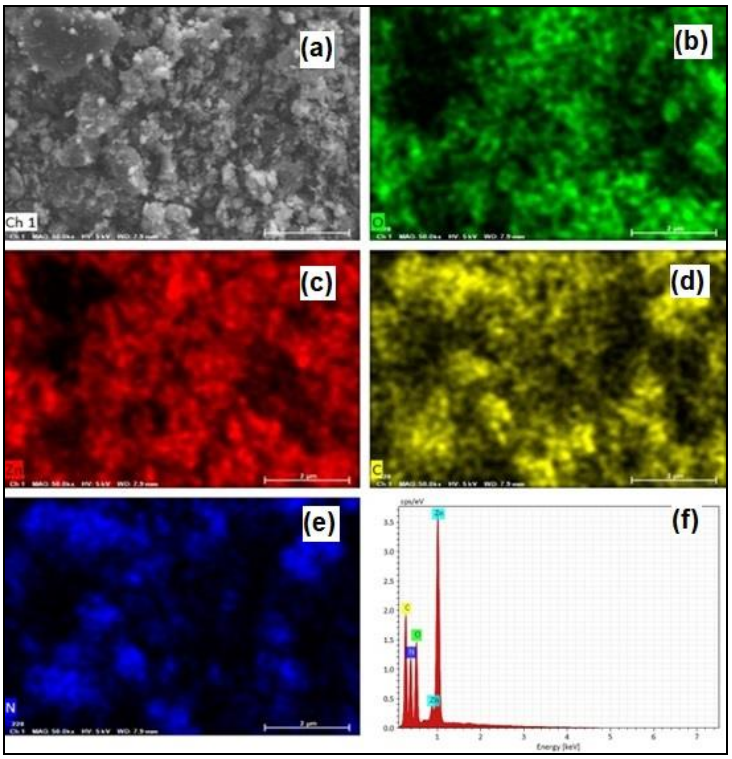

Figure 3. (a) FESEM image and elemental mapping (b) oxygen (c) zinc (d) carbon (e) nitrogen and (f) EDX spectrum of g-C_3N_4/ZnO

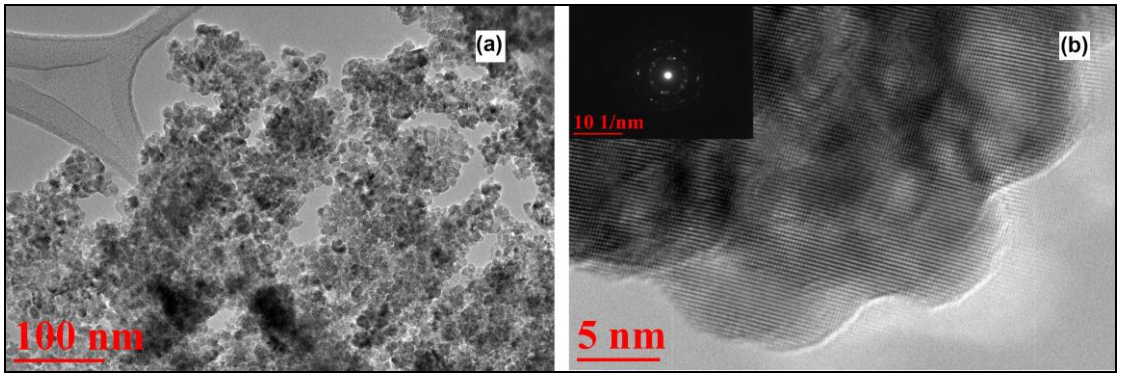

Figure 4. (a) TEM image of g-C_3N_4/ZnO at 100k magnification (b) High resolution image of g-C_3N_4/ZnO and SAED image at (100) plane

Figure 5 represents the UV-Vis reflectance spectra of ZnO, g-C_3N_4, and g-C_3N_4/ZnO. As can be observed, the composite materials exhibit the red shift towards the visible light region. Tauc plot for ZnO, g-C_3N_4, and g-C_3N_4/ZnO calculated based on the equations (2) to (4) [36]. From the reflectance spectra, a tauc plot was drawn, and the values of the band gaps can be obtained.

$$(\alpha h\upsilon) = A(h\upsilon - E_g)^n \qquad (2)$$

where α is the absorption coefficient of the material corresponding to a value of wavelength λ, h is Planck's constant, A is the proportionality constant, n is the frequency of light, E_g is the band energy, and n = ½ (for direct transition mode materials). The absorption coefficient is evaluated using equation (3):

$$\alpha = k \ln\left(\frac{R_{max} - R_{min}}{R - R_{min}}\right) \qquad (3)$$

where k is a constant, R_{max} is the maximum reflectance and R_{min} is the minimum reflectance. Consideration of equations. (2) and (3) gives equation (4),

$$(\alpha h\upsilon)^2 = A'(h\upsilon - E_g) \qquad (4)$$

where A′ is a constant. From Equation (4), a tauc plot can be drawn of $(\alpha h\nu)^2$ versus hν as shown in Figure 6. The point of the extrapolation of the linear part that meets the abscissa gives the value of the band gap energy of the material. It was found that the calculated band gap of ZnO is 3.31 eV. The band gap of g-C_3N_4 prepared is 2.81 eV whereas the band gap of g-C_3N_4/ZnO was observed to be 2.92 eV which is lower than the pristine ZnO. The reduced band gap of composite materials is attributed to the presence of g-C_3N_4 in the crystal lattice. This will cause the shifting of the valence and conduction bands, subsequently narrowing the band gap.

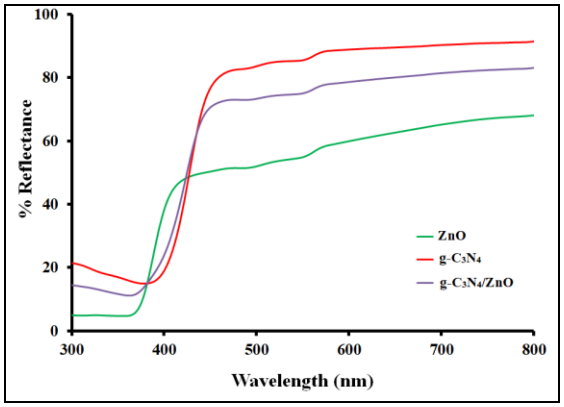

Figure 5. Reflectance spectra of ZnO, g-C_3N_4 and g-C_3N_4/ZnO

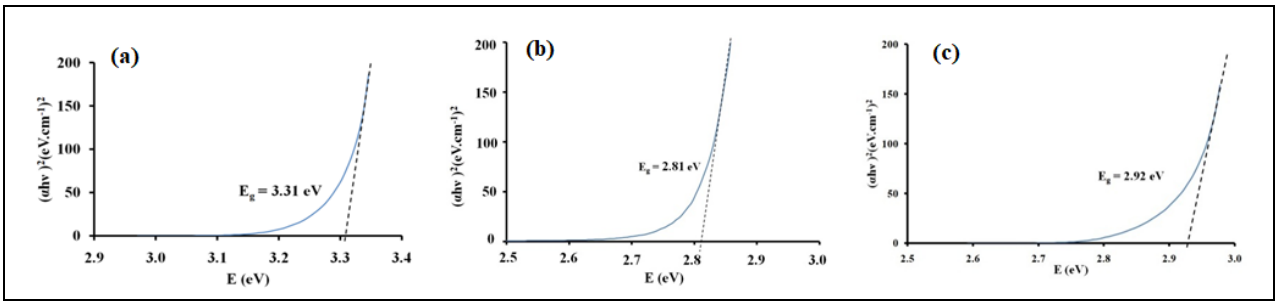

Figure 6. Tauc plot of ZnO, g-C_3N_4 and g-C_3N_4/ZnO

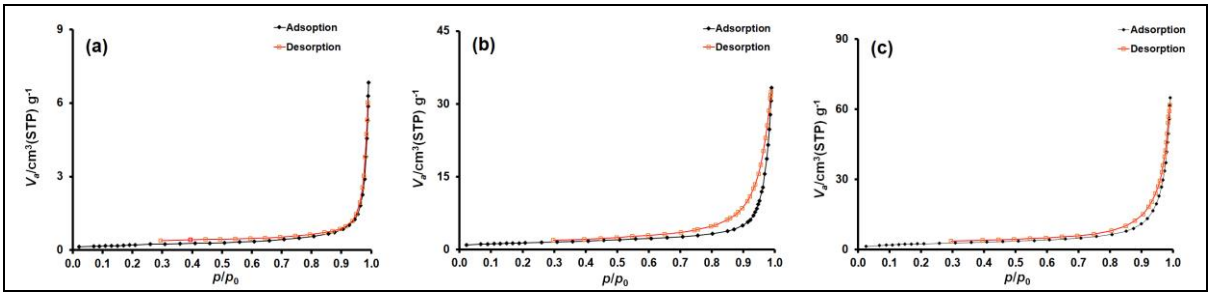

Figure 7. N_2 adsorption-desorption isotherm of (a) ZnO (b) g-C_3N_4 (c) g-C_3N_4/ZnO

Table 1 shows the values of total pore volume, pore diameter, and specific surface area of the sample from the N_2 sorption analysis as well as the percent degradation of OFL. The g-C_3N_4/ZnO had a surface area and pore volume of 8.30 m^2g^{-1} and 0.010 cm^3g^{-1}, respectively, with an average pore diameter of 46.14 nm, which is in the mesoporous range. The surface area of g-C_3N_4/ZnO is higher in comparison with that of pure g-C_3N_4. Specific surface area increases along with lower pore volume, suggesting that ZnO is loaded onto g-C_3N_4, which also enhances the photocatalytic activity [37]. The isotherm plot of g-C_3N_4/ZnO in Figure 7 shows a discerned pattern belongs to type IV and H3 hysteresis loop which represent the existence of mesoporous [38].

The percent degradation of 10 mg/L of OFL was shown in Figure 8 under irradiation of light for 180 min. The optical properties of ZnO may exhibit an absorbance potential that is suitable for the UV spectrum only, which explains the only 5.3% degradation efficiency of ZnO. The photocatalytic performance of g-C_3N_4 shows 47.9% in 180 min higher than ZnO due to the active light response in the visible light. The degradation of g-C_3N_4/ZnO is 63.4% in 180 min, which is 11 times higher than that of pristine ZnO and double than that of pristine g-C_3N_4. The reduced band gap energy of g-C_3N_4/ZnO may result in better absorption of light in the visible region, favoring more electron-hole pair formation and thus improving photocatalytic performance of g-C_3N_4/ZnO. [39]. The photocatalytic performance is influenced by the crystallinity of the photocatalyst and the surface area for both light absorption and molecule adsorption. It is shown that high surface area and pore volume of g-C_3N_4/ZnO can improve photocatalytic degradation due to a larger number of active sites that absorb and mineralize the contaminant through the inter-associated porous structure [40].

Table 1. Surface characteristics analysis and photocatalytic performance of photocatalysts

Sample	Total Pore Volume (cm^3g^{-1})	Mean Pore Diameter (nm)	Surface Area (m^2g^{-1})	Types of Pores	% Degradation
ZnO	0.009	54.10	7.22	Macroporous	5.5
g-C_3N_4	0.005	45.27	4.54	Mesoporous	47.9
g-C_3N_4/ZnO	0.010	46.14	8.30	Mesoporous	63.4

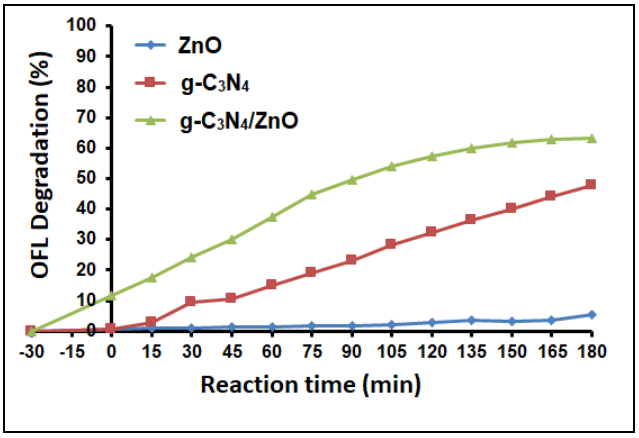

Figure 8. The percentage degradation of OFL under exposure of light at optimized condition in 180 min (Operating parameters: 0.25 g of catalyst loading, 10 mg/L concentration OFL)

Conclusion

In this work, the g-C_3N_4/ZnO photocatalyst was successfully prepared via sol-gel, thermal decomposition, and followed by impregnation methods. The prepared g-C_3N_4/ZnO photocatalyst was successfully characterized with a nanospherical shape, and a higher surface area compared to the pristine. From the band gap analysis, it was found that the band gap of g-C_3N_4/ZnO was reduced from 3.31 eV to 2.92 eV. The reduction of the band gap energy improved the performance of the photocatalytic activity in visible light. The photocatalytic activity of OFL is higher than that of pristine g-C_3N_4 and ZnO, which takes 180 min to degrade 63.4% of the OFL.

Abstract

Isatin and thiocarbohydrazide exhibit a broad spectrum of biological functions including antibacterial, antiviral, antioxidant and antimalarial activities. In this study, copper(II) and zinc(II) complexes derived from isatin thiocarbohydrazide were synthesized and assessed for their potential as antileukemia agents. ^{1}H and ^{13}C NMR, infrared spectroscopy, UV-Vis spectroscopy, thermal and elemental analysis were used to elucidate the structures of the synthesized compounds. The complexation was observed from the shifting frequencies of the *v*(C=N) and the appearance of new peaks assigned as *v*(M-N) and *v*(M-O) at 499 and 583-594 cm^{-1}. The formation of the complexes is also supported by the d-d transition in UV-visible spectra. Using proper DFT functionals and basis sets, the optimized geometries and electronic energies of the complexes were ascertained. Theoretical simulations provide important insights into the stability and electrical structure of the complexes, assisting in understanding their potential biological actions. Cytotoxicity screening was conducted against the human leukemia K562 cell line and low activity was reported, thus indicating minimal toxic profile of the complexes.

Keywords: cytotoxicity, characterization, density functional theory, isatin, thiocarbohydrazide

Abstrak

Isatin dan tiokarboidrazida mempunyai fungsi biologi yang luas seperti aktiviti antibakteria, antivirus, antioksidan dan antimalaria. Dalam kajian ini, kompleks kuprum(II) dan zink(II) telah disintesis daripada isatin tiokarboidrazida dan dinilai potensinya sebagai agen antileukemia. Kaedah spektroskopi iaitu ^{1}H dan ^{13}C NMR, inframerah, UV-Vis, analisis haba dan unsur digunakan untuk menjelaskan struktur sebatian tersintesis. Pengkompleksan diperhatikan daripada frekuensi peralihan *v*(C=N) dan puncak penampilan baharu yang boleh ditetapkan kepada *v*(M-N) dan *v*(M-O) di 499dan 583-594 cm^{-1}. Pembentukan kompleks juga disokong oleh peralihan d-d dalam spektrum UV-Cahaya Nampak. Menggunakan fungsi dan set asas DFT yang sesuai, geometri

molekul dioptimumkan dan tenaga elektronik kompleks telah dikenalpasti. Simulasi teori memberikan gambaran penting tentang kestabilan dan struktur elektrik kompleks, membantu dalam pemahaman potensi tindakan biologi mereka. Saringan sitotoksisiti telah dijalankan terhadap garisan sel leukemia manusia K562 dan sitotoksisiti yang rendah dilaporkan, dengan itu menunjukkan profil toksik kompleks.

Kata kunci: sitotoksisiti, pencirian, teori fungsi ketumpatan, isatin, tiokarboidrazida

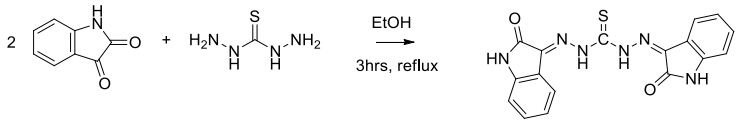
Introduction

In contemporary medicinal chemistry, isatin is a privileged scaffold with a wide range of biological activity. Using nitric and chromic acids, Erdmann and Laurent originally isolated it as an indigo oxidation byproduct [1]. Isatin consists of two cyclic rings, which are a six-membered ring with an aromatic character and a five-membered ring possessing an anti-aromatic character [1]. A literature survey reported that isatin is known to have anticancer [2, 3], antiviral [4, 5], antioxidant [6], analgesic [7] and antimicrobial [8, 9] properties. Another important part of the production of the ligand is the higher homologue of thiosemicarbazide, known as thiocarbohydrazide. Thiocarbohydrazide has an extra nitrogen atom that can serve as a metal-coordinating center [10]. Compared to thiosemicarbazide, there are limited studies on the theoretical study and cytotoxicity effects of the thiocarbohydrazide. Therefore, the present work was done to screen for their respective cytotoxicity activity against human leukemia K562 cancer cell lines.

Copper and zinc are chosen as the metal ions to be bound with the isatin-derived thiocarbohydrazide ligand in this work. Formerly, the addition of copper was reported to have increased the antiproliferative activity of salicylaldehyde monothiocarbohydrazide against breast cancer and human prostate adenocarcinoma cell lines [11]. On top of that, zinc(II) complexes also appear to be extremely appealing because zinc is substantially less toxic in larger dosages than other metals [12]. The computational analysis using the B3LYP method with 6-31G+ (d,p) and LANL2DZ basis set has been done on all the compounds to explore their electronic properties. Subsequently, all parameters like the relationships between the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energies were used to explain the anticancer activity.

Materials and Methods

Materials

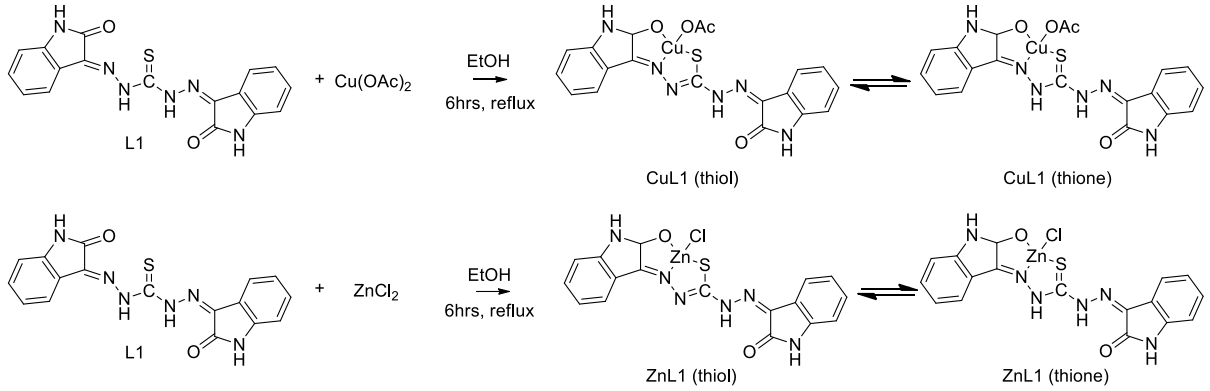


All chemicals used in this study were purchased from Sigma Aldrich Company, St Louis, USA and were used without further purification.

Instrumentation

Elemental analysis (C, H, N and S) for the ligand and complexes were determined using a Thermo Scientific Flash Smart analyzer. The magnetic susceptibility of the complexes was determined using Sherwood Auto Magnetic Susceptibility at room temperature. Molar conductivities were measured using a conductivity standard of 1413 µS/cm. Perkin Elmer 1600 Spectrometer was employed in obtaining the FTIR spectra for ligand and complexes as KBr disc in the region of 400-4000 cm^{-1}. Proton (^{1}H) and carbon (^{13}C) NMR (400 MHz) spectra were recorded using Jeol ECZS spectrometer in DMSO-d_6. The UV-Vis spectra were obtained on Perkin Lambda 365 in acetonitrile at $1x10^{-4}$ M solution using a quartz cuvette in the range of 200-800 nm. Thermal analyses were performed in nitrogen atmosphere using TA Instruments Q50 TGA analyzer with a heating rate of 10 °C/min in a temperature range between 25 and 500 °C. Powder XRD patterns were collected using PANalytical X'pert PRO in Bragg-Brentano reflecting geometry with CuKα (k= 1.5418740 Å). The X-ray tube was utilized for a copper tube operating at 45 kV and 40 mA. Data were collected in 2θ range of 5-90° with 0.0167° and 10 s exposure per step.

Synthesis of ligand



The ligand was prepared with a modification from previous studies [13, 14] by dissolving isatin and thiocarbohydrazide in hot absolute ethanol (30 mL) and the reaction mixture was refluxed for three hours. A yellow precipitate was filtered off, washed with cold ethanol and air-dried overnight. The remaining filtrate was left for recrystallization.

Scheme 1. Synthesis of L1

Synthesis of complexes

Cu(II) and Zn(II) complexes were synthesized by refluxing the ligand with metal salt (copper(II) acetate monohydrate and zinc(II) chloride) with the ratio of 1:1 in a solution of absolute ethanol for six hours. The resulting precipitates were filtered off, washed with cold ethanol and air-dried.

Scheme 2. Synthesis of CuL1 and ZnL1

Computational methods

The structures of the ligand and the complexes were built using Gaussian view 16.0. DFT calculations were then carried out using Gaussian 09 program and B3LYP method [15, 16]. The geometrical optimizations were done against the ligand using the 6-31G+ (d,p) [17] basis set and the complexes using LANL2DZ [18].

Cytotoxicity

A 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) cell proliferation assay described by Mossmann [19] was used to assess the cytotoxicity activity of all the synthesized compounds against human leukemia K562 cell line with slight modification. In a 96-well culture plate, the cells ($5x10^4$ cells/mL) were seeded and incubated for 24 hours. Subsequently, the cells were treated with the compounds at 100, 50, 25, 12.5, 6.25 and 3.125 µM for 48 hours. Each well received 20 µL of MTT solution, which was then incubated for an additional four hours to observe for cell viability. DMSO was used to dilute the purple formazan in the well and the absorbance was measured at 570 and 690 nm. The cytotoxicity activity of the compounds was expressed as IC_{50}. Doxorubicin was used as a positive control against the cancer cell line.

Results and Discussion

The compounds were colored, stable in air and insoluble in most organic solvents except for DMSO and DMA. The elemental analyses for the complexes displayed that they formed in a ratio of 1:1. The analytical findings and the theoretical formula are in good agreement. CuL1 possessed a magnetic moment of 1.71 B.M. which is relatively lower than the regular spin-only value of 1.73 B.M. and showed a square planar geometry, while ZnL1 is diamagnetic affording a tetrahedral geometry [20]. The physical and elemental analysis data are summarized in Table 1.

Table 1. Analytical data of the ligand and its metal complexes

Compounds	Molecular Formula	Color	Yield %	$\mu_{eff.}$ (B.M.)	Λm $\Omega^{-1}mol^{-1}cm^2$	% Found (Calc.)			
						C	H	N	S
L1	$C_{17}H_{12}N_6O_2S$	Yellow	91.46	-	-	56.38 (56.04)	3.58 (3.32)	22.46 (23.06)	8.03 (8.80)
CuL1	$C_{19}H_{20}CuN_6O_6S$	Black	85.78	1.71	0.010	43.73 (43.55)	3.80 (3.85)	16.28 (16.04)	6.10 (6.12)
ZnL1	$C_{17}H_{15}ClN_6O_3SZn$	Red	64.77	Diamagnetic	0.006	42.25 (42.17)	2.92 (3.12)	17.39 (17.36)	6.64 (5.90)

Infrared spectroscopy

The emergence of *v*(C=N) at 1697 cm^{-1} confirmed the formation of Schiff base ligand L1 according to Figure 1, while bands at 499 cm^{-1} and 583-594 cm^{-1} correspond to *v*(M-N) and *v*(M-O) respectively, showing the formation of the proposed complexes, CuL1 and ZnL1 [21, 22]. The strong *v*(C=O) band appeared at 1750 cm^{-1} in the free ligand and shifted in CuL1 and ZnL1. The shifting of the *v*(C=O) band indicates that the carbonyl oxygen participated in coordination with the metal ions [23]. The broad band recorded at 3254 cm^{-1} in the ligand spectrum was attributed to the stretching vibration for *v*(N-H). This band was later shifted to lower frequencies in CuL1 at 3160 cm^{-1} and ZnL1 at 3164 cm^{-1}. The O-H stretching of the water molecules, which are connected by a dense web of hydrogen bonds, results in a strong and broad absorption that is centered at 3474 cm^{-1} in ligand, 3460 cm^{-1} in CuL1 and 3429 cm^{-1} in ZnL1 [24]. The tetrahedral and square planar geometry of ZnL1 and CuL1 was stabilized through coordination with water molecules.

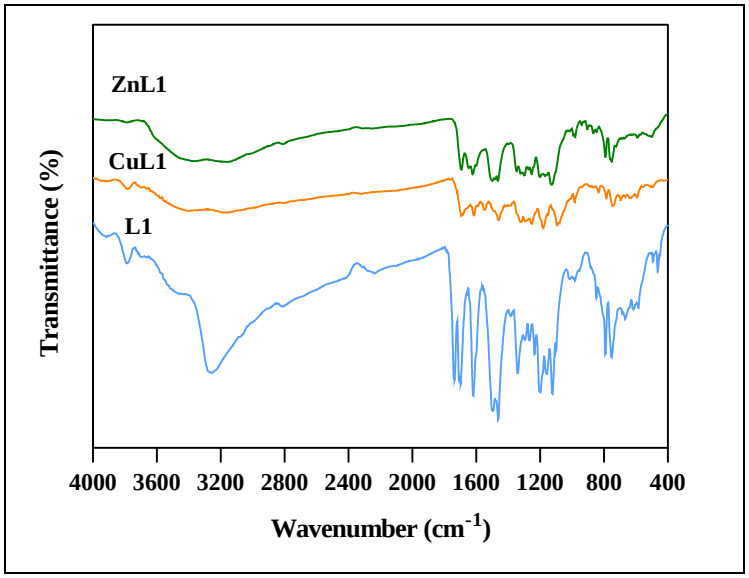


Figure 1. Infrared spectra of the ligand and metal complexes

^{1}H-NMR spectroscopy

The ^{1}H NMR spectra of both ligand and zinc(II) complex were examined to determine each distinct type of hydrogen nuclei. On the contrary, the NMR signal of the copper(II) complex was unable to be examined due to its paramagnetic property. Singlet peaks were found between 12.94 and 11.34 ppm in both spectra, which were attributed to isatin NH and NH thiocarbohydrazide, respectively. The multiplets of the aromatic protons of the isatin ring were recorded at 7.60, 7.42, 7.14, and 6.98 ppm. ZnL1 showed similar aromatic proton peak.

^{13}C-NMR spectroscopy

Based on the ^{13}C NMR spectrum, L1 displays its aromatic carbons between 112.16-138.35 ppm. The signal for thione (C=S) was detected at 175.30 ppm while those for azomethine (C=N) and carbonyl carbon (C=O) were detected at 162.55 and 138.50 ppm, respectively. Thione signal in ZnL1 appeared at a higher range of 178.50 ppm compared to its parent ligand. The peak was seen for azomethine and carbonyl carbon in the range of 164.0 ppm and 144.0 ppm. As a result, it can be inferred that azomethine nitrogen, carbonyl oxygen, and thione sulphur participated in the coordination of complexes, which was further supported by the results from the infrared spectroscopy [25].

UV-visible spectroscopy

The ligand's UV-visible spectrum in Figure 2 showed two absorption peaks that were identified as $\pi \rightarrow \pi^*$ for benzene and $n \rightarrow \pi^*$ transitions for the azomethine group (C=N) at 243 nm and 373 nm, respectively [26]. The two peaks appeared to have bathochromic or red shifting in both copper(II) and zinc(II) complexes. A redshift stipulates that the energy of the π-π^* transition decreases due to metal chelating. The copper(II) and zinc(II) complexes spectra displayed ligand-to-metal transfer (LCMT) peaks 509 and 484 nm [27].

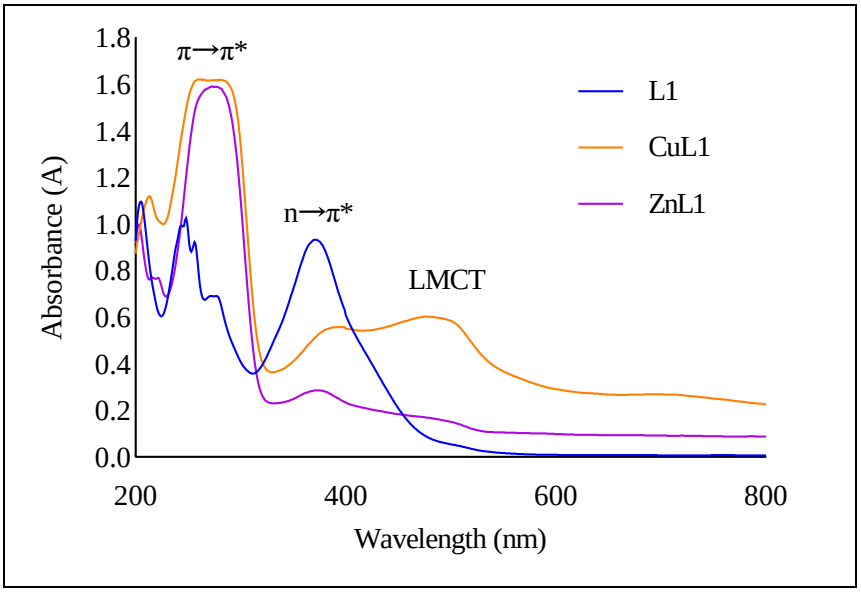

Figure 2. UV-visible spectra of the synthesized compounds

TGA studies

The thermal stability of the copper(II) and zinc(II) complexes was determined using the thermogravimetric (TGA) analysis. TGA aids in separating the coordinated water molecule present in the compound from the lattice water molecule [28]. Based on the curves in Figure 3 and data in Table 2, CuL1 breaks down into two phases, according to the thermogram. Dehydration of the initial lattice water molecule, with a weight loss of 2.30 percent, occurs in the first stage at temperatures between 50 and 125 °C. The second step showed a weight loss of 2.57 % indicating the elimination of the second lattice water molecule. Adversely, ZnL1 revealed a decomposition of water molecules through one stage with a weight loss of 3.10 %.

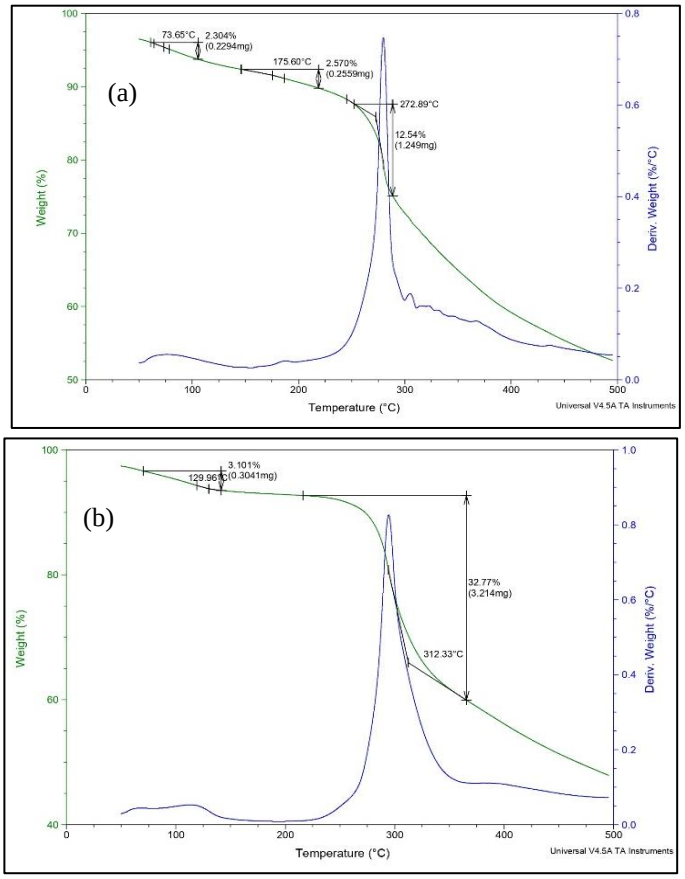

Figure 3. Thermogravimetric curves for (a) CuL1 and (b) ZnL1

Table 2. Decomposition temperature and the percentage weight loss of complexes

Compound	Decomposition Temperature (°C)	Weight Loss (%)		Lost Species
		Found	Calc.	
CuL1	50-125	2.30	3.43	One lattice water molecule
	150-200	2.57	3.43	One lattice water molecule
ZnL1	100-130	3.10	3.72	One lattice water molecule

Powder XRD studies

All compounds were then examined using powder diffraction XRD patterns due to unsuccessful attempts in generating ligand and complexes as single crystals. The 2θ = 5-90 range lattice constants were used to record the powder diffraction patterns. The compounds were found to be crystalline (L1) and semi-crystalline (CuL1 and ZnL1). The X-ray diffractometry patterns for complexes displayed in Figure 4 are entirely distinct from those of the ligands, indicating the discovery of new compounds [29].

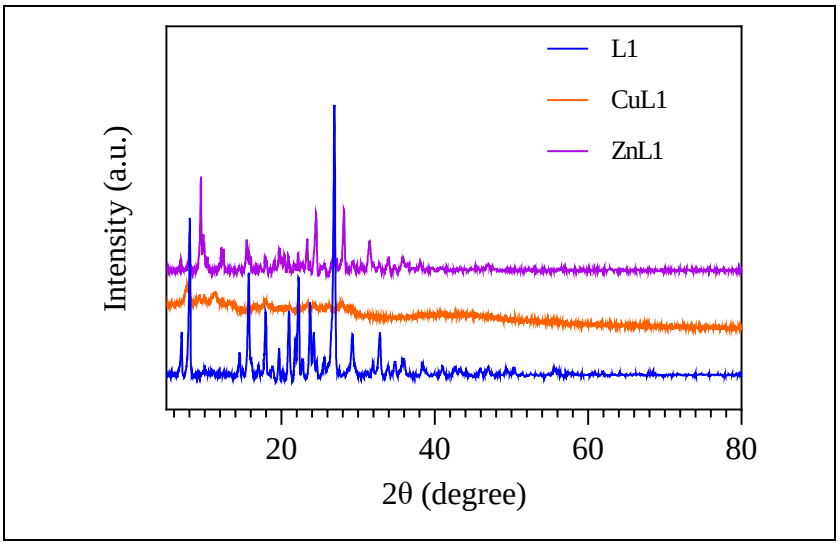

Figure 4. Powder XRD patterns for all synthesized compounds

Computational analysis: Frontier molecular orbitals

The frontier molecular orbitals are used to explore the chemical reactivity of the molecules. The highest occupied molecular orbitals (HOMO) and the lowest unoccupied molecular orbitals (LUMO) are split into molecular orbitals alpha (spin ↑) and beta (spin ↓) because of the doublet multiplicity in the complexes' molecular geometry. The B3LYP/6-31G+ (d,p) and LANDL2DZ level theory's calculations of the molecular orbital energies (E_{HOMO} and E_{LUMO}) reveal that they are all negative, indicating that the ligand and both copper(II) and zinc(II) complexes are stable. The HOMO region of the ligand and complexes are mainly localized around the electronegative sulphur and nitrogen atoms. Both atoms are bonded to the metal ions and are able to attract electrons away from their aromatic rings, thus reducing the HOMO electron density around the rings. This explains why the rings contributed significantly to the LUMO as according to Figure 5. The value of the energy gap between the HOMO and LUMO in Table 3 conveyed the stability and reactivity of each compound. The energy gap of L1 is 3.143 eV, which is considered to be similar to that of a previously reported Schiff base [30]. In comparison, the energy gap of the zinc complex for the alpha spin is the lowest among the ligand and copper complex, indicating that the zinc complex has a greater affinity for receiving electrons [31].

Table 3. The HOMO, LUMO and gap energies of the synthesized compounds

Compounds		**E_{HOMO} (eV)**	**E_{LUMO} (eV)**	**ΔEgap (eV)**
L1		-6.044	-2.901	3.143
CuL1	Alpha	-6.006	-3.085	2.921
	Beta	-6.007	-3.500	2.507
ZnL1	Alpha	-4.987	-3.187	1.800
	Beta	-6.193	-3.434	2.759

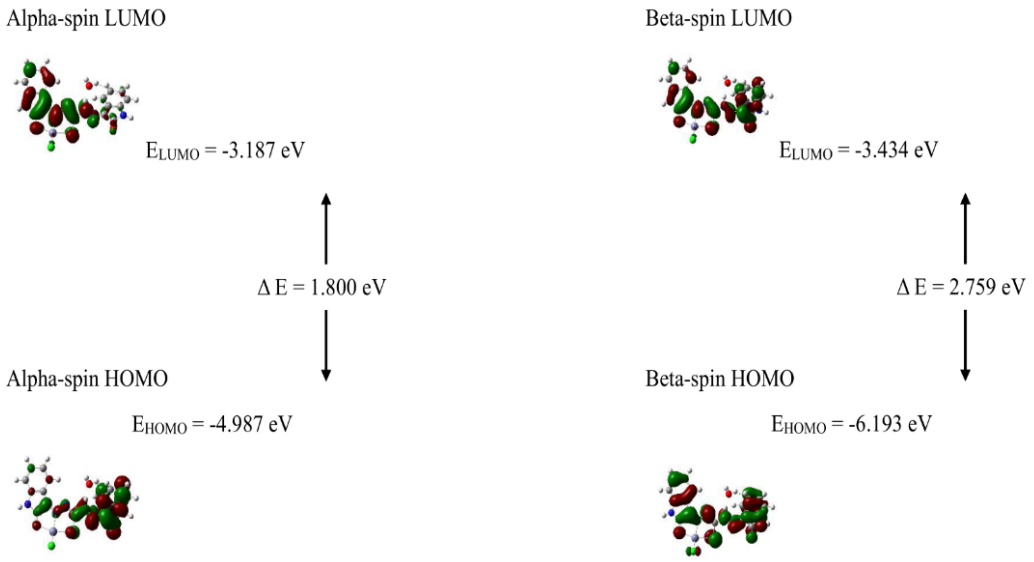

Figure 5. The energy gaps for ZnL1

Global chemical reactivity descriptors (GCRD)

Soft molecules are made of molecular systems with low gap energies and low chemical hardness (η), which in this case is ZnL1 as shown in Table 4. The small energy of ZnL1 indicates that the charge may be transferred easily, and therefore provides an impact on the compounds biological activity [32]. The negative value of chemical potential (μ) indicated that the molecule is capable of accepting electrons from the environment [33] and ZnL1 is considered to have the lowest. Thus, it is suggested that ZnL1 will have the highest chemical reactivity. The dipole moment is one of the parameters responsible for the potential biological activity. The compound with the highest polarity, ZnL1 is expected to display high bio-efficiency [34].

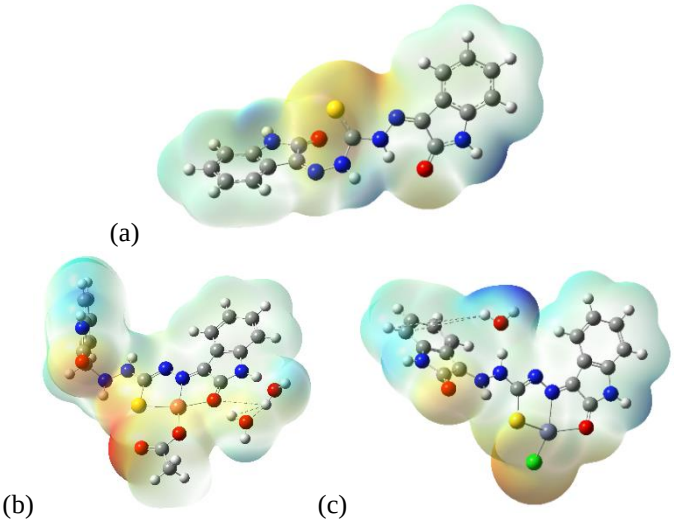

Table 4. The electronic parameters of the ligand and metal complexes

Property	Ligand and Metal Complexes				
	L1	CuL1		ZnL1	
		α	β	α	β
EA (eV)	2.901	3.085	3.500	3.187	3.434
IP (eV)	6.044	6.006	6.007	4.987	6.193
X (eV)	4.473	4.546	4.754	4.087	4.814
η (eV)	1.572	1.461	1.254	0.900	1.380
S (eV^{-1})	0.318	0.342	0.399	0.556	0.362
μ (eV)	-4.473	-4.546	-4.754	-4.087	-4.814
ω	6.363	7.073	9.011	9.280	8.397
Total Energy (Hartree)	-1532.21	-1722.05		-1300.98	
Dipole moment (Debye)	1.885	9.452		14.394	

Molecular electrostatic potential (MEP)

The binding properties of the compounds are presented using the molecular electrostatic potential (MEP) map in Figure 6. The electron density is displayed by the molecular electrostatic potential, which helps to identify the sites of electrophilic and nucleophilic reactions as well as hydrogen bonding interactions [35]. The electronegative potential which is represented by red color is concentrated around the oxygen atoms in the isatin moiety of all the compounds and the acetate ion of the copper complex. The blue color portrays the

electropositive potential, which is centered around the nitrogen atoms and water molecules.

Cytotoxicity

The cytotoxicity of all synthesized compounds was evaluated against human leukemia K562 cell line, whereby three independent studies were conducted and data for each test were reported in triplicates. The anticancer drug, Doxorubicin was used as the positive control. Based on the results shown in Table 5, the ligand and its complexes gave IC_{50} values of more than 100 µM. This indicated that the compounds are poor inhibitors of the human cancer cell line, thus proving to have a low toxicity effect. L1, CuL1 and ZnL1 show low toxicity to human cells due to the presence of the imine group in the structure that may interfere with the cytotoxicity of the compounds [36]. According to Noruzi and co-workers, the toxicity of copper derivate increased as the concentration increased to 200 µg/mL [37].

Table 5. IC_{50} values of the compounds against human leukemia K562 cancer cell line

	IC_{50} values in cancer cells (µM)
Compound	K562
L1	>100
CuL1	>100
ZnL1	>100
Doxorubicin[a]	0.26 ± 0.06

Conclusion

Copper(II) and zinc(II) complexes were synthesized through a condensation process with a Schiff base ligand, N,2-bis(2-oxoindolin-3-ylidene)hydrazine carbothioamide resulting in excellent yields. The characterization using spectroscopic techniques confirmed the formation of the desired complexes and ensured their chemical structure. The molar conductivity values for the complexes gave an insight into their non-electrolytic properties. The infrared spectra highlight the shifting of *ν*(C=N) and the appearance of new bands which are *ν*(M-N) and *ν*(M-O) for complexes. Apart from that, ^{1}H and ^{13}C NMR spectra displayed peaks that located the protons and carbon present in each compound. UV-visible spectra confirmed the complexation of metal ions with ligand using the d-d transition. The zinc(II) complex has a better tendency to accept electrons since it has the lowest

energy gap for the alpha spin compared to the ligand and copper(II) complex. From the chemical reactivity descriptors, ZnL1 was predicted to have better cytotoxicity activity compared to the ligand and CuL1. However, low cytotoxicity was reported for all compounds against human leukemia K562 cancer cell line. This indicated a potential development for all compounds due to their minimal toxic profile. In addition, the contradiction between experimental and theoretical results may be due to the solubility of the compounds. Colored compounds may have interfered with the reading of the OD values.

Acknowledgement

The experiments were carried out using the facilities in Universiti Teknologi MARA and Universiti Sains Malaysia. This research was funded by Universiti Teknologi MARA under the grant number 600-RMC/GIP 5/3 (040/2022).

Abstract

Early techniques to develop latent fingerprints have shown many drawbacks such as being costly, time-consuming, less stable, highly toxic, low selectivity, low sensitivity, and low contrast. Numerous studies have been introduced to improve the identification of latent fingerprint techniques. The application of starch as a based material or binding agent offers advantages since this biomaterial is nontoxic, easily available, abundant, and cost-saving. Studies show that starch-based materials have good potential in the detection of latent fingerprints. However, studies related to the use of starch-based material in the development of latent fingerprints are still limited. Therefore, this mini-review highlights the techniques used in the detection of latent fingerprints and the potential alternative in detecting latent fingerprints using starch particularly as coating and coated materials.

Keywords: latent fingerprints, powder dusting, quantum dots, carbon nanoparticles, starch

Abstrak

Kajian terdahulu berkaitan kaedah untuk mengesan cap jari tidak kelihatan mempunyai banyak kelemahan seperti mahal, kurang stabil, bertoksid, tahap selektiviti yang rendah, kepekaan yang rendah, serta kontras yang juga rendah. Terdapat banyak penyelidikan yang telah dilakukan bagi mengkaji pelbagai kaedah untuk meningkatkan pengenalpastian cap jari tidak kelihatan. Penggunaan kanji sebagai bahan asas menawarkan beberapa kelebihan seperti tidak bertoksid, mudah didapati, banyak, dan dapat menjimatkan kos. Kajian menunjukkan penggunaan kanji adalah berpotensi dalam pengesanan cap jari tidak kelihatan. Walaubagaimanapun, kajian berkenaan penggunaan kanji sebagai bahan asas dalam teknik pengesanan cap jari tidak kelihatan masih terhad. Sehubungan itu, ulasan ringkas ini memfokuskan kepada kaedah-kaedah yang digunakan dalam mengesan cap jari tidak kelihatan dan kaedah alternatif yang berpotensi dengan menggunakan kanji dalam pengesanan cap jari tidak kelihatan terutamanya sebagai bahan salutan atau bahan bersalut.

Kata kunci: cap jari tidak kelihatan, debu serbuk, titik kuantum, nanopartikel karbon, kanji

Introduction

In forensic analysis, the primary physical evidence that may link to the criminal is fingerprints. This forensic evidence is an imperative method for identifying criminals through examinations at crime scenes. It is also a useful approach for collecting reliable records of evidence against the accused. In the world of law enforcement, fingerprints are regarded as the gold standard for depicting biometric and scientific evidence [1]. Fingerprints are distinctive and easier to verify due to the capillary tube-shaped channels at the fingertips that are connected to the sweat glands and they are unique for each individual, remain permanent, and do not change [2–6]. When a finger contacts a solid object, its secretion leaves a distinctive ridge pattern on the surface. Due to their weak optical contrast with the substrates, these patterns are sometimes referred to as latent fingerprints, which are undetectable to the naked eye [7].

Cyanoacrylate fuming, ninhydrin, 1,8-diazafluoren-9-one method, powder dusting, silver nitrate, silver nanoparticles, and small particle reagent method are among the techniques used to identify latent fingerprints [3, 8, 9] since they are straightforward, effective, and simple to apply [9]. However, these techniques are costly, time-consuming, less stable, high toxicity of the developing reagents, have a low selectivity of the specificity of emerging materials, low sensitivity of the clarity and visibility of the ridge detail due to enormous and irregular particle size, and low contrast due to the non-fluorescence of most powders [3, 8, 9]. Recently, improved latent fingerprint formation has been achieved using novel techniques including nanotechnology such as quantum dots and fluorescent carbon nanoparticles [1]. The latent fingerprints produced by quantum dots have several advantages such as enhanced sensitivity, contrast, and selectivity. However, there are rising concerns about their intrinsic toxicity thus limiting their long-term usage since quantum dots contain heavy metal cores [1].

Fluorescent carbon nanoparticles have been created as an alternative method for the detection of latent fingerprints in substitution of quantum dots since it is biocompatible and non-toxic to nature, people, and the environment [10]. Even so, these fluorescent carbon nanoparticles can lose their luminous properties easily, making it difficult to convert them into brilliant powder. The addition of starch seems able to generate a strong blue fluorescence in its dry solid form and overcome the limitation. The fluorescent powder employed in this process produces distinct images of latent fingerprints on diverse surfaces, and a stain made from carbogenic fluorescent powder is used to disclose the latent fingerprints [1].

The present study aims to review the techniques used in the detection of latent fingerprints and the potential alternative in detecting latent fingerprints using starch particularly as coating and coated materials. Starch is a natural polymer stored in plants. Its major compounds are amylose and amylopectin. Starch is nontoxic, easily available, abundant, and cost savings [5]. Thus, the use of starch in the detection of latent fingerprints is more economical and safer.

An overview of latent fingerprints

Latent fingerprints are invisible to the naked eye. It is skin friction impressions of the fingers left accidentally on surfaces by eccrine sweat and greasy substances such as sebum. The volar pads transfer a small coating of translucent chemical residue [11] known as triglycerides which are composed of hummed, fatty acids, and amino acids in the shape of individual skin ridges, leaving behind latent fingerprints [12]. It can be used as evidence in criminal investigations and may help to identify suspects using three levels of fingerprint recognition.

The different levels of features in a latent fingerprint are divided into three namely Level 1, Level 2, and Level 3. The primary use of Level 1 features (macro-details) is to classify patterns but non-recognizable for fingerprint identification. The arch, tented arch, left loop, right loop, double loop, and whorl, are visible to the naked eye which assists in manual fingerprint matching and visual scrutiny [13]. Level 2 features (minutia points) are recognizable, consistent, and commonly used to verify a fingerprint's uniqueness. Their characteristics consist of hooks, bifurcations, and

ridge ends. However, it may not be retrieved effectively due to the low quality of evidence caused by ridge smudging. The appropriate reconstruction and refinement are necessary to remove false features. The dimension parameters of the ridges known as Level 3 features (pores and ridge contours) provide more precise and reliable details for accurate fingerprint recognition, resulting in a significant performance improvement [14]. There are enduring characteristics that may be identified from a sample, such as pores, line patterns, and scars. Yet, it is difficult to extract such properties due to resolution restrictions. Thus, all of these level features are typically combined to attain the best possible matching results [13].

Latent fingerprints detection techniques

The initial stage of processing latent fingerprints known as latent fingerprint upliftment involves the process of detecting, enhancing, preserving, collecting, and matching the prints from a crime scene [13]. There are various approaches such as cyanoacrylate fuming, ninhydrin, 1,8-diazafluoren-9-one method, powder dusting method, and silver nitrate [3, 8, 9] that commonly used for rendering fingerprint visibility [13].

Cyanoacrylate fuming

Cyanoacrylate fuming which is known as super glue fuming is a chemical technique for detecting latent fingerprints on non-porous surfaces like glass and plastic [15, 16]. Alkyl 2-cyanoacrylate is an ester of the acrylate class that contains cyano or nitrile group. It produces vapours that react with certain of the eccrine elements of the latent finger mark residues, polymerised, and give them a white colour [15]. Tough this fuming technique provides a flexible and successful approach for identifying latent fingerprints on almost all non-porous substrates, particularly rough surfaces, nevertheless, it has a variety of health and safety concerns. Vapours and liquid cyanoacrylate esters are likely to damage mucous membranes, skin, and eyes severely. In addition, the cyanoacrylate fuming method tends to over-fume the fingerprints affecting the fine ridge features to be largely covered by the white polymers, thus reducing the growing sensitivity [9].

Ninhydrin method

Ninhydrin is an amino acid reagent used to develop latent fingerprints on porous surfaces such as paper and cardboard. This reagent exhibits Ruhemann's purple resulting from a reaction with the amino acid (eccrine) component of the finger mark deposit [17, 18]. The complete ninhydrin development may take 24 to 48 hours at room temperature and humidity [9]. Thus, to shorten the process, temperature and humidity shall be increased. A high-humidity environment of 50% to 80% is suggested and the treated fingerprints shall remain cool in the dark since light and oxygen will degrade Ruhemann's purple [9,18]. The use of higher temperatures requires careful monitoring due to its flammable properties [19] and has the potential to significantly discolour the background resulting in reduced contrast and sensitivity [9]. The ninhydrin method also can cause background staining and ink dissolution [18,19].

The 1,8-diazafluoren-9-one method

The 1,8-diazafluoren-9-one method is a ninhydrin analogue which is another amino acid reagent that is used to identify latent fingerprints on porous surfaces, particularly paper [20]. Due to its high sensitivity, high efficiency, and simple operation, this technique is believed to be crucial for fluorescently generating latent fingerprints on porous surfaces. Nevertheless, the method is considered hazardous and causes carcinogenic effects [9]. Contrary to ninhydrin, heat is necessary to elevate the reaction but prolonged exposure to high heat and humidity will affect the luminescence of the treated fingerprints. Thus, employing a heat press at 180 °C for 10 s or heating at 100 °C not exceeding 20 minutes is advisable [18, 21]. It is often recommended to perform ninhydrin treatment after the 1,8-diazafluoren-9-one method since this reagent may not react with some types of amino acids present in the exudate to obtain the best result [22].

Silver nitrate method

The silver nitrate technique is an old method introduced more than 100 years ago to develop latent fingerprints on porous surfaces before ninhydrin. Silver ions that react with chloride ions from the remaining fingerprints remains forming the silver

chloride compound. Upon exposure to light, it will develop black, brown, or violet stain prints. The silver nitrate approach is not recommended as a standard method since the appearance of the prints and the paper background may strongly change with time [9,23].

Powder dusting method

Powder dusting is the simplest and most commonly used technique for developing latent fingerprints. It is also the oldest technique used by fingerprint experts with one of its earlier references dating back to 1891 [5]. The effectiveness with which the powder adheres to the ridges depends on the particle morphology. Small, fine particles adhere more easily than large, coarse particles [5, 24]. Moreover, the thicker coating of micron- or larger-sized powders tends to reduce the little ridge features, particularly the sweat pores thus reducing its sensitivity [9]. Therefore, most formulations consist of either very fine, rounded particles (with a diameter of about 1 μm) or fine flake particles (with a diameter of about 10 μm) [24]. The efficacy of using fingerprint powder also depends on the colour of the fingerprint powder itself to ensure a good contrast, the age of the fingerprint under investigation, temperature, and the nature of surfaces in which the latent fingerprints are deposited either porous or non-porous [5]. Several powder formulations have been terminated due to the hazardous effects of heavy metals and their salts. Numerous studies have suggested that powder formulations pose health risk to experts in fingerprinting [24]. Current research has improved the method such as using non-toxic substances to overcome the issues.

Carbon dots

Carbon dots can be classified as graphene quantum dots, carbon quantum dots, carbon nanodots, and carbonized polymer dots [25]. Carbon dots are smaller-size fluorescent carbon-based nanoparticles that are generally defined as discrete, zero-dimensional carbonaceous materials of less than 10 nm in size with an identical form of surface passivation [26]. The application of carbon dots to develop fingerprints can be divided into two aspects which are carbon dots in a solution phase and a powdered form. However, carbon dots in a solution phase require a long development time (usually an hour or more), which is an obvious obstacle to the rapid development of latent fingerprints at crime scenes. Carbon dots in the solid state still suffer from aggregation-induced luminescence quenching, so only small amounts of carbon dots have been incorporated into some sort of solid to maintain their flowability and fluorescence when used for dusting. This results in weak luminescence intensity, thus giving a low contrast between the fingerprint and the background [3]. Researchers develop new methods based on carbon dots to overcome the limitations. The improved carbon dots exhibited unique features, like aqueous solubility, low toxicity, chemical inertness, functional ability, biocompatibility, photochemical stability, good conductivity, and environmental friendliness. It has been hugely applied in the fields of bio-imaging, therapeutics, diagnosis, chemo-sensing, nanomedicines, drug delivery, fluorescent marker, and optoelectronic devices [27].

Application of starch in latent fingerprints detection

Starch in nano or micro size is a suitable compound for picturing latent fingerprint impressions. The main components of starch are amylose and amylopectin with abundant hydroxyl groups as shown in Figure 1. The combination of amylose from starch-based non-conventional powders such as gram flour, wheat flour, and corn flour with the fat deposits in the fingerprints can produce high-quality fingerprints [5]. Moreover, starch-based particles offer several benefits over other techniques, including affordability, biodegradability, availability, nontoxic, and natural abundance. Despite being highly hygroscopic, starch is capable in detecting latent fingerprints for a very long period [28]. The application of starch in the development of latent fingerprints commonly as coating materials and coated materials is particularly for fluorescent powder to enhance its optical properties. Starch also undergoes a simple grinding process with fluorophore powder to enhance the visibility of the prints.

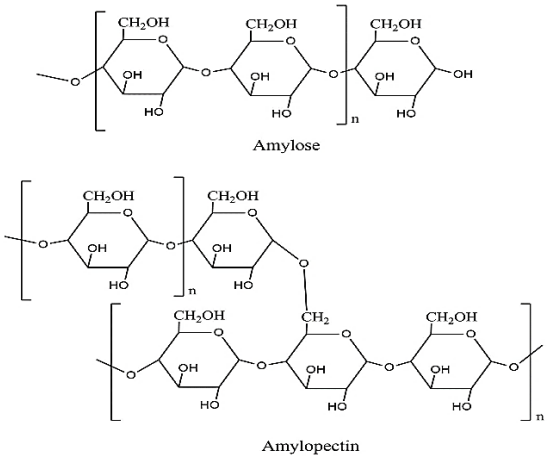

Figure 1. Chemical structure of starch

Starch as coating materials

The adherence of fluorescent powders to fingerprint residue increases after the incorporation of dye into the starch matrix due to the interaction between the matrix and dyes through hydrogen bonding [29, 30]. These powders preserved selectivity and retained sufficient contrast when tested on fingerprints and were effective as commercially available fluorescent powders [30]. This indicates that starch is a good coating material. The optical properties of fluorescent powder increase after incorporation of dye into the starch matrix due to an increase in photostability and fluorescent yield of the dye [29, 31]. Coating of dye with starch prevents photodecomposition since it helps to isolate dye from oxygen and water from the ambient [29].

Starch as coated materials

Starch plays a role as coated materials for research based on starch-fluorescent carbon nanoparticles in the development of latent fingerprints. This fluorescent carbon dots nanoparticle then coating on starch to form phosphors. The process is needed since fluorescent carbon nanoparticles must be combined with hydroxyl groups to emit fluorescence [1]. In one study, malic acid and ammonium oxalate are used as the starting materials for the development of a pyrolysis technique to synthesis N-doped carbon nanoparticles. When the fluorescent carbon nanoparticles are coated on starch (0.1:10 weight ratio) it gives extraordinarily intense blue fluorescence images under UV irradiation on non-porous surfaces in a solid state. Developing latent fingerprints by using this technique on non-porous surfaces [1] is interesting because of their great stability, adjustable fluorescence emission, and luminosity [32]. The author concludes that this fluorescent powder has better sensitivity than iodine vapor [1].

On the other hand, Dong et. al. was the first group of researchers who had studied red fluorescence carbon dots powder for latent fingerprint detection and established an artificial intelligence program to evaluate the similarity of the developed latent fingerprint images quantitatively. The intense red fluorescence of developed phosphors under green light irradiation enhanced the ridge patterns of latent fingerprints without interference from background fluorescence [7].

Carbonized polymer dots have a polymer/carbon hybrid structure rather than the main body carbon structure, which contributes to the predominant properties of carbonized polymer dots. They have unique properties such as high oxygen/nitrogen content, excellent aqueous solubility, and outstanding photoluminescence quantum yield, which are due to the polymer/carbon hybrid structure and the special photoluminescence mechanism [25]. Coating the carbonized polymer dots on the starch surface makes the fingerprints that had been aged for a long period and fingerprints on frequently used substrates are easily

recognised where the created latent fingerprint images reveal the distinct, well-defined ridge features [10].

Starch-based near-infrared organic fluorophores

Near-infrared irradiation has a higher potential over visible light for imaging latent fingerprints. This is due to less interference by the background fluorescence of the bio-tissue and has higher contrast and resolution. The technique is independent of the substrate material and may be used for latent fingerprint formation in a variety of scenarios [33]. Near-infrared radiation is safe for DNA in fingerprint residue during fingerprint development and less harmful to users' skin and eyes than UV light [34]. Ran et. al. developed a new near-infrared-emissive composite material composed of a near-infrared fluorophore, and porous starch via a simple grinding method. The fluorophore powder showed strong near-infrared emission, while the porous starch enabled high adsorption capability for fingerprints. This near-infrared composite offers advantages such as reduced background fluorescence, ease of handling, high photostability, low cost, and low toxicity to developers, indicating its great potential in the field of trace inspection and biological imaging [35].

Future directions

The application of starch in latent fingerprint detection commonly focuses on the role of starch as a coating and coated material. The method is quite simple through the blending of different materials in solvents at a certain time and temperature. The mechanism involved is not clearly mentioned on how starch reacts with fluorescent powders and fat deposits from latent fingerprints. A particular emphasis will be put on the physicochemical principles of latent fingerprint detection and coated/coating principles to enhance the selectivity, sensitivity, and stability of the fluorescent powders.

Conclusion

Amongst other methods in developing latent fingerprints, powder dusting become the one that is most used. Researchers have improvised this method to overcome its limitation. One of the techniques is by incorporating starch forming a fluorescent powder. The friction ridges of the fingerprints using this powder give sharp edges, provide better resolution and offer less background interference. The application of starch has been used quite successfully in the detection of latent fingerprints. Further research is needed as the study on starch powder dusting in the detection of latent fingerprints is still limited.

Abstract

The sharks from Johor waters were investigated to evaluate certain heavy metal concentrations and their potential human health concerns. This study obtained 25 *Scoliodon laticaudus* as bycatches from the local fishermen's market in Johor and stored them at a low temperature before further analysis. The sharks were divided into gill, muscle, fin, stomach, and liver samples with oven drying at 60°C. Certain heavy metals (As, Cd, Cr, Cu, Fe, Hg, Pb, and Zn) were then evaluated using an Inductively Coupled Plasma Mass Spectrometer (ICP-MS) after the digestion process using nitric acid (HNO_3). This study presented the ascending metal concentration sequences as Fe > Cd > Hg > Pb > Cr > As > Cu > Zn for livers, Cd > Hg > Fe > Pb > Cr > As > Cu > Zn for stomach linings, Cd < Hg < Pb < Fe < Cr < Cu < As < Zn for fins, Hg < Cd < Fe < Pb < Cr < Cu < As < Zn for gills, and Cd < Hg < Fe < Pb < Cr < Cu < As < Zn for muscles. Therefore, the average pollutant load indexes (PLIs) (contamination levels) for livers, stomach linings, fins, gills, and muscles were 3.31, 2.23, 3.15, 2.47, and 3.35, respectively. Based on the PLI values, this study successfully indicated a moderately polluted contamination level.

Abstrak

Ikan yu dari perairan Johor telah dianalisis untuk menilai jumlah logam berat tertentu dan potensi risiko kesihatan terhadap manusia. Kajian ini memperoleh 25 *Scoliodon laticaudus* sebagai tangkapan sampingan dari pasar nelayan tempatan di Johor dan disimpan pada suhu rendah sebelum dianalisis selanjutnya. Ikan yu dibahagikan kepada sampel insang, otot, sirip, perut, hati, dan dikeringkan di dalam ketuhar pada suhu 60°C. Logam berat tertentu (As, Cd, Cr, Cu, Fe, Hg, Pb, dan Zn) dinilai menggunakan spektrometri jisim plasma gadingan aruhan (ICP-MS) selepas proses pencernaan dengan asid nitrik (HNO_3). Kajian ini menunjukkan kepekatan logam menaik iaitu Fe > Cd > Hg > Pb > Cr > As > Cu > Zn untuk hati, Cd > Hg > Fe > Pb > Cr > As > Cu > Zn untuk perut, Cd < Hg < Pb < Fe < Cr < Cu < As < Zn untuk sirip, Hg < Cd < Fe < Pb < Cr < Cu < As < Zn untuk insang,

dan Cd < Hg < Fe < Pb < Cr < Cu < As < Zn untuk otot. Oleh itu, purata indeks bebanan pencemaran (PLIs) (tahap pencemaran) untuk hati, perut, sirip, insang, dan otot ialah 3.31, 2.23, 3.15, 2.47, dan 3.35. Kajian ini berjaya menunjukkan tahap pencemaran sederhana berdasarkan nilai PLI.

Kata kunci: spektrometri jisim plasma gadingan aruhan, indeks bebanan pencemaran, pencemaran, organisma, Selat Melaka

Introduction

A crucial and significant habitat for sharks is commonly found in the Malaysian waters of Johor. Nonetheless, Johor is an agricultural and industrial state that discharges a substantial amount of ocean waste [1]. This waste includes heavy metals, which are metallic substances with a considerably higher density than water [2]. Since weight and toxicity are related, heavy metals typically include metalloids (arsenic) and are hazardous at low exposure levels. Although numerous natural events (weathering and volcanic eruptions) greatly influence heavy metal poisoning incidents, human activities are primarily responsible for environmental contamination and human exposure concerns [3]. The largest heavy metal concentrations are generally recorded in apex predators at the top of the food chain. Hence, top predators like elasmobranchs (sharks) are more susceptible to environmental pollution.

The biomagnification and bioaccumulation processes absorb the contaminants in the food chain. For example, sharks acquire greater amounts of Hg (particularly monomethyl mercury) than other fish species, which is the most toxic form of metal [4]. Sharks are frequently the “apex” or top predators in their ecosystems as they have few natural predators. Additionally, sharks’ prey on species in the lower food web levels, aiding the regulation and maintenance of the marine ecological equilibrium. Since these predators directly impact their prey populations, the prey populations of the sharks’ prey are also affected. Most top predators consume diverse foods, and the top predators can switch prey species. This switch enables prey species to survive when certain prey populations are depleted [5].

Scoliodon laticaudus, or spade nose shark, is discovered in the Johor markets, one of the smallest tropical carcharhinid sharks inhabiting shallow coastal waters [6]. Generally, these sharks are observed in coastal and estuarine waters at depths ranging from 10 to 75 m (typically less than 50 m), prefer muddy and sandy substrates, and are commonly found around major freshwater outflows. Other spade nose sharks’ characteristics include a yearly litter of 6 to 20 pups, an early maturity age of two years, and a 4.5-year generation time [7]. Nonetheless, shark-based research in Malaysia still requires further investigation. Moreover, the *Scoliodon laticaudus* species are highly demanded as bycatches in the local markets of Johor. This study determined the heavy metal levels in sharks and the correlation between heavy metals and shark weights using statistical analysis.

Materials and Methods

Sample collection and preparation

A total of 25 *Scoliodon laticaudus* were acquired from the local fishermen in Malaysia (see Figure 1). These sharks were purchased from a port or a market in Johor in March 2022 (see Figure 2), which were bycatches from trawls and gillnets while being sold to the locals. The 25 sharks were labelled and stored at a low temperature in a refrigerator until further use. Initially, the sharks were defrosted, dissected, and analysed in a laboratory. The length and weight of the sharks’ whole bodies were also measured. Subsequently, the gender of the sharks was determined using a clasper. A ceramic knife dissected the sharks into muscle, fin, stomach lining, liver, and gill samples. These organs were transferred into a preheated oven at 60 °C until constant dry weights were achieved. Finally, the organs were homogenised into powder form using a pestle and mortar, and the processing equipment was cleaned with ethanol for each sample [8].

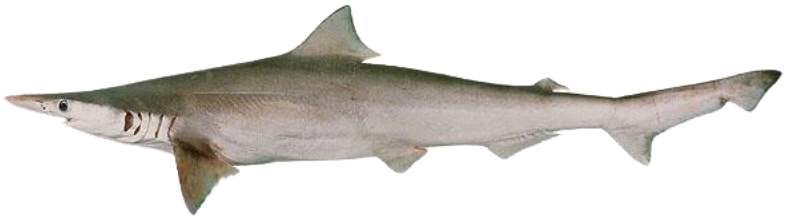

Figure 1. The *Scoliodon laticaudus* or spade nose shark

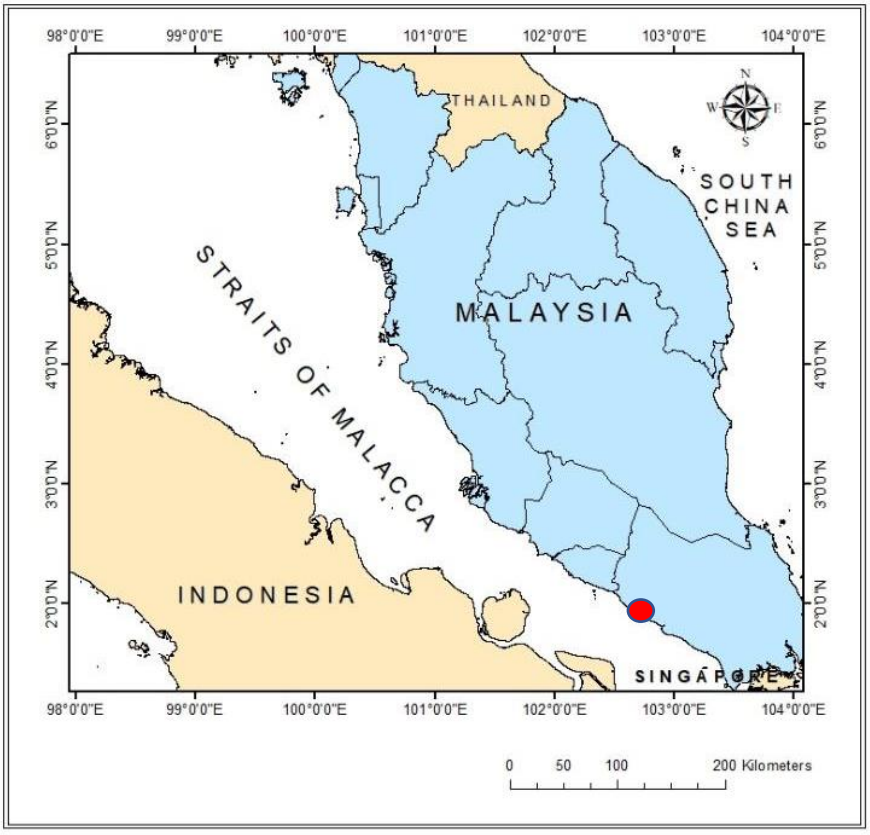

Figure 2. The Johor state map and the Pontian District

Acid digestion technique

The heavy metal contents in the liquid biota samples were measured using the Teflon bomb digestion approach for biological samples. Initially, 0.05 g of the homogenised material was weighed and placed in a 25 mL Teflon beaker containing 1.5 mL of 65% nitric acid (HNO_3) [9]. Since HNO_3 is a strong acid, the approach was conducted within a perchloric fume hood. The Teflon beaker was then tightly sealed to prevent acid leakage throughout the acid digestion process. All Teflon bombs were heated in an oven at 100°C for 8 h to aid digestion [9, 10]. The Teflon bombs were then allowed to cool to room temperature before transferring the solution to separate centrifuge tubes. These tubes were added with deionised water until the 10 mL marks were reached. Simultaneously, the blank and certified

reference material samples (DOLT-4 Dogfish liver) were analysed to assess the accuracy of the procedure. Lastly, the Arsenic (As), Cadmium (Cd), Chromium (Cr), Copper (Cu), Iron (Fe), Lead (Pb), Mercury (Hg), and Zinc (Zn) heavy metal concentrations were evaluated using an Inductively Coupled Plasma Mass Spectrometry (ICP-MS, Elan 6000) [11, 12]. Table 1 lists the detection and quantification limits of the ICP-MS instrument.

Table 1. Summary of the detection and quantification limits of the ICP-MS instrument

Metal	Mass	Detection Limits (µg/L)	Quantification Limits (µg/L)
Ar	075	0.590	1.950
Cd	112	0.003	0.010
Cr	052	0.110	0.380
Cu	063	0.210	0.690
Pb	207	0.020	0.050
Fe	055	8.260	27.54
Hg	200	0.006	0.020
Zn	065	0.260	0.850

Data analysis

The Pearson correlation test was utilised to examine the correlation between heavy metal concentrations and shark weights. All analyses used *p*-values less than 0.05 ($p < 0.05$). Meanwhile, the heavy metal contamination levels were evaluated using the pollutant load index (PLI) [13]. No action was necessary if the PLI value was below 50. Otherwise, monitoring was essential if the PLI value was higher than 50. If the PLI value was greater than 100, extreme pollution was indicated, requiring immediate action [14]. An equation is used to calculate XX as follows:

$$PLI = (CF1 \times CF2 \times CF3 \times \cdots \times CFn)^{1/n} \quad (1)$$

where *n* represents the number of metals.

Results and Discussion

Table 2 tabulates the average length and weight of the *Scoliodon laticaudus*; the maximum weight and length of the shark are 41.3 cm and 295 g, respectively. Meanwhile, the corresponding minimum weight and length were 33 cm and 162 g, respectively. Thus, the shark's average length demonstrated the significant maturity of the sharks [7]. This outcome was supported by Ali and Lim [15] study, which reported that male and female spade nose sharks reached their maturity ranging from 24 to 36 cm and 33 to 35 cm lengths, respectively [15]. When maturity was achieved, an extended survival period for the sharks in the wild was indicated, bioaccumulating a specific number of heavy metals. The weight of the sharks aided in determining the shark's health, which reflected the sharks' condition in their habitat. This factor suggested that the greater the sharks' weight of a certain length, the better their physiological conditions. Consequently, more preys were available for the sharks, which could assess if an ecosystem was healthy or contaminated [16, 17].

Tissue samples reveal the highest Zn and Cu concentrations, which Zn is a required metallic trace element for microbes, plants, animals, and humans. Although Cu and Zn are key minerals offering substantial health benefits and are necessary for metabolic synthesis, they are still potentially toxic metals. For example, Cu is vital as an enzyme cofactor and in Fe consumption [18]. Conversely, excessive Cu in the fish system (particularly in sharks) can harm organs and systems while suppressing the immune system [19]. Another example involves Zn as a crucial inorganic trace element in regulating numerous physiological activities, including defence mechanisms, growth performance, immune system, and radical and free ion resistances [20]. Nonetheless, high Zn concentrations produce deaths in fish by causing damage to the gill tissues. Stress and death are also

induced due to the continuously lethal concentrations [21]. Thus, the World Health Organization (WHO) and the Food and Agriculture Organization (FAO) established the Joint FAO/WHO Expert Committee on Food Additives (JECFA). In JECFA, standards were developed for evaluating the safety of chemicals in foods that were compatible with current risk assessment concepts while considering toxicology advancements and other relevant fields [22].

Cr	2.00
As	0.12
Zn	0.05
Hg	0.05
Fe	-
Cu	30.0

Significant As concentrations are observed in tissue samples due to pesticides (agricultural, fertiliser, and animal feeding activities) in the captured shark areas [23, 24]. Since As compounds are predominantly soluble, they are more likely to accumulate in seafood [25]. On the contrary, these amounts should not cause a concern considering the As ratio in less organic fishes to pure organic fishes was low [26]. Although As is the third-highest heavy metal concentration and a non-essential element, necessary precautions are still required. As is detrimental to the locals' health if these sharks are consumed. **Tables 4** to **8** summarise the heavy metal concentrations in the gill, muscle, liver, stomach lining, and fin samples, respectively. The mean, minimum, and maximum heavy metal concentrations were recorded, and standard errors or deviations accompanied the mean values. As the sharks were obtained from the same environment, the weight-dependent heavy metal concentrations were most likely determined by the sharks' physical states. Additionally, strong physical conditions with greater lipid tissue contents produced a relative dilution of the stored contaminants in the organs [17, 27].

Table 4. Summary of metal concentrations in spade nose sharks (gills)

The lowest Hg content was measured in the gill samples, and the heavy metal distributions in the muscles and internal organs were influenced by environmental pollution [28, 29]. The liver sample also absorbed large quantities of ecological pollutants, which was important for pollutant storage, redistribution, detoxification, and transformation [30, 31]. In addition, the liver and stomach samples contained larger heavy metal amounts than other tissue samples. These heavy metal amounts in tissue samples could vary depending on several factors, such as size, gender, dietary habits, and environment. Furthermore, lower metal absorptions were produced due to the decreased free metal ion activities as salinity increased [32]. Table 9 presents the correlation coefficient interpretations from Mukaka's and Schober et al. studies [33, 34]. Meanwhile, Figures 3 to 7 depict the coefficient correlation curves between shark weights and heavy metal concentrations.

The Cu and Pb concentrations were low in gill tissues (see Figure 3), and their concentrations did not vary significantly with body weights. In contrast, the correlations between Cr and Cd concentrations and shark weights were not statistically significant. The correlation coefficients for Zn, As, Hg, and Fe were less than 0.3, indicating a substantial relationship between

shark weights and heavy metal concentrations. In the muscle samples (see Figure 4), a very weak correlation was recorded for all metals between shark weights and heavy metal concentrations. Although the correlation coefficient values for Cr, Fe, Zn, Cd, Pb, As, and Hg were less than -0.2, the values remained in the negative regions (see Figure 5). This outcome suggested that the heavy metal concentrations acquired no significant changes. Likewise, Cu concentration increased slightly with shark weight, which was deemed insignificant.

Table 9. Summary of the correlation coefficient interpretations

Size of Correlation	Interpretation
0.90 to 1.00 (-0.90 to -1.00)	Very high positive (negative) correlation
0.70 to 0.90 (-0.70 to -0.90)	High positive (negative) correlation
0.50 to 0.70 (-0.50 to -0.70)	Moderate positive (negative) correlation
0.30 to 0.50 (-0.30 to -0.50)	Low positive (negative) correlation
0.00 to 0.30 (0.00 to -0.30)	Negligible correlation

In the stomach tissue samples (see Figure 6), the Fe, Cu, Pb, Hg, Zn, and As exhibited significant changes in weight as their concentrations increased. On the contrary, Cr and Cd revealed weak positive and negative significances, respectively. A moderate correlation between Cr and shark weight was also computed in the liver tissue samples (see Figure 7). This result occurred due to the increased sample weight when the Cr concentration decreased. Interestingly, Hg, Cd, and Zn produced corresponding correlation values of -0.32, -0.37, and -0.3, thus indicating significant changes in shark weights and heavy metal concentrations. Lastly, the low Pb, As, and Fe concentrations were deemed insignificant.

The impacts of multiple external aspects (such as the marine environment) and internal factors (fish carcass features) can induce variations in metal accumulations and inter-metal correlations among fish species, locations, and seasons. Generally, the size-age effect on metal content is a well-established study whereby Hg content increase with size and age (particularly in predatory fishes). Nevertheless, this characteristic is not observed in all metals. Certain metals, such as Cr, Cu, Fe, Cd, As, and Pb, have inverse associations with the size or age of the fish. Hence, heavy metal concentrations vary by species, location, and tropic level, generating challenging comparison and interpretation processes [35]. Moreover, negative correlations are more common than positive ones, making it difficult to explain them [36].

All the coefficient values in gills for Cr-Zn, Cu-Cd, Fe-Cd, Fe-Zn, Cu-Cd, Zn-Cd, Cd-As, and Pb-Hg were between 0.5 and 0.7 (see Table 10). Subsequently, all the coefficient values for muscles for Cr-Fe, Cr-Cu, Fe-Zn, Fe-Cd, Fe-Pb, Fe-As, Fe-Hg, and Cu-As were low or negative (see Table 11). Meanwhile, all the coefficient values in fins for Fe-Zn, Fe-Cd, Fe-Hg, Zn-Cd, Cd-Hg, Pb-Hg, and As-Hg were between 0.5 and 0.9 (see Table 12). Alternatively, all the correlation coefficient values for the stomach tissues for Fe-Cu, Fe-Zn, Fe-Pb, Fe-Hg, Cu-Pb, Cu-Hg, Zn-Pb, Zn-Hg, and P-Hg were from 0.5 to 0.9 (see Table 13). Finally, all the correlation coefficient values in liver tissues for Cr-Fe, Cr-Cu, Cr-Zn, Cr-Pb, Cr-As, Cr-Hg, Fe-Cu, and Fe-Cd were low (see Table 14).

Positive correlation coefficients implied that the potentially exposed and bioaccumulated tissue samples originated from the same source. Likewise, the Malacca Strait included waste from both terrestrial and marine sources. For example, the vessels in the areas were accompanied by accident-related platform activities. Therefore, the heavy metal contamination of fish in Johor was likely caused by urban activities [37, 24]. The predatory fish in this study acquired a higher trophic level while accumulating more heavy metals. Since carnivorous fish are active swimmers, these fishes mostly ingest fingerlings, shrimps, and zooplankton. These activities can result in large heavy metal accumulations in the body. Furthermore, the surroundings and dietary habits determine the heavy metal accumulations. Another concern lies in fishes with steady growth rates that inhabit contaminated settings, which stabilise the heavy metal accumulations [38].

Based on present data, the livers contained the highest metal concentrations than other tissue samples, and contaminants tend to concentrate in tissues with high lipid content. This outcome suggested that sharks possessed high lipid concentrations in their livers. Similarly, other elasmobranchs also accumulated pollutants [26]. Table 15 lists the results following the calculated average PLI values in Table 14. The overall average results indicated that the samples were moderately contaminated and that no immediate action was necessary for the research region.

Table 15. Summary of the PLI values in this study

Tissue Sample	PLI
Gills	3.31
Muscles	2.23
Fins	3.14
Stomach Linings	2.47
Livers	3.35

Conclusion

This study successfully demonstrated the heavy metal concentrations in tissue samples, which were ascending. The orders were Hg < Cd < Fe < Pb < Cr < Cu < As < Zn for gills, Cd < Hg < Fe< Pb < Cr < Cu < As < Zn for muscles, Cd < Hg < Pb < Fe < Cr < Cu < As < Zn for fins, Cd < Hg < Fe < Pb < Cr < As < Cu < Zn for stomach linings, and Fe < Cd < Hg < Pb < Cr < As < Cu < Zn for livers. The livers acquired the most heavy metals, while Zn was the highest among all tissue samples. Furthermore, shark size was not the only factor determining heavy metal concentrations. Several factors involving eating habits, environment, gender, and species type, could influence heavy metal concentrations. Consequently, this study concluded that no immediate action was required based on the PLI values. Nevertheless, considerable precautions were still needed as most bioaccumulated heavy metals originated from the same source.

Abstract

The study focused on the utilization of pineapple peel activated carbon (PineAC) biosorbent, produced through a low–cost and environmentally friendly method, for the adsorption of methylene blue (MB) and methyl red (MR) dyes. PineAC was characterized using various techniques such as surface analysis, scanning electron microscopy (SEM), energy–dispersive X–ray (EDX), and Fourier–transform infrared (FTIR) spectroscopy. ANOVA analysis was conducted to assess the significance of different factors, with *p*–values below 0.05 considered statistically significant. The obtained *F*–values, compared to *F*–crit values, indicated the overall significance of the tests. The kinetic data agreed with the Polymath Mass Transfer (PMT) model, which accurately captured the adsorption behaviour. The PMT model precisely predicted the adsorption surface area (a_m) as 612.60 m^2/g, closely aligning with the actual mesopores surface area of 547.85 m^2/g for the MB dye. Conversely, the PMT model for the MR dye failed to match the actual calculation, suggesting that the MR dye exhibited unfavourable adsorption characteristics towards PineAC. This demonstrated the reliability and robustness of the PMT model in describing the adsorption process. Exploring the potential functionalization of PineAC could offer opportunities for enhanced performance and broader applications in sustainable wastewater treatment.

Keywords: polymath mass transfer, activated carbon, mass transfer, methylene blue, methyl red

Abstrak

Kajian ini memberi tumpuan kepada penggunaan karbon teraktif kulit nanas (PineAC), dihasilkan melalui kaedah yang murah dan mesra alam, untuk penjerapan pewarna metilena biru (MB) dan metil merah (MR). PineAC telah dicirikan menggunakan pelbagai teknik seperti analisis permukaan, mikroskopi imbasan elektron (SEM), sinar–X tersebar tenaga (EDX), dan spektroskopi inframerah transformasi Fourier (FTIR). Analisis ANOVA telah dijalankan untuk menilai kepentingan faktor–faktor berbeza, dengan nilai p yang kurang daripada 0.05 dianggap signifikan secara statistik. Nilai F yang diperoleh, berbanding dengan nilai *F*–kritikal, menunjukkan kepentingan keseluruhan ujian tersebut. Data kinetik selari dengan model pemindahan jisim polimat (PMT), yang menggambarkan dengan tepat tingkah laku penjerapan. Selain itu, model PMT secara tepat meramalkan kawasan permukaan

penjerapan (a_m) sebagai 612.60 m^2/g, hampir seiring dengan kawasan permukaan mesopor sebenar 547.85 m^2/g bagi pewarna MB. Sebaliknya, model PMT bagi pewarna MR gagal sejajar dengan perhitungan sebenar, menunjukkan bahawa pewarna MR menunjukkan ciri–ciri penjerapan yang tidak menguntungkan terhadap PineAC. Ini membuktikan kebolehpercayaan dan ketahanan model PMT dalam menggambarkan proses penjerapan. Meneroka potensi pemekaan PineAC boleh memberi peluang untuk prestasi yang lebih baik dan aplikasi yang lebih luas dalam rawatan air sisa lestari.

Kata kunci: pemindahan jisim polimat, karbon teraktif, pemindahan jisim, metilena biru, metil merah

Introduction

The presence of organic dyes in industrial effluent are responsible for releasing a considerable number of dyes, including substances like methylene blue (MB) and methyl red (MR) dyes, into wastewater during synthesis and processing [1]. MB dye, for example, exhibits remarkable stability to oxidizing agents, light, and heat, due to the high intensity of its amino groups and chromophore's positive ion, making it difficult to degrade or remove from aqueous solutions [2]. The harmful effects of dyes are not limited to the environment but also extend to both human and animal forms, causing various health issues such as respiratory difficulties, nausea, eye irritation, excessive sweating, vomiting, and cognitive confusion [3–5]. Consequently, the removal of MB and MR dyes from wastewater using activated carbon (AC) is of utmost importance to prevent their release into the environment.

Pineapple peels–based AC (PineAC) as an adsorbent offers a practical approach for removing MB and MR dyes from wastewater. PineAC possesses a high surface area and porosity, providing adsorption sites for dye molecules to adhere to its surface through physical interactions such as electrostatic attraction, van der Waals forces, and π–π stacking [6]. These properties make PineAC an ideal choice for the adsorption of MB and MR dyes, facilitating their removal from wastewater prior to its discharge into the environment. The effectiveness of the adsorption process is greatly influenced by variables like temperature, pH, contact duration, and the amount of biosorbent used [7, 8]. Longer contact times and higher biosorbent dosages enhanced the adsorption capacity of AC, while an optimal pH range and temperature can promote favourable dye–biosorbent interactions [9, 8, 10]. Additionally, the mesopores in the PineAC structure can enhance its accessibility and surface area, leading to improved dyes adsorption performance [11].

In this work, mass transfer simulation improved the estimation of mesopores in PineAC structures for dyes adsorption. By employing mass transfer simulation techniques, researchers better understood the intricate processes involved in dyes adsorption within the mesopores [12]. This simulation allowed for a more accurate estimation of the mesopores' effectiveness and their contribution to the overall adsorption capacity of PineAC structures [13]. Based on the reported findings by Mohamad Yusop et al. [14–16], the observed alignment of adsorption kinetics with the mass transfer simulation using the Polymath mass transfer (PMT) model underscored the robustness and reliability in effectively describing the adsorption process. Such optimization endeavours were crucial in ensuring the judicious utilization of resources and achieving the desired level of dye removal efficacy [16]. Moreover, mass transfer simulation enabled the prediction of breakthrough behaviour in dye adsorption systems, contributing to its long–term sustainability and effectiveness [14].

In recent studies conducted by Mohamad Yusop et al. [13–16], the kinetics of dye adsorption were investigated using the PMT model for mass transfer simulation. These investigations' findings suggested that a major factor in the adsorption of dyes was the mass transfer mechanism between the biosorbent and adsorbate. Mohd Ramli et al. [13] observed that the mass transfer coefficient decreased as the initial concentration of MB dye increased when using AC biosorbent derived from the jengkol peel. In the adsorption of the remazol brilliant blue R (RBBR) dye, Mohamad Yusop et al. [14] correctly anticipated the adsorption surface area (a_m) to be 790.04 m^2/g utilizing meranti wood–based AC. This

figure was quite near the 825.58 m^2/g surface area of the mesopores. Similarly, when teak wood–based AC was employed in the adsorption of RBBR dye, the PMT model predicted the a_m value of 940.79 m^2/g, which closely aligned with the actual mesopores surface area of 983.25 m^2/g [15]. Furthermore, the PMT model successfully predicted the a_m of 807.77 m^2/g for jackfruit–based AC in the adsorption of malachite green (MG) dye, which was comparable to the actual mesopores surface area of 714.25 m^2/g with an error of 11.58% [16]. Regarding the kinetics data, the PMT model provided the best fit, and the rate constant (k_{PTM}) was found to increase from 3.96 to 4.34 h^{-1} and 4.84 to 5.22 h^{-1} as the initial RBBR dye concentration increased using meranti wood and teak wood–based AC, respectively. Conversely, jackfruit–based AC exhibited a decrease in K_{PMT} from 1.20 to 0.41 h^{-1} as the MG dye concentration increased from 25 to 300 mg/L. Overall, these studies demonstrated the significance of the PMT model in describing the kinetics of dye adsorption and the influence of various factors, such as dye concentration and biosorbent type, on the mass transfer process.

Meanwhile, ANOVA was employed to evaluate the influence of different factors on dye adsorption. Following ANOVA, post hoc Bonferroni correction analysis was conducted to thoroughly investigate the experimental groups' differences in dye adsorption capacities. This post hoc analysis allowed researchers to perform pairwise comparisons between biosorbents or conditions, identifying cases where significant differences in dye adsorption performance were observed [17]. By employing this analytical framework, valuable insights were gained regarding the relative efficacy of different biosorbents or experimental conditions, aiding in the identification of the most promising candidates for efficient dye removal.

In this study, the MB and MR dyes adsorption using PineAC was done similarly to Rosli et al. [6] work in order to understand the mass transfer simulation and statistic approach studies in adsorption studies. The PineAC was characterized using a surface analyser, Fourier Transform Infrared (FTIR), Energy Dispersive X–ray (EDX), and scanning electron microscopy (SEM). The equilibrium isotherm of PineAC–MB and PineAC–MR dyes adsorption based on different temperatures were also discussed. The study introduced the Polymath mass transfer (PMT) model for the analysis of kinetic data in the PineAC–MB and PineAC–MR dyes adsorption system, representing a novel approach. In comparison to the traditional pseudo–first–order (PFO) and pseudo–second–order (PSO) kinetic models, the PMT model offered distinct advantages, notably its capability to predict the specific surface area implicated in the adsorption process. This characteristic of the PMT model provided researchers with valuable insights, further enriching their comprehension of the underlying adsorption mechanism. By repurposing pineapple peel, disposal costs can be minimized, and the environmental impact of waste accumulation can be reduced.

Materials and Methods

Materials

The studies of the PineAC were determined using 4–dimethylaminoazobenzene–2–carboxylic acid (MR) and 3,7–bis(dimethylamino)phenazathionium chloride (MB) (82%), purchased from Sigma–Aldrich (M) Sdn. Bhd., Malaysia. Potassium hydroxide (KOH) pellets (85%) were procured from Merck in Germany. For pH adjustments during the experiment, hydrochloric acid (HCl)(37%) and sodium hydroxide (NaOH) (99%) were acquired from Merck and Essex, respectively.

Preparation of PineAC and instrumental analysis

The raw material for PineAC, known as pineapple peel, was sourced from Parit Buntar, Perak, Malaysia. To prepare the pineapple peel raw material, it underwent a washing process and was subsequently dried in an oven for two hours, as described by Iamsaard et al. [18] study. The PineAC preparation method employed in this study was a two–step pyrolysis process based on the work conducted by Rosli et al. [6, 8, 10]. The work optimized the conditions for PineAC preparation, and these optimal conditions were used in the current study. The optimal parameters included an impregnation ratio (IR) of 3.0, a carbonization temperature of 732 °C, and a carbonization duration of 1.96 hours, which represented the weight ratio of KOH to char. These specific parameters were chosen based on their ability to yield

PineAC samples with suitable properties and achieved optimal adsorption performance, as demonstrated in the findings of Rosli et al. [6]. Figure 1 illustrates the process of PineAC preparation, which involves the steps mentioned above. PineAC's characteristics were studied using suitable analytical techniques similar to Rosli et al. [6, 8].

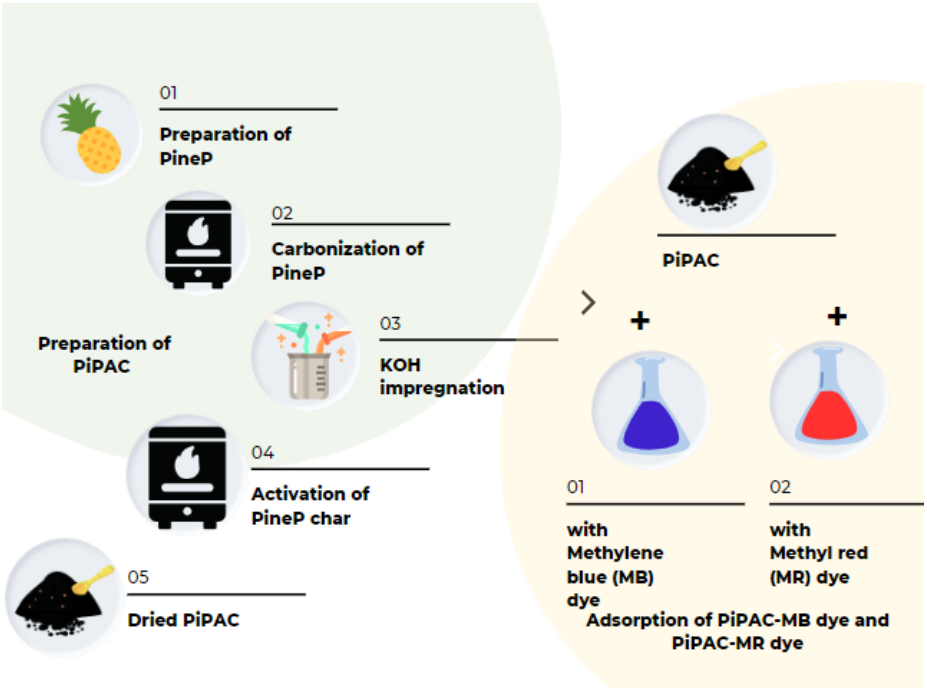

Figure 1. The flowchart for the PineAC preparation process

Adsorption studies

The batch adsorption experiments were conducted based on the methodology described in the works of Rosli et al. [6, 8]. The MB and MR dyes' maximum wavelength was 664 nm and 410 nm, respectively (Figure S1 and S2). In order to investigate the effects of initial adsorbate concentration and contact time on the adsorption process, various initial concentrations ranging from 25 to 300 mg/L for both MB and MR dyes were prepared, and the experiments were conducted over 24 hours. The impact of solution pH on the adsorption process was explored by adjusting the initial pH of the solutions within the range of 2 to 12. Furthermore, the influence of solution temperature on adsorption was investigated by conducting experiments at three different temperatures: 30, 45, and 60 °C.

Results and Discussion

Characterization of PineAC

PineAC exhibited a significant BET surface area of 1160 m^2/g. With an average pore diameter of 2.17 nm and a surface area of 547.85 m^2/g, PineAC's mesoporous character was evident [6]. The increased pore volume and surface area of PineAC were attributed to the removal of volatile matter and moisture content during the carbonization and pyrolysis of pineapple peel raw material (Figure 2(a)) [6–8]. As a result, the overall pore volume of PineAC increased from 0.173 cm^3/g to 0.544 cm^3/g. This is due to the carbonization process effectively enlarging the average pore width in the mesoporous regions [5]. The surface morphology of PineAC is shown in Figure 2(b), which highlights an uneven, sizable pore structure on the surface. The heterogeneous pore structure of PineAC was able to grow thanks to the KOH impregnation. The physiochemical treatment that created porous PineAC

enhanced the adsorption capability of MB and MR dyes [19].

The EDX analysis (Figure 2(c)) showed that the PineAC consisted of 0.14% sulphur, 67.18% carbon, 14.05% oxygen, 12.79% N_2, 4.62% potassium, 0.44% magnesium, and 0.79% calcium, implying that it was a specific sort of AC created by heating carbonaceous materials in the presence of a chemical agent [8]. Figure 2(d) shows the FTIR spectra of PineAC, revealing multiple peaks corresponding to various functional groups. The O–H stretching of the hydroxyl group appeared in the wavelength range of 3865-3610 cm^{-1}. The C≡C stretching of the alkyne group was observed within the range of 2399-2094 cm^{-1}. The presence of the C=O stretching in aldehydes and ketones was indicated by a characteristic peak at approximately 1732 cm^{-1}. Furthermore, the C=C stretching of the aromatic group generated a distinct peak at around 1527 cm^{-1}. Lastly, the =C–H bend of alkenes contributed to the spectrum by exhibiting a peak around 991 cm^{-1}. These specific wavelength ranges provided valuable insights enabling its identification and characterization in MB and MR dye removal [6,16].

Batch adsorption studies and statistical analysis

The adsorption capacity (q_t) for PineAC–MB dye increased from 23.993 to 165.177 mg/g as the starting concentration increased to 300 mg/L at 60 °C (Figure 3(a)). Initial MB dye concentrations ranging from 25 to 100 mg/L were observed to reach equilibrium more quickly (< 5 hours) compared to between 20 to 24 hours. This can be attributed to a lower ratio of MB dye to available sites, allowing for efficient adsorption at lower concentrations. However, the removal of MB dye (%) decreased at higher concentrations due to the larger ratio of MB dye to accessible sites. This removal efficiency decrease occurred because many PineAC surface sites were initially accessible for adsorption [5, 19]. Similarly, in Figure 3(b), the adsorption uptakes of PineAC–MR dye at equilibrium increased from 14.48 to 94.870 mg/g as the starting concentration was raised from 25 to 300 mg/L. This can be attributed to a stronger mass transfer force driving greater uptake of MR dye at higher concentrations. The presence of other adsorbate species in the solution and the delayed diffusion of solute molecules into the bulk of the biosorbent were additional contributing factors [8]. Furthermore, at 60 °C, the amount of MB dye adsorbed rose from 129.77 mg/g to equilibrium, while the adsorption uptakes of PineAC–MR dye increased from 54.85 mg/g (Figure 3(d)). The rate of adsorbate molecule diffusion into the internal pores of the biosorbent particles and across the external boundary layer was accelerated by the rise in temperature [6, 19].

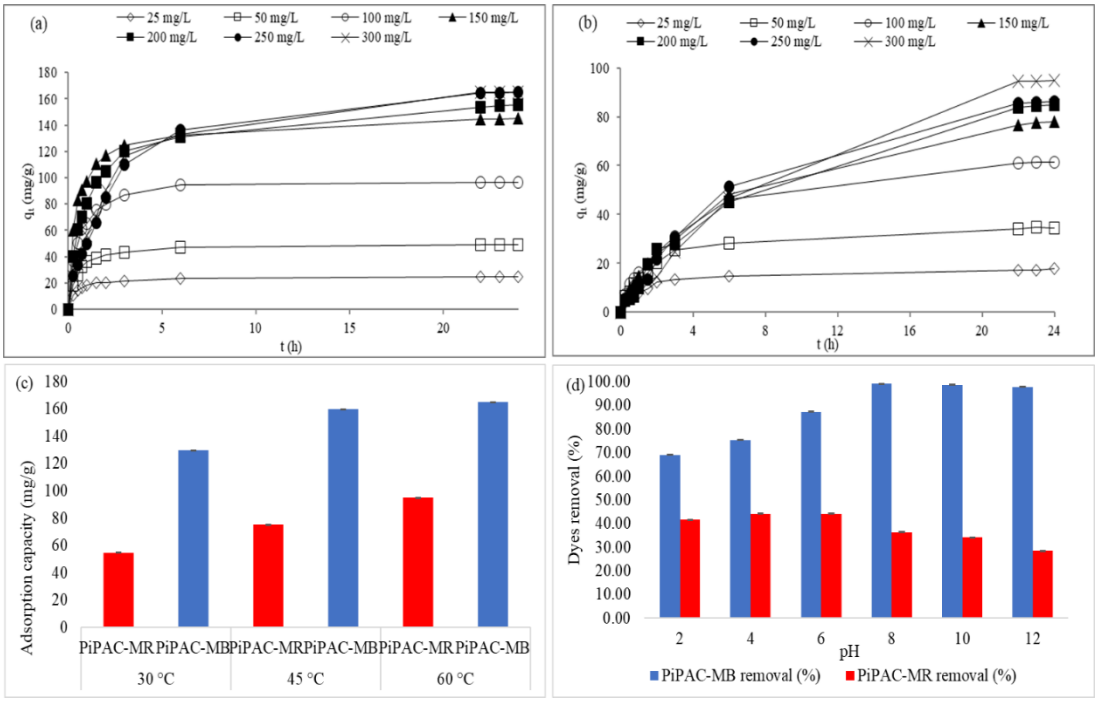

Figure 3. The q_t of (a) PineAC–MB dye and (b) PineAC–MR dye were measured at 60°C within 24 hours (25 to 300 mg/L). The effect of (c) temperature and (d) pH on PineAC–MB and PineAC –MR dyes were also shown

Based on the data presented in Figure 3(d), it was observed that the removal of PineAC–MB dye increased with an increase in pH in the solution. The maximum removal of PineAC–MB dye, reaching 99%, was achieved at pH 8. Moreover, the adsorption of MB dye remained relatively constant above pH 8. At low pH levels, the low adsorption of PineAC–MB dye was attributed to the abundance of H^+ ions competing with the MB dye cation for adsorption sites on the PineAC surface. Conversely, the negatively charged PineAC surface exhibited an attractive electrostatic force at high pH levels, promoting the elevation and adsorption of the positively charged MB dye cation [6]. On the other hand, PineAC–MR dye adsorption displayed a

preference for an acidic environment, with optimal adsorption observed at pH 6. This can be attributed to the abundance of positively charged PineAC sites under acidic conditions, facilitating the adsorption of MR dye. Additionally, as the pH rose above 6, there were more negatively charged sites. The increased adsorption of MR dye with a drop in pH value was explained by the attraction between the azo dye and more H^+ ions in the solution [8, 10].

Because of its azo group–based chemical structure, MR dye had lower adsorption uptakes than PineAC–MB dye. However, MB dye, a basic dye, has cationic properties because of its positive charge, which was frequently dispersed throughout the chromophoric system [20]. Notably, PineAC shared the same hexatomic ring of carbon atoms (Figure 4), enabling it to naturally form π–π interactions with both MB and MR dyes. Due to reduced electrostatic interactions, this showed that van der Waals forces were more important than hydrogen bonding in preserving the stability of the complex [8, 10]. These results suggested that the intensity and frequency of van der Waals interactions within the system affected the binding of PineAC with MB and MR dyes as well as the consequent adsorption capacities and overall stability. These results suggested that the intensity and frequency of van der Waals interactions within the system affected the binding of PineAC with MB and MR dyes as well as the consequent adsorption capacities and overall stability.

The ANOVA test was a statistical tool utilized to assess significant differences among the means of multiple groups in this study. In the context of adsorption studies, ANOVA analysis enabled the investigation of various factors' impacts on the adsorption process and determined their statistical significance [21]. ANOVA tests were conducted to evaluate the significance of four primary adsorption parameters, temperature, initial dye concentration, pH, and contact time, on the PineAC with MB and MR adsorption. The influential factors were identified by examining the statistical significance of these variables, and their effects on the adsorption process were understood. The variables in this study were defined as contact time (24 hours), initial dye concentration (25-300 mg/L), pH (2-12), and temperature (30-60 °C). The summary statistical analysis in Table 1 presented the effects of major interactive variables, including degrees of freedom (df), *F*–values, *F*-crit, sum of squares (SS), mean square (MS), and *p*–values. A *p*–value below 0.05 indicated the significance of the models in the regression analysis considering the independent variables. The analysis of the ANOVA models was conducted by assessing the significance of each term, considering *p*–values below 0.05 as statistically significant. The larger *F*–values compared to *F*-crit values indicated the overall significance of the tests. Consequently, these statistical outcomes supported the acceptance of the alternative hypothesis, suggesting significant differences between the means of the analysed parameters.

However, as the ANOVA test alone does not provide specific information regarding the significant differences between individual parameters, a post–hoc test with Bonferroni correction was conducted to analyse the data further. Table 2 presents a summary of the Post–Hoc Tests (Bonferroni Correction) conducted to assess the effects of temperature, initial dye concentration, and pH on the adsorption of PineAC–MB and PineAC–MR dyes [22]. The *t*–test with adjusted *p*–values were performed for each parameter, and the Bonferroni correction method was employed to account for multiple comparisons. By adjusting the alpha level (0.05) based on the provided data, the likelihood of Type I errors resulting from multiple hypothesis testing was effectively controlled. The analysis yielded significant results, as evidenced by the calculated adjusted *p*–values. Specifically, for PineAC–MB dye, statistically significant differences were observed between contact time and initial dye concentrations of 100-300 mg/L, as well as between pH and dye removal (%). In the case of PineAC–MR dye, all combinations of initial dye concentration, contact time, and pH, with the percentage of dye removal, were found to be statistically significant. These findings further underscore the significance of the analysed parameters and offer more comprehensive insights into their respective effects on the adsorption process.

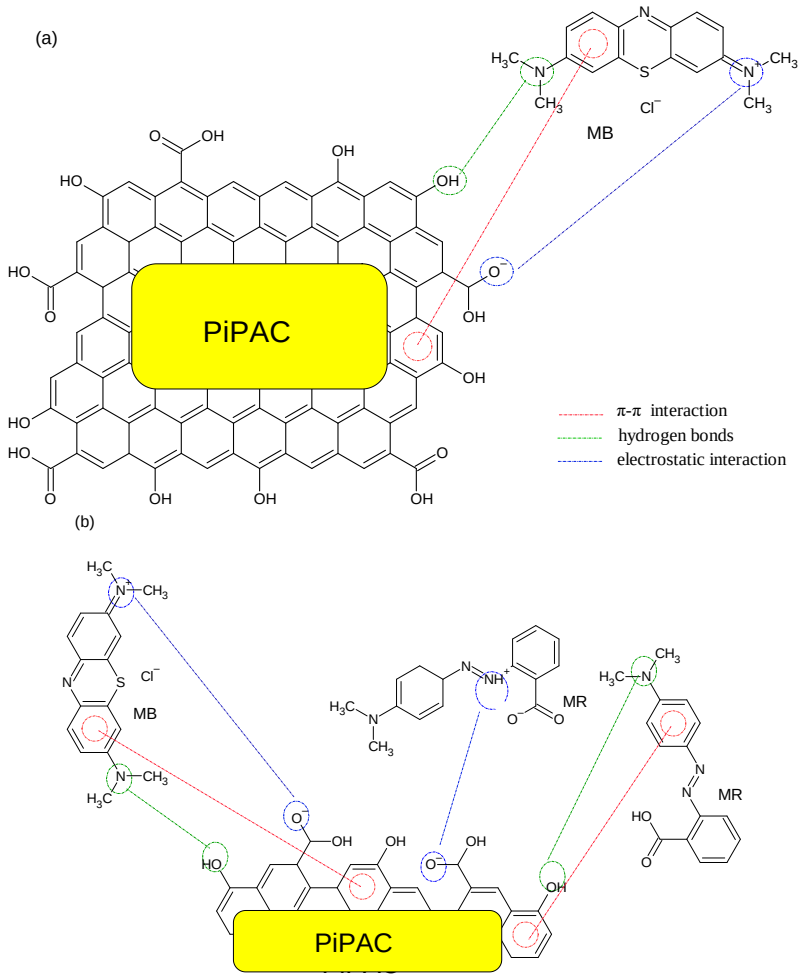

Figure 4. The mechanism of (a) PineAC–MB and (b) PineAC–MR dyes adsorption

Adsorption isotherm studies

In this study, the Langmuir and Freundlich isotherm models were selected to analyse the experimental equilibrium data. Figure S3 illustrates the adsorption equilibrium curves obtained from each isotherm model and compares them with the experimental values for PineAC–MB and PineAC–MR dyes at 30 to 60 °C. The goodness of fit for each model was assessed based on the R^2 values, as shown in Table 3. The Langmuir isotherm model exhibited in agreement with the experimental data ($R^2 > 0.99$) for the adsorption of both PineAC–MB and PineAC–MR dyes at 60 °C. The Langmuir model suggested a monolayer adsorption behaviour, and the maximum adsorption capacities (Q_m) were determined as 168.528 mg/g and 107.798 mg/g for PineAC–MB and PineAC–MR dyes, respectively [6]. On the other hand, the Freundlich isotherm parameters showed that the adsorption process for PineAC–MB and PineAC–MR dyes was favourable at 30 to 45 °C. The Freundlich model describes a physical adsorption process and provides information about the heterogeneity and adsorption intensity of the biosorbent [23]. The results indicated that PineAC demonstrated favourable adsorption characteristics for both PineAC–MB and PineAC–MR dyes. The Langmuir model represented the monolayer adsorption behaviour at 60 °C, while the Freundlich model confirmed the favourable physical adsorption process at lower temperatures.

The studies discussed highlighted the diverse applications of pineapple peel and its derivatives as effective biosorbents for pollutant removal. These findings contributed significantly to the field of water and wastewater treatment, showcasing the potential of pineapple–based materials. To further contextualize and add depth to these discussions, a comparative analysis with existing literature and a focus on the novelty of the PineAC biosorbent was elucidated. Comparative studies with existing literature revealed the uniqueness of PineAC in terms of its adsorption capacities. While Ugbe et al. [24] and Chaiyaraksa et al. [25] reported q_{max} values for the removal of Eosin Yellow and Basic Red 9 using untreated pineapple peel, the development of PineAC surpassed these capacities. PineAC achieved a remarkable q_{max} of 165.17 mg/g at pH 8 for the removal of a pollutant, exceeding the reported values in previous studies [22]. This significant enhancement in adsorption capacity could be attributed to the specific activation methods and processing techniques employed in the synthesis of PineAC, setting it apart from traditional pineapple peel–based biosorbents.

The utilization of pineapple peel for hydrogel development, as demonstrated by Dai et al. [26], showcased high adsorption capacities for Congo Red removal. However, PineAC outperformed these hydrogels, achieving a q_{max} of 165.17 mg/g compared to the reported values of 114.940 mg/g for water pineapple peel hydrogels. The alkali and bleaching pineapple peel hydrogels also demonstrated lower q_{max} values of 77.520 mg/g and 138.890 mg/g, respectively. This suggested that the specific formulation and activation process of PineAC contributed to its superior adsorption performance. Activation methods played a crucial role in enhancing the adsorption capacity of biosorbents. While Turkmen et al. [27] activated pineapple peel using $ZnCl_2$ and observed an increased q_{max} for the adsorption of Zn(II), the PineAC biosorbent, activated through a different method, achieved a higher q_{max} at 165.17 mg/g. Similarly, the H_2SO_4–activated pineapple peel showed promise with a q_{max} of 36.99 mg/g, but PineAC surpassed this capacity, indicating the effectiveness of the novel activation method used in its synthesis.

Furthermore, the comparative analysis extended to the temperature–dependent biochar production process explored by Shakya and Agarwal [28]. Pineapple peel biochar exhibited q_{max} values ranging from 23.81 to 33.33 mg/g for Cr(VI) adsorption. In contrast, PineAC demonstrated a significantly higher q_{max} of 165.17 mg/g at pH 8, highlighting the superiority of PineAC for pollutant removal. The investigation of pineapple peel for Cd(II) removal by Yusoff et al. [29] reported a q_{max} of 1.91 mg/g. In comparison, PineAC showcased a substantially higher adsorption capacity of 165.17 mg/g at pH 8. This emphasized the versatility of PineAC across a broad spectrum of pollutants and pH conditions, and its efficacy in comparison to conventional pineapple peel–based biosorbents.

Thus, the presented comparative discussion emphasizes the pioneering nature of the PineAC biosorbent. The innovative approach to activation and processing techniques led to a significant enhancement in adsorption capacities, outperforming existing literature across various pollutants and pH conditions. The development of PineAC opened new avenues for sustainable and efficient solutions in water and wastewater treatment, showcasing its potential as a leading biosorbent in the field. Further research and optimization of PineAC and similar derivatives held promise for advancing the landscape of environmental remediation technologies.

Table 4. Comparative analysis of the adsorption capacity of pineapple peel adsorbate based on different pollutant

Adsorbent Name	q_{max} (mg/g)	pH	Pollutant	Ref.
Pineapple peel as biosorbents	11.76	–	Eosin Yellow	[24]

Adsorption kinetic studies and mass transfer simulation

This study utilized three kinetic models: the PFO, PSO, and PMT models. The PFO and PSO models' q_e (mg/g) values showed a rise with increasing starting concentration, from 25 to 300 mg/L at 30 to 60 °C (supplementary data). This trend indicated that as the initial concentrations of MB and MR dyes increased, the adsorption capacity of PineAC also increased, suggesting a stronger affinity between the MB and MR dye molecules and the adsorption sites on PineAC [6]. Comparing the two models, the PSO kinetic model demonstrated higher consistency regarding R^2 and Δq_t values than the PFO model. Additionally, the k^2 value showed a non–linear pattern with increasing initial concentration, suggesting the influence of various mechanisms on the adsorption of PineAC–MB and PineAC–MR dyes.

Table 5 summarizes the kinetic parameters based on different temperatures for PFO, PSO, and PMT, showing relatively high average R^2 values at 30 to 60°C. However, for PineAC–MB dye adsorption, both the PFO and PSO models exhibited relatively high average Δq_t percentages, ranging from 29.01 to 72.59% and 6.55 to 77.12%, respectively, at 30 to 60°C. Similarly, for PineAC–MR dye adsorption, the PFO and PSO models showed relatively low average Δq_t percentages, ranging from 5.50 to 54.11% and 60.82 to 26.96%, respectively, compared to PineAC–MB dye adsorption. These percentages suggested that these models were not able to accurately predict the uptake of PineAC–MB and PineAC–MR dyes at equilibrium, $q_{e,\,cal}$ [13]. In contrast, the PMT model of PineAC–MB and PineAC–MR dyes adsorption demonstrated relatively low average Δq_t percentages of 1.3526 to 1.53% and 0.36 to 1.01%, respectively, at 30 °C to 60 °C, indicating the best fit for the kinetic data.

Moreover, the PMT model (Figures 5 and 6) accurately predicted the highest adsorption surface area to be 612.60 m^2/g (with an error percentage of 1.35%) for the MB dye, closely matching the actual mesopores surface area of 547.85 m^2/g [14]. However, the PMT model for the MR dye showed the highest adsorption surface area of 192.55 m^2/g (with an error percentage of 0.41%) and was unable to correspond to the actual mesopores surface area. This discrepancy was likely due to the low percentage of removal of the MR dye by PineAC, making it less favourable for adsorption. The investigated study explored the relationship between the initial concentrations of MB and MR dyes and mass transfer rates, with a focus on the formation of concentration gradients and the resulting mass transfer driving force [15]. Further analysis revealed that as the initial concentrations of MB and MR dyes increased from 25 mg/L to 300 mg/L, the PMT $q_{e,\ exp}$, and $q_{e\ cal}$ exhibited similar values and increased at 30 to 60°C. Generally, higher initial concentrations of MB and MR dyes resulted in more significant concentration gradients, leading to a more substantial mass transfer driving force. Consequently, this relationship typically led to higher rate constants and increased mass transfer rates [16].

Table 5. The summary of the kinetic model for PFO, PSO, and PMT constant parameters of PineAC–MB and PineAC–MR dyes adsorption at 30 to 60°C

T (°C)	Kinetic Parameters	PineAC–MB Dye			PineAC–MR Dye

Conclusion

The physiochemical treatment employed during the production of PineAC resulted in the formation of a porous structure, significantly enhancing its adsorption capacity for MB and MR dyes. The observed surface morphology was consistent with N_2 adsorption isotherm, EDX, and FTIR analysis. The ANOVA models indicated statistically significant differences (*p*–values <0.05), and the larger *F*–values compared to *F*–crit values supported the acceptance of the alternative hypothesis, suggesting significant differences between the means of the analysed parameters. In–depth, kinetic studies revealed that the PMT model provided the best fit for the investigated adsorption system. Notably, the PMT model accurately predicted the MB dye adsorption surface area to be 612.60 m^2/g, closely matching the measured value of PineAC's mesopores surface area. This high level of precision underscores the reliability and accuracy of the PMT model in describing the adsorption process. These findings highlight the potential of PineAC as an efficient and cost–effective adsorption system for the removal of MB and MR dyes. Further research and development in this direction can contribute to the advancement of PineAC–based adsorption systems for effective dye removal.

Abstract

Heavy metals and endocrine disrupting chemicals (EDC) have disruptive effects on an intact organism or its progeny. Due to the widespread presence of heavy metals and EDC in waterways, it is important to determine how effectively these compounds are removed from the environment. Their concentration has attained dangerous levels because of numerous anthropogenic activities such industrial operations, particularly mining, agricultural processes, and the disposal of industrial waste materials. Heavy metals and EDC have been removed using a variety of effective approaches, including chemical oxidation, biodegradation, liquid extraction, membrane techniques, chemical precipitation, ion exchange, reverse osmosis, coagulation, flocculation, etc. These methods have several drawbacks, including a high reagent requirement, unpredictable metal ion removal, the generation of toxic sludge, etc. Adsorption is a method that shows promise because of its simple design, low cost, and high efficiency. Its ability to remove hazardous and micropollutants from wastewater is what makes it the method of choice. The use of graphene nanoplatelets (GNPs) as adsorbents in the treatment of water has been established by research. A wide range of water pollutants, including but not limited to organic molecules and inorganic heavy metals, are reported to be effectively remedied by GNPs. The high surface areas and modifiable functional groups of GNPs can be used to remove various contaminants in water and wastewater treatment processes. More significantly, because GNPs are mainly made up of carbon, this characteristic makes it easier to use these carbon-based materials for adsorbing pollutants in water and wastewater treatment systems. In the present review, the mechanisms of adsorption are demonstrated by investigating the kinetics, isotherms, and thermodynamics of adsorption. Besides that, pH, contact

time, adsorbent dosage, and initial analyte concentration were investigated.

Abstrak

Logam berat dan bahan kimia pengganggu endokrin (EDC) mempunyai kesan yang mengganggu pada organisma yang utuh atau keturunannya. Disebabkan kehadiran meluas logam berat dan EDC dalam laluan air, adalah penting untuk menentukan keberkesanan sebatian ini dikeluarkan dari alam sekitar. Kepekatan mereka telah mencapai tahap berbahaya kerana banyak aktiviti antropogenik seperti operasi perindustrian, terutamanya perlombongan, proses pertanian, dan pelupusan bahan buangan industri. Logam berat dan EDC telah dialih keluar menggunakan pelbagai pendekatan yang berkesan, termasuk pengoksidaan kimia, biodegradasi, pengekstrakan cecair, teknik membran, pemendakan kimia, pertukaran ion, osmosis songsang, pembekuan, pemberbukuan, dll. Kaedah ini mempunyai beberapa kelemahan, termasuk yang tinggi. keperluan reagen, penyingkiran ion logam yang tidak dapat diramalkan, penjanaan enap cemar toksik, dsb. Penjerapan ialah kaedah yang menjanjikan kerana reka bentuknya yang ringkas, kos rendah dan kecekapan tinggi. Keupayaannya untuk membuang bahan pencemar berbahaya dan mikro daripada air sisa adalah yang menjadikannya kaedah pilihan. Penggunaan graphene nanoplatelets (GNPs) sebagai penjerap dalam rawatan air telah ditubuhkan oleh penyelidikan. Pelbagai bahan pencemar air, termasuk tetapi tidak terhad kepada molekul organik dan logam berat bukan organik, dilaporkan akan dipulihkan dengan berkesan oleh KNK. Kawasan permukaan yang tinggi dan kumpulan fungsi GNP yang boleh diubah suai boleh digunakan untuk membuang pelbagai bahan cemar dalam air dan proses rawatan air sisa. Lebih ketara, kerana KNK kebanyakannya terdiri daripada karbon, ciri ini memudahkan penggunaan bahan berasaskan karbon ini untuk menjerap bahan pencemar dalam sistem rawatan air dan air sisa. Dalam kajian ini, mekanisme penjerapan ditunjukkan dengan menyiasat kinetik, isoterma, dan termodinamik penjerapan. Selain itu, pH, masa sentuhan, dos penjerap, dan kepekatan analit awal telah disiasat.

Kata kunci: kepingan nano grafit, sebatian mengendala endokrin, logam berat, isoterma, kinetik, termodinamik

Introduction

Heavy metals are one of the environmental contaminants present in water [1]. In this era, heavy metals have emerged as life-threatening pollutants if left untreated. Heavy metals are one of pollutant that has been thoroughly studied in the research that have worked on the development of graphene applications in the sectors of water and wastewater treatment technologies. Heavy metals include lead, arsenic, cadmium, cobalt, copper, gold, palladium, and zinc, among others. Heavy metals are known for its toxicity and carcinogenicity to human beings. Long term exposure to heavy metals can cause a detrimental to human body. Along with unlimited discharge of wastewater effluents, pollution of heavy metal has become a worldwide concern, which poses a potential threat to human and animals. For instance, lead ion (Pb^{2+}) exists widely in the wastewater, and it could enter human body with food or water, once excessive intake of them for a period, probably leads to some diseases including convulsions, renal failure, even cancer. Besides that, heavy metal ions have non-biodegradable properties which can cause severe health problems in animals and human beings.

Endocrine disrupting chemicals (EDC) are external drug or mixture that may interfere with or modify the functions of the endocrine system, resulting in undesirable health effects in an organism, its offspring, or (sub) populations [2]. The substance may interfere with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body, which are responsible for the maintenance of homeostasis, reproduction, development, and/or behaviour, as well as the regulation of developmental processes [3-5]. These two pollutants tend to harm the lives of living organisms, thus a lot of materials have been developed and their effectiveness in the removal of heavy metals is being studied. Nanotechnology is presently reclaiming a significant amount of effort due to their high surface area, small particle size, tremendous potential, excellent inherent reactivity, and capacities as a catalytic reagent of a pollutant through modifying reaction mechanisms. Therefore, due to their high efficacy in a wide range of contaminants – including organic compounds, inorganic compounds, pharmaceutical compounds, chlorinated

compounds, and nitro-groups – nanomaterials have been widely used in environmental applications. These nanomaterials for pollutant removal showed an effective wastewater treatment system under small-scale production; it is anticipated to be less expensive compared to other more traditional methods of removal [1].

Graphene has gained attention as a nanomaterial. Recent studies have been concentrating on the removal of various water pollutants using graphene in its pristine, functionalized, or composite forms [6], due to its flexibility in introducing functional groups and to its easy operation [7-9]. Graphene is composed of carbon atoms organized in a 2D hexagonal array, which gives graphene its characteristic honeycomb structure. Every carbon atom creates three covalent bonds with its closest neighbour as a result of the sp2 hybridized orbitals being coplanar and aligned at 120° to one another, while the remaining 2pz orbital forms a bond with an electron density that is above and below the basal plane. The exceptional electrical and thermal properties of monolayer, bilayer, and few-layer graphene are brought about by the aromatic electron cloud and honeycomb crystal lattice [10]. According to Stoller et al., graphene is suited for adsorption due to its high porosity and exceptional specific surface area of 2600 $m^2.g^{-1}$ [11]. Graphene layer, turbostratic carbon, bilayer graphene, trilayer graphene, multi-layer graphene (MLG), few-layer graphene (FLG), exfoliated graphite (EG), graphene oxide (GO), and reduced graphene oxide (rGO) are all well-known graphene-based materials. This combination of excellent properties has made graphene-based material a promising material for a wide range of applications, such as biological engineering, drug delivery, biosensor [12], biological agents [13], tissue engineering [14], and contaminant sensing [15].

Due to the difficulty and complexity of graphene fabrication, graphene nanoplatelets (GNPs) are also being extensively explored. GNPs are more approachable, have similar characteristics, and can be utilized for the same applications as graphene [16]. GNPs in one of the graphene derivatives consisted of a single to a few layers of sp^2-bonded carbon atoms that interacted to generate nanometre-sized two-dimensional particles. GNPs are composed of single and few layer graphene mixed with thicker graphite; hence, structurally they are in between graphene and graphite [17]. GNPs with a typical thickness of 5–10 nanometres are available in diameters as large as 50 microns. GNPs are cheaper and simpler to create than single-layered graphene and carbon nanotubes, making their utilization appealing [18]. These fascinating nanoparticles consist of 10–30 platelet-shaped graphene sheets identical to those seen in the walls of carbon nanotubes, but in a planar form retaining the single-layer characteristics [19]. Due to their platelet structure, they have a surface area per unit mass that is significantly larger than that of graphite and carbon nanotubes [20]. Considering all these characteristics, GNPs are valuable in numerous domains of research. It can be utilized as a novel and effective analytical adsorbent material [21]. Due to the direct exfoliation of affordable graphite flakes, e.g. by ultrasonics in acid baths, followed by chemical oxidation and reduction of graphite oxide nanoplatelets, GNPs are currently regarded as one of the most remarkable materials [22]. GNPs has recently attracted significant interest as a new and ideal material for the detection of environmental pollution involving water treatment [23], heavy metal ion detection [24], and green technology. Graphene is hydrophobic; therefore, stable dispersions in polar liquids can only be achieved by using the appropriate surfactants [17]. Figure 1 summarizes the chemical properties of graphene-based materials.

The aspect ratios of GNPs can range into the thousands. They exhibit the same thermal and mechanical properties as carbon nanotubes but have greater surface areas or aspect ratios. Considering this, GNPs can be used to improve the properties of a wide range of polymeric materials, including thermoplastic and thermoset composites, natural or synthetic rubber, thermoplastic elastomers, adhesives, paints, and coatings. The GNPs are offered in a granular form that in water, organic solvents and polymers with the right choice of dispersion aids, equipment and techniques [25].

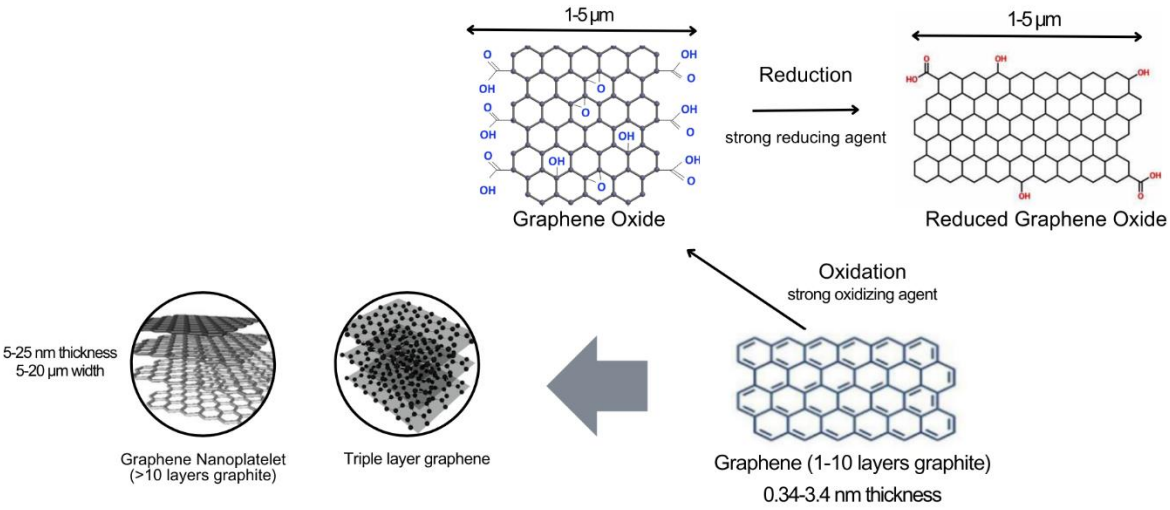

Figure 1. The chemical properties of graphene-based materials

An et al. conducted research on two types of graphene flakes manufactured by the non-oxidative and oxidative routes. In this work, their morphology, crystallographic order, gas adsorption potential, and electrical conductivity were examined [26]. The morphological differences of graphene nanoplatelets produced by oxidative (rGO-NP) and nonoxidative (GIC-NP) processes were compared using several analytical techniques. The adsorptive potential peaks of rGO-NP were found to be significantly more dispersed over the basal and non-basal regions than those of GIC-NP, indicating a heterogeneous surface. Comparing the Raman spectra and transmission electron microscope (TEM) pictures of the rGO-NP and GIC-NP, distinct crystallographic flaws were discovered in the rGO-NP. Compared to the GIC-NP, the R-ratio values evaluated at the edge and basal plane of the rGO-NP were substantially similar. Based on the overall analytical results and characteristics demonstrated in this comparative study, it is believed that GIC-NP is a more advantageous material than rGO-NP for numerous applications, such as conductive inks and conductive additives for batteries, where electric conducting properties are crucial. Consequently, the degree of disagreement in the R-values between the edge and basal plane can be employed as a significant criterion in the quality control of graphite nanoplatelets produced via diverse ways [26].

Exfoliated graphite nanoplatelets (xGnP) are a novel efficient adsorbent material with high adsorption capacity, good stability, and rapid adsorption, with platelet thicknesses in the nanometre range but platelet areas in the micrometre range [27, 28]. In addition, xGnP may be easily extracted from inexpensive, natural graphite in huge quantities, without the requirement for dimension expansion, for water purification applications. These materials are cheaper than carbon nanotubes, can be included into water treatment procedures, and are simple to remove or renew [29].

GNPs exhibit its large surface area, accessible surface, high hydrophobicity, and high mechanical properties, enabling it to be explored and used widely in the removal of heavy metals and EDCs. Moreover, enormous, delocalized π-π electron system that GNPs owe enables the formation of strong bonding with heavy metals and EDCs [30], making the removal process efficient. This article provides a general overview of GNPs being used for the removal of heavy metals. Adsorptive removal of heavy metals is discussed by studying the kinetics, isotherms, and thermodynamics of adsorption. Adsorption parameters which include pH, are also investigated.

Graphene nanoplatelets as adsorbents for the removal of heavy metal ions

According to Briffa et al. [31], heavy metals are defined as naturally occurring elements with high atomic weights and densities greater than 5 g/cm^3 that are

characterised by high stability but low levels of biodegradability, which cause bioaccumulation and biomagnification in living things. According to their toxicological characteristics, heavy metals can either be essential or non-essential for enzymatic activity [32]. The first is crucial for living things and can be present in little amounts; it only becomes harmful at a particular concentration threshold. Disease or abnormalities are caused by an essential heavy metal's excess or deficiency. The most hazardous substances, on the other hand, are non-essential heavy metals since they are difficult to break down through biological and photochemical processes and have harmful effects on both plants and animals, including people. According to Sall et al. [33], heavy metals have a number of negative health impacts, including impaired growth and development, cancer, organ damage, and, in larger amounts, death.

Heavy metals are one of the pollutants that has been thoroughly studied in the development of graphene applications in the sectors of water and wastewater treatment technologies. Heavy metals include lead, arsenic, cadmium, cobalt, copper, gold, palladium, and zinc, among others. Heavy metals have piqued the interest of researchers who are interested in finding a solution to this problem, which can have detrimental impacts on human health and the environment. Bioreactors [34], degradation and photodegradation [35-38], filtration [39], photocatalysis [40, 41], photo-Fenton and Fenton-like [42, 43], coagulation [44] and adsorption [45, 46] are all utilized to remove contaminants from water. Among these technologies, adsorption is the most popular and effective method for treating wastewater. This methodology is superior and considered powerful alternatives to conventional methods [47] because of its low cost, ease of operation, high efficiency, high capacity, simplicity, dependability, and low energy usage [48, 49]. Due to its large specific surface area, delocalized π-electron system, which can form strong interactions with other which is perfect for adsorption, GNP are utilized as an adsorbent to remove the contaminants [30].

The research by Kucherova et al. [50] focused on the adsorption of Pb(II) ions onto graphene materials prepared through the exfoliation of a hydrolysed extended graphite intercalation compound. Few-layered oxidized graphene suspension (FLOGS), multi-layered graphene paste (MLGP), and few-layered graphene paste (FLGP) were employed as adsorbents for the removal of Pb(II) from aqueous solutions. These adsorbents were reported to have maximum experimental Pb(II) adsorption capabilities of 850, 230, and 170 mg/g, respectively. To fit the experimental data, two adsorption isotherm models were applied: Langmuir and Freundlich. The Langmuir model assumes that adsorption occurs at specific homogeneous sites on the adsorbent surface. For non-ideal sorption onto heterogeneous surfaces with multiple layers, the Freundlich model is reported to be more fit. The Type III S-shaped isotherms observed for FLOGS suggest a transitional porous structure of the adsorbent with a complex pore space topology and a wide range of pore sizes. Additionally, the nature of that isotherm's steepness shows that the adsorbent has mostly very small pores. From the origin to the inflection point, the lower portion of the S-shaped curve corresponds to the creation of a monomolecular layer, and the subsequent rise of the curve is explained by the transition from mono- to multi-molecular adsorption. It can be assumed that the adsorption isotherms created for the FLGP and MLGP correspond to L-type curves.

Using functionalized graphite nanoplatelets (FGN) based electrodes, Mishra et al. [51] demonstrated the simultaneous removal of sodium and both pentavalent and trivalent forms of arsenic from an aqueous solution. Furthermore, these electrode-based water filters were employed to extract various metals from seawater. The preparation of graphite nanoplatelets (GNP) involved acid intercalation followed by thermal exfoliation, with additional acid treatment to functionalize the GNP. The performance of a supercapacitor-based water filter was evaluated for removing high concentrations of trivalent and pentavalent arsenic, sodium, and for desalinating seawater, using cyclic voltammetry (CV) and inductively coupled plasma-optical emission spectroscopy (ICP-OES) techniques. The transient behaviour of the metal adsorption process was analysed using the Elovich and intra-particle diffusion kinetic models. Solutions containing sodium arsenate and

sodium arsenite with an initial arsenic concentration of 300 ppm were employed to study the concurrent transient behaviour of sodium and arsenic adsorption. Both the Elovich and intra-particle diffusion kinetic models provided comparable fits for the metallic impurities. The Elovich model pertains to diffusion, while the intra-particle diffusion kinetic model is derived from chemical reaction kinetics. The removal efficiency of the supercapacitor-based water filter was investigated for salt removal, both forms of arsenic, and desalination of seawater. Approximately 72% of arsenic (As) and 75% of sodium (Na) removal efficiency was achieved for sodium arsenate-containing water, while for sodium arsenite-containing water, the removal efficiency was determined to be 73% for arsenic and 76% for sodium. These results were obtained over 20 repeated cycles with 100 mg of FGN loading on each electrode.

Ion et al. [28] conducted an investigation into the sorption behaviour of Pb(II) onto exfoliated graphite nanoplatelets (xGNPs). Among various factors such as specific surface area and solution composition, the presence of surface functional groups emerges as the paramount determinant influencing Pb(II) adsorption on xGNPs. Nitric acid (HNO_3) oxidation plays a crucial role in modifying the ion-exchange capacity, leading to the development of distinct acidic functional groups on the surface, which exhibit dissociation at varying pH levels. Due to the surface functionalization by HNO_3 and additional oxygen-containing groups like hydroxyl, carbonyl, and carboxyl, the adsorption capability of xGNPs treated with concentrated HNO_3 exhibit a substantially enhanced capacity of 13.09 mg/g. The sorption characteristics are profoundly impacted by pH, the presence of active sites and the surface dimensions. The influence of pH was revealing that adsorption percentages reach 100% at pH 6, but rapidly decreased at more acidic pH values. At low pH levels, lead is present as free cations, which is explained by the fact that at these pH levels, the H^+ concentration is large, and protons can compete with lead ions for surface sites. The deprotonation of the sorbent functional groups causes a decrease in positive surface charge as pH rises. The sorption properties of the adsorbent in water were described using the Langmuir and Freundlich isotherm models. Both models displayed excellent agreement with experimental data, as evidenced by correlation coefficient values of 0.9996 and 0.994 for Langmuir and Freundlich, respectively with the optimum initial concentration of 200 ppm at 30 min.

Sheng et al. also conducted an investigation into functionalized graphene nanoplatelets (FGN) by the acidic treatment of graphene nanoplatelets (GNPs) with HNO_3 for removing Pb(II) from solution. Through nitrogen desorption isotherm analysis, BET data revealed FGN's surface area is 714.5 m^2/g, with an average pore size of 4.8502 nm and a pore volume of 0.8598 cm^3/g. These findings indicate FGN's uniform and mesoporous nature. The specific surface area and effective adsorption sites of FGN facilitated Pb(II) adsorption at lower initial concentrations. However, as the initial Pb (II) concentration increased, the percentage removal was decreased due to the electrostatic repulsion among heavy metal ions and increased competition between heavy metal ions for adsorption sites. This study also stated that the capacity for Pb(II) adsorption notably increased as pH shifted from 6 to 7, resulting in approximately 100% removal efficiency of Pb(II) by FGN at pH 7 due to precipitation and adsorption coefficients. The dominant role of monolayer chemical adsorption on FGN's surface was reported while the pseudo-second order kinetic model achieved an R^2 of 0.998, indicating a better fit for the latter. This suggests that valence forces, involving electron exchange or sharing between FGN and Pb(II), may govern the rate-limiting step in the adsorption process [52].

Nandi et al. conducted research on GNPs obtained from human nails and synthesized via a novel *in-situ* synthetic technique involving ferric chloride. This work suggests that the surface of GNPs is mostly positively charged pH < 6 and predominantly negatively charged pH > 6. The highest sorption capacity was reported at pH = 7.0 since the surface of GNPs is almost neutral. However, the sorption capacity of GNPs towards As (III) is decreased at lower or higher pH values than pH = 7.0. The sorption of As(III) on the surface of GNPs happens at pH 7.0 via ion-dipole interaction. The sorption of As(III) fitted the Langmuir model (R^2 = 0.97) can be attributed to the GNPs' high specific surface area and more accessible

opening sites at lower adsorbate concentrations. Notably, the pseudo-second order model provided the best agreement with the experimental data. In addition, thermodynamic analysis offered insight into the reaction's feasibility, nature, and direction. The negative value of ΔG^0 indicated the spontaneous nature of the As(III) adsorption process on GNPs with respect to temperature changes. The positive ΔH^0 value indicated an endothermic reaction, while the increase in entropy ΔS^0 suggested greater randomness at the solid-liquid interface [53].

Zhu et al. have developed magnetic graphene nanoplatelet composites (MGNCs) by synthesizing core-shell Fe-Fe_2O_3 nanoparticles (NPs) through a straightforward one-pot thermal decomposition process. According to this study, MGNCs, comprising GNPs decorated with NPs, showed robust magnetization for magnetic separation and efficiently adsorb arsenic(III) from polluted water. This is due to the magnetic graphene nanoplatelets increasing the adsorption sites. Other than that, the solution pH dominantly affects the surface charge of the adsorbent, and the optimum adsorption capacity of 11.34 mg/g was achieved when the sample solution is at pH 7. Langmuir and Freundlich models fit well (R^2 >0.95), revealing a specific homogenous adsorption mechanism. MGNC's greater surface area (42.1 m^2/g) enhances adsorption capacity. Favourable adsorption is shown by Freundlich parameter (n = 2.79 > 1) and fitted with pseudo-second order kinetics (R^2 = 0.994) and describe the As (III) removal with the chemisorption process [54].

Samaraweera et al. studied the significance of the adsorption method, particularly when dealing with pollutant removal, such as Cu^{2+} ions. In their research, they investigated the potential of using a hybrid material consisting of graphene and pine wood biochar (GPBC) as an adsorbent for Cu^{2+} ions. The study found that biochar, when functionalized with nanomaterials like graphene, can greatly enhance its ability to remove pollutants. This enhancement occurs when both the nanomaterial and the biochar surface act as effective adsorption sites for the target pollutants. Interestingly, the researchers used different types of graphene nanosheets (GNPs) with varying surface areas (G1, G2, and G3) to create GPBCs. They noted that GPBCs with lower surface areas were produced using GNPs with larger surface areas. This counterintuitive observation was attributed to potential pore-filling and pore-blocking effects of the nanomaterials within the biochar. The study focused on GPBC-1, which had the lowest nanophase surface area but the highest Cu^{2+} ion adsorption capacity. This finding challenges the conventional belief that higher surface area always leads to better adsorption. In the case of GPBC-1, Cu^{2+} removal occurred through electrostatic interactions, inner sphere surface complex formation, and other attractive forces with oxygenated functional groups on the GPBC-1 surface. The researchers employed Langmuir and Freundlich isotherm models to understand the interaction between the adsorbate (Cu^{2+}) and the adsorbent (GPBC-1). The Langmuir model, which assumes monolayer adsorption, provided a better fit to the data. Additionally, kinetic models revealed that the adsorption process followed pseudo-second order kinetics, indicating a strong interaction between Cu^{2+} ions and GPBC-1. Thermodynamic studies also showed that Cu^{2+} sorption on GPBC-1 was an endothermic process, requiring energy input. The negative values of ΔG at various temperatures indicated that the adsorption was spontaneous. Positive ΔS^o values suggested an increase in randomness during the adsorption process, controlled by entropy [55].

Rosenzweig et al. investigated Cu^{2+} ion adsorption on various nanomaterials, including carbon nanotubes and different types of graphene nanoparticles (GNPs). They found that functionalized GNPs, such as GNP-COOH and GNP-O^+, exhibited better stability in water, a crucial factor for effective pollutant removal. The study applied these optimized conditions to Cu^{2+} adsorption experiments using GNPs. The adsorption behaviour was analysed using the Freundlich model, revealing that GNPs with 1/n values significantly > 1 had weaker adsorption power, likely due to the formation of irreversible aggregates caused by strong van der Waals forces within multilayer nano-sheets. These aggregates could reduce the adsorption capacity of GNPs by concealing adsorption sites. However, functionalized GNPs maintained high colloidal stability, thanks to oxygen-containing groups at their edges, preventing

excessive aggregation and ensuring a larger accessible surface area for adsorption. This study highlights the importance of nanomaterial properties, especially colloidal stability, in Cu^{2+} ion adsorption, and underscores the impact of functionalization on the effectiveness of GNPs in water treatment applications [56].

Capra et al. examined the removal of Sb(III) from drinking water using oxidized exfoliated graphite nanoplatelets (ox-xGNP). They observed irregularly shaped Sb(III) particles ranging from 50 to 200 nm in TEM images. Notably, the adsorption capacity increased significantly, reaching 16.0 mg/g at a pH of 9.0, a phenomenon influenced by both the composition of metal ions in the solution and alterations in surface functional groups on the adsorbent. Zeta potential measurements confirmed the negative charge on the ox-xGNP surface, which contributed to optimal colloidal stability at pH 9.0 due to electrostatic attractions. Despite the typical drinking water pH range of 6.0 to 8.0, experiments were conducted at pH 7.0 in anticipation of future Sb (III) removal applications. The established optimal removal conditions included a pH of 7.0, 1.0 mg ox-xGNP per 100 mL solution, a temperature of 293 K, 1.0 mg L^{-1} Sb(III), and a 25-minute contact time. Kinetic analysis favoured the pseudo-first order model (R^2 = 0.999), which accurately estimated the adsorption capacity at equilibrium. Furthermore, the Langmuir adsorption isotherm model best described the process, indicating monolayer adsorption on homogeneous ox-xGNP surfaces, emphasizing the favourable Sb(III) adsorption. Thermodynamic analysis unveiled spontaneous and favourable adsorption, potential randomness at the solid-solution interface, and an exothermic process [57].

Smith et al. studied a method for removing Cu(II), Zn(II), and Pb(II) ions from water using single-wall carbon nanotube-graphene nanoplatelet (SWCNT-GNP) aerogels, with varying amounts of carbon nanomaterials (0.2 wt.% and 2.0 wt.%). They tested the pH of metal (II) ion solutions to confirm that metal ion removal was solely due to adsorption and not precipitation, which occurred only at pH > 6.19. The adsorption of Cu(II) onto the aerogel followed a pseudo-second order kinetic model. Initially, there was a rapid adsorption phase for about 75 minutes, after which the adsorption capacity gradually increased, reaching equilibrium at approximately 105 minutes for the 2.0 wt.% aerogel and 90 minutes for the 0.2 wt.% aerogel. The initial rise was attributed to the open valence of Cu(II) ions interacting with the network, saturating the carbon nanomaterial (CNM) aerogel. The sponge-like structure of the aerogel provided more adsorption sites, increasing surface area. The adsorption behaviour for Cu(II) ions was generally similar to that of Zn(II) and Pb(II) ions. However, the uptake capacity for Pb(II) decreased considerably within 120 minutes. This decrease was because Pb(II) has a higher molecular weight and ionic radius compared to Cu(II) and Zn(II), making it more challenging to adsorb as many ions as possible due to the direct association between uptake capacity and these parameters. Interestingly, the equilibrium isotherms for all three metals displayed a largely linear behaviour, unlike the typical Langmuir or Freundlich-type models [58].

Ahmad et al. explored the efficacy of three different adsorbents, namely hybrid graphite nanoflakes/mesoporous silica nanoparticles (GNP-MSN), amine-functionalized mesoporous silica (NH_2-MSN), and graphite nanoflakes (GNP), for the removal of lead from aqueous solutions. The surface area of GNP-MSN was reduced, likely due to the silica coating on GNP surfaces, and the pore size of GNP-MSN was slightly larger than that of GNP, influenced by the presence of ionic template C16PyBr. Furthermore, functionalizing MSNs with amine groups led to a decrease in surface area and pore volume, attributed to the integration of amine groups onto pore surfaces. The maximum lead(II) adsorption for all three adsorbents occurred at pH 4 within 20 minutes. Lower pH hindered adsorption due to hydronium ions surrounding GNP surfaces, obstructing lead(II) ion binding sites. At higher pH, metal cation precipitation occurred. Adsorption kinetics revealed that the pseudo-second order model was the most suitable for describing lead(II) ion adsorption on both GNP and NH2-MSN, suggesting chemisorption. The pseudo-first order and pseudo-second order models yielded lower R^2 values for GNP-MSN, indicating adsorption controlled by physical adsorption or chemical adsorption involving weak

intermolecular forces or strong surface complexation of metal ions with oxygen-containing groups. Langmuir and Freundlich adsorption isotherms were applied, with Langmuir better representing lead(II) ion adsorption by GNP and NH_2-MSN. This suggests monolayer coverage on their surfaces. Conversely, the Freundlich model indicated multilayer adsorption on GNP-MSN's surface, supporting the pseudo-second order kinetic model's suggestion of physisorption involving Van der Waals or dipole-dipole forces [30].

Bogdan et al. investigated the adsorption of ammonium ions from aqueous solutions using exfoliated graphite nanoplatelets (xGNP) as adsorbents. The study examined adsorption characteristics under different conditions, including contact times, initial ammonium ion concentrations, and temperatures. Optimal adsorption parameters were identified as 70 ppm ammonium ions at 25°C with 30 minutes of stirring. The adsorption mechanisms were analysed using pseudo-first order, pseudo-second order, and intra-particle diffusion models. Among these, the pseudo-second order model (R^2 = 0.9831) provided the best fit for describing the adsorption kinetics of ammonium ions onto xGNP. To explain how solutes interacted with the nanostructured carbon-based adsorbents at equilibrium; various isotherm models including Freundlich, Langmuir, Temkin, Halsey, and Harkins-Jura were applied. The data showed that equilibrium data fit well with Freundlich, Langmuir, Harkins-Jura, and Halsey adsorption isotherm models, indicating advantageous, multilayer adsorption, a heterogeneous surface, and pore distribution on xGNP. Thermodynamic parameters were also determined, revealing that the adsorption process was feasible due to the negative value of ΔG^0. The positive value of ΔS^0 suggested ammonium molecules agglomerated at the solid/solution interface, and the endothermic nature of the adsorption process was indicated by the positive value of ΔH^0 [59].

Yin et al. conducted a study on the dispersive magnetic solid-phase extraction (MSPE) of copper and lead in Panax notoginseng using Fe_3O_4/graphene magnetic nanoparticles (Fe_3O_4@G) as adsorbents. They prepared Fe_3O_4/graphene magnetic nanoparticles by adding $FeCl_3.6H_2O$ and $(NH_4)_2Fe(SO_4)_2.6H_2O$ to dispersed graphene nanoparticles. To develop a highly sensitive method for simultaneous determination of Cu(II) and Pb(II) in Panax notoginseng, they optimized various experimental conditions. The optimal sorbent dose for extracting Cu and Pb from samples was found to be 36 mg. pH played a critical role in the MSPE procedure, with the optimal pH at 7. The retention percentage of lead and copper ions on the sorbent decreased at pH values higher than 7, likely due to the precipitation of lead and copper ions in the hydroxide form, reducing the concentration of free ions. An equilibration time of approximately 12 minutes was required for quantitative extraction of the analytes from the solution into the solid phase. The method was validated by applying it to determine the content of Cu^{2+} and Pb^{2+} in Panax notoginseng using standard addition and recovery techniques. The results indicated spiked recoveries for the target metal ions in the range of 96.4% to 102.0%. Furthermore, the concentrations of the two ions were found to be very low in Panax notoginseng samples, demonstrating the effectiveness of the adsorbent in recovering copper and lead as described in the methods [60].

Kucherova et al. examined the adsorption of lead ions (Pb^{2+}) using graphene-based nanocomposites derived from hydrolysed expanded graphite intercalation compound. Three distinct nanocomposites-suspension of graphene nanoplatelets (SGN), paste of multi-layered oxidized graphene (PMOG), and paste of few-layered oxidized graphene (PFOG)-were employed as adsorbents for Pb^{2+} extraction. The adsorption kinetics revealed an initial rapid Pb^{2+} adsorption rate that subsequently slowed, ultimately reaching equilibrium at 30 min. Remarkably, the adsorption capacities achieved were 457 mg/g (SGN), 103 mg/g (PMOG), and 38 mg/g (PFOG). The initial adsorption rate was influenced by the surface area energy of the adsorbents, resulting in a sudden increase in adsorption due to the presence of active adsorption sites. To discern the nature of the adsorption process (diffusion or chemisorption), various kinetic models, including the pseudo-first order, pseudo-second order, Elovich, and intraparticle diffusion models, were applied. Notably, the pseudo-second order model exhibited an excellent fit to the adsorption process, as evidenced by a high correlation coefficient

value ($R^2 = 0.999$) [50].

La et al. highlighted the potential of graphene nanoplatelets (GNPs) as a platform for even distribution of adsorbent nanoparticles to enhance electron exchange and ion transport for heavy-metal adsorption. They employed a thermal decomposition method to create a graphene-supported Fe-Mg oxide composite for efficient arsenic removal from aqueous solutions. The study investigated various factors affecting arsenic adsorption, including different Mg/Fe weight ratios, with initial As(V) concentrations at 10 ppm, an adsorbent dosage of 200 mg/L, pH 7, and room temperature. The addition of GNPs and Fe-Mg oxide significantly improved As(V) adsorption under these optimized conditions. Adsorption isotherms were used to assess arsenic adsorption and calculate the maximum As (V) adsorption capacity of the GNP/FeMg oxide composite. The Freundlich model provided a better fit (correlation coefficient of 0.985) compared to the Langmuir model (correlation coefficient of 0.935) for describing the adsorption behaviour of As(V) by the composite. Additionally, the kinetics of As(V) adsorption on the GNP/FeMg oxide surface were examined using the pseudo-second order model, showing a well-fitted correlation coefficient of 0.957. This suggests electron exchange occurred during the chemical adsorption process between the composite and arsenic. The selectivity of the GNP/FeMg binary oxide adsorbent for arsenic was tested in the presence of common metal ions typically found in drinking water, such as Na^+, K^+, Ca^{2+}, and Mg^{2+}. Notably, only a minimal amount of Na^+, K^+, and Ca^{2+} ions were adsorbed by the composite, whereas over 95% of arsenic was effectively removed. Interestingly, the release of Mg from the adsorbent led to a 10% increase in the concentration of Mg^{2+} in the solution after adsorption [61].

Li et al. conducted research on the adsorption of Pb^{2+} and Cd^{2+} onto GNPs prepared through thermal exfoliation from water. The study investigated the influence of four key factors: pH, adsorption time, temperature, and initial concentration on the adsorption of Pb^{2+} and Cd^{2+} onto GNPs, ultimately determining the maximum adsorption capacities under optimized conditions. The results revealed that the adsorption percentages of Pb^{2+} and Cd^{2+} onto GNPs were 96.27% at pH 5.80 and 76.75% at pH 6.30, respectively. The adsorption process reached equilibrium rapidly, within just 30 minutes, indicating that GNPs have great potential as effective adsorbent materials. Furthermore, the adsorption capacity increased with higher equilibrium concentrations of metal ions, gradually reaching saturation. Notably, Pb^{2+} exhibited a more pronounced adsorption capacity increase with increasing equilibrium concentration compared to Cd^{2+}, suggesting that Pb^{2+} adsorbs more readily onto GNPs. The temperature-adsorption relationship indicated that the adsorption of metal ions onto GNPs is an exothermic reaction, with room temperature being favourable for the adsorption process. Additionally, the study highlighted the inverse relationship between pore size and uptake capacity, with GNPs exhibiting a high content of micro- and mesoporosity, making them excellent candidates for the removal of Pb^{2+} and Cd^{2+} ions [62]

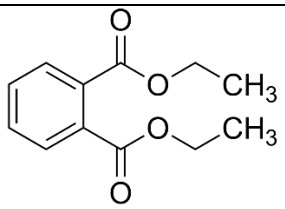
Table 1. Summary of adsorption of heavy metals onto graphene nanoplatelets

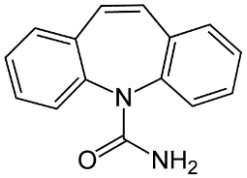
Adsorbent	Heavy Metal Ions	Adsorption Conditions	Adsorption Isotherm Model	Adsorption Kinetics Model	Adsorption Thermodynamic	Adsorption Capacity (mg/g) / Removal Efficiency (%)	Additional Remarks	Ref.
Multi-layered graphene paste	Pb(II)	CT=10min, [A]=200-350mg/L	Langmuir and Freundlich	-	-	230	FLGP and MLGP correspond to L-type curves which typical for Type IV isotherms.	[50]
Functionalized graphene nanoplatelets	Pentavalent and trivalent forms of arsenic	CT=40min, AD=100mg [A]=300mg/L	Langmuir and Freundlich	Elovich model (diffusion) Intra-particle diffusion (chemical reaction kinetics)		27mg/g for arsenate, 29mg/g for arsenite / 72%	The adsorption takes place at specific homogeneous sites located on the adsorbent surface.	[51]
Exfoliated graphene nanoplatelets	Pb(II)	CT=30min, pH=6.0, [A]=200mg/L	Langmuir and Freundlich	-	-	13.09	-	[28]
Functionalized graphene nanoplatelets	Pb(II)	CT=12h, pH=6.0, AD=50mg, [A]=30 mg/L	Langmuir	Pseudo-second order	-	57.77	Five cycles of repeated use.	[52]
Graphene nanoplatelets	As(III)	CT=3h, T=300K, pH=6.0, AD=25, [A]=5.0	Langmuir	Pseudo-second order	Endothermic, spontaneous process and reaction has occurred at the solid-liquid interface with increasing randomness	247.22mmol.kg^{-1}	When the sample is at pH <7 the water molecules adsorb on GNPs surfaces more than As (III) species. At higher pH	[53]

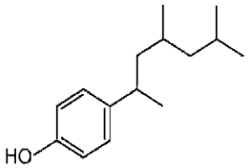
							values (>7.0), GNPs surfaces become predominately negative. These both phenomena lead to the less interaction of GNP with As (III).	
Magnetic graphene nanoplatelets composites	As(III)	CT=60min, pH=7.0, [A]=20	Langmuir Freundlich	Pseudo-second order	-	11.34	The larger deviation of the solution pH from the neutral state, the lower adsorption capacity is observed either in acidic or basic solutions.	[54]
Graphene/pine wood biochar hybrid	Cu(II)	CT=24h, pH=6.0, AD=0.05g, [A]= 5mg/L, T=25 ±0.5°C	Langmuir	Pseudo-second order	Endothermic, spontaneous process and increase randomness	4.7 – 10.6	Uses of higher surface area GNPs produced the lower surface areas hybrid adsorbents. This is because biochar loaded with nanomaterials can have a pore filling and pore-blocking effect.	[55]

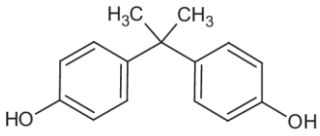
GNP-COOH, GNP-P, GNP-O^+	Cu(II)	AD=0.1 g, [A]=0.53-0.59mg/L	Freundlich	-	-	16.7	Functionalized GNPs showed good colloidal stability which shows a good adsorbent in water because pollutants must have free and quick access to all adsorptive sites on the adsorbent surface.	[56]
Oxidized exfoliated graphite nanoplatelets (ox-xGnP)	Sb(III)	CT=25min, pH=7.0, AD=1.0mg, [A]=1.0mg/L, T=293K	Langmuir	Pseudo-first order	Exothermic, spontaneous process and increase in randomness	8.91	At range of pH 9.0, a significant increase in the adsorption capacity of Sb (III) on the ox-xGnP surface.	[57]
Single-wall carbon Nanotube-graphene nanoplatelet	Cu(II) Zn(II) Pb(II)	CT=100min, pH=6.1, [A]=0.1mg/L	Langmuir Freundlich	Pseudo-second order	-	-	Pb (II) lower in average uptake capacity compared to Cu (II) and Zn (II) due to larger molecular weight and ionic radius.	[58]
GNP-MSN GNP	Pb(II)	CT=2h, pH=4.0, AD=10mg, [A]=10mg/L	Langmuir	Pseudo-second order	-	23.94 1.11	At lower pH, adsorption was unfavourable due to the	[30]

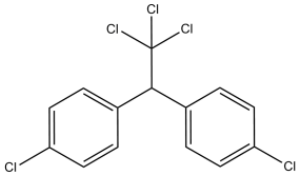
							surface of the GNP could be surrounded by the hydronium ions (H_3O^+) that hinder lead (II) ions from reaching the binding site on the surface of the GNP.	
Exfoliated graphite nanoplatelets	Ammonium	-	Freundlich, Langmuir, Harkins-Jura and Halsey	Pseudo-second order	Exothermic, feasibility process and increase in randomness	12.04	-	[59]
Fe_3O_4/graphene magnetic nanoparticles	Cu(II) Pb(II)	CT=12min, pH=7.0, AD=36mg	-	-	-	96.4 102.2	Decrease in the percentage of lead and copper ions on the sorbent at pH values higher than 7 is due to precipitation of lead and copper ions in the hydroxide form which leads to decreasing the concentration of free lead and copper ions in the sample.	[60]

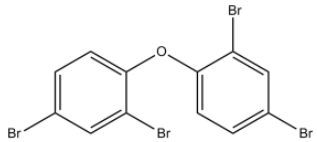












Suspension of graphene nanoplatelets (SGN)	Pb(II)	AD=0.01g, [A]=1,040mg/L	-	Pseudo-second order	-	457	Pb (II) adsorption is initially quite rapid. Then, the adsorption rate gets slower over time and reaches the constant value at 30 min	[63]
GNP/Fe-Mg oxide composite	As(V)	pH=7 AD=200mg/L, [A]=10 mg/L	Freundlich	Pseudo-second order		40.3	-	[61]
Graphene nanoplatelets	Pb(II) Cd(II)	CT=30min, pH=Pb^{2+} 5.80; Cd^{2+} 6.30, AD=15mg, [A]=500mg/L	-	-	-	460.20 72.39	The adsorption capacity increases with increasing equilibrium concentration of metal ions, and reaches saturation progressively.	[62]

Abbreviations: FLOGS = few-layered oxidized graphene suspension; MLGP = multi-layered graphene paste; FLGP = few-layered graphene paste; FGN = functionalized graphite nanoplatelets; GNP-MSN = hybrid graphite nanoflakes/mesoporous silica nanoparticles; NH_2-MSN = amine functionalized mesoporous silica; GNP = graphite nanoflakes; SGN = suspension of graphene nanoplatelets; PMOG = paste of multi-layered oxidized graphene; PFOG = paste of few-layered oxidized graphene; CT = contact time [h], T = temperature [◦C], AD = adsorbent dose [g/L], [IC] = initial concentration [mg/L]

Graphene nanoplatelets as endocrine disrupting chemicals adsorbents

Kumar et al. [64] highlighted growing concerns over the presence of endocrine-disrupting chemicals (EDCs) in aquatic water bodies, especially fresh water environments, and their potential disruptive effects on indigenous fauna. In the past few decades, environmental toxins have interfered with the endocrine systems of humans and animals, leading to deleterious effects, particularly in reproduction and the development of secondary sexual traits [29, 3]. An endocrine disruptor is an external drug or mixture that may interfere with or modify the function(s) of the endocrine system, resulting in undesirable health effects in an intact organism, its offspring, or (sub)populations [2]. The substance may interfere with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body, which are responsible for the maintenance of homeostasis, reproduction, development, and/or behaviour, as well as the regulation of developmental processes [3-5]. Table 2 below shows the several examples of EDCs.

Table 2: Some known EDCs molecular structure and their uses

Example EDCs	Category/Use	Molecular Structure	Molecular Weight (g/mol)
Diethyl phthalate	Personal care products		222.24
Carbamazepine	Pharmaceutical		236.269
Nonylphenols	Industrial surfactants		220.35
Bisphenol A	Food contact materials		228.29
Dichlorodiphenyltrichloroethane	Pesticides		354.48
Polybrominated diphenyl ethers	Brominated flame retardants		564.7

According to Ternes et al. [65] and Shi et al. [66] human and animal excretions as inactive polar conjugates such glucuronides and sulphates and their incomplete removal in sewage treatment plants were the main causes of the presence of EDCs in water bodies and sediments. The primary environmental source for these chemicals is the direct discharge of untreated sewage to surface waters. EDCs can also leach from septic tanks or landfills, infiltrate the ecosystem through surface runoff, or enter the water directly by direct discharge from treatment plants [67-73]. Therefore, this emerging class of pollutants need effective treatments. The best approach for removing contaminants is adsorption because no byproducts would be created and water and the adsorbent could both be recycled. As a result, researchers are constantly looking for novel adsorbents and trying to come up with new, effective removal techniques. GNPs are a brand-new, very effective adsorbent material that has a high capacity for adsorption, good stability, and quick adsorption. The platelet thickness is in the nanometer range, but the areas are in the micrometre range [28, 74]. In addition, GNPs may be easily produced in huge quantities from inexpensive natural graphite without the requirement for dimensional enlargement for use in water purification. These materials are less expensive than CNTs, can be used in water treatment procedures, and are simple to remove or regenerate, making them an excellent option for EDC adsorption [29].

Zaka et al. [75] analyzed the diclofenac sodium removal effectiveness of GNPs in water. To figure out the optimal parameters for DCS removal by GNPs, many factors were explored. The different parameters include contact time, adsorbent dosage, the initial concentration of DCS, pH and temperature. At 25°C temperature, 3.5 g/L dosage of GNPs, pH of 5, 5 ppm concentration of DCS, and contact time of 40 minutes, the maximum elimination of 99% was recorded. The interaction of adsorbents with ionizable contaminants has been found to be strongly influenced by electrostatic attractions or repulsions. Under acidic pH conditions, DCS functions as a neutral molecule and is more attracted to the graphene surface. The hydrophobic effects as well as the π–π electron-donor attractions play a significant role in the adsorption process for pH < pKa of DCS since GNPs has a negative charge on the surface for pH values larger than 2.2. The removal effectiveness is shown to diminish at pH levels higher than 4.2 because DCS ionises to produce a negatively charged ion that is electrostatically attracted to the surface of GNPs. Adsorption isotherms were plotted for each model to gain a better knowledge of the adsorption process and insight into the relationships between adsorbent and adsorbate. The adsorption isotherms were obtained under optimal conditions. In addition, the interactions between molecules of adsorbate and adsorbent were investigated using three distinct isotherm models: Langmuir, Freundlich, and Temkin. The data were determined to be best suited by the Langmuir isotherm, which had an R^2 value of 0.9967. The Langmuir isotherm model assumes that there are no lateral interactions between adsorbate molecules on the surface during monolayer adsorption. To comprehend the kinetics of DCS adsorption on GNPs, pseudo-first order and pseudo-second order kinetic models were utilised. With a rate constant of K_2 = 1.8218 g/mg min, it was discovered that the adsorption process followed pseudo-second-order kinetics. The process was confirmed to be exothermic and spontaneous when the thermodynamic properties were computed using Sip's model and indicated the negative value of change in Gibbs free energy and the change in enthalpy was equal to -3.9089 KJ/mol.

Radu et al. [29] utilized exfoliated graphite nanoplatelets (xGnP) as adsorbents for bisphenol A (BPA). This research investigates the possibility of eradicating this endocrine disruptor. The influence of the following parameters on the sorption behaviour of xGnP was investigated: contact time, starting BPA concentration, temperature, ionic strength, and pH. The influence of solution pH on BPA removal was examined. It was found that BPA adsorption decreased when the pH value is below 4, likely as a result of protonation of the xGnP surface's negative charge. The deprotonation of BPA causes a decrease in the hydrophobic interactions between the electrons of the graphite surface and the electrons of the C=C double bonds of BPA above a pH value of 10, and as a result, the adsorption of BPA on the xGnP surface. Between pH 3 and 7, it was seen that BPA adsorption marginally

increased, and between pH 7 and 9, it started to decline. Based on research, the ideal circumstances were (0.1 mg of xGnP and 50 mL of 1-10 mg/L BPA at 298.15 K, pH = 5.5, and contact period 30 minutes). It was also investigated how the ionic strength of the working solutions affected the elimination of organic contaminants. Salts and organic materials from the environment increase the adsorption of BPA on xGnP surfaces. The ideal concentration of NaCl in aqueous solution was determined to be 0.037 M. At low concentrations of NaCl in solution, the adsorption of BPA with a nonplanar and flexible structure greatly increases, and at higher concentrations, it starts to decline. The distribution of the Na+ and Cl- ions among the negatively charged graphite platelets may account for this activity, creating a screening effect that facilitates the adsorption of BPA molecules. BPA is less soluble in solution when NaCl is present, and its ability to bind to xGnP is improved. Because Na^+ and Cl^- ions are present, the "butterfly" or lying-down form of BPA may make it easier for more accessible adsorption sites to be occupied. It was shown that the adsorption capacity reduced at concentrations greater than 0.05 M, most likely as a result of competition amongst the species engaged in the process. In this study, equilibrium adsorption was represented by Langmuir, Freundlich, Harkin-Jura, and Temkin isotherms. When the adsorption process approaches equilibrium, the interactions between the adsorbent and the adsorbate are indicated by the adsorption isotherm models. The adsorption of BPA on xGnP most closely resembles the Langmuir isotherm based on a comparison of R^2 values, indicating a monolayer adsorption system on the surface. The kinetics of the adsorption process were studied using pseudo-first and second order models as well as intraparticle diffusion one. The experimental adsorption capacity, q_e exp (850 mg/g), was in greater agreement with the calculated one based on the pseudo-second order model, according to the results. Due to the large system of graphene, which is a strong electron acceptor, it favours a configuration that allows the interaction with the negatively charged sites of BPA. The physisorption of BPA on graphene is aided by charged controlled interactions in addition to van der Waals interactions; chemisorption is less significant on pure xGnP. The thermodynamic parameters provide insights as to how the internal energy evolves throughout the adsorption process. A process is exothermic when the change in enthalpy value is negative. The absence of normal free energy denotes a spontaneous process.

Al-Khateeb et al. researched the adsorption and removal characteristics of pharmaceutical pollutants such as aspirin (ASA), acetaminophen (APAP), and caffeine (CAF) onto GNPs from aqueous solutions. The TEM characterization analysis reveals that GNPs have many wrinkles and a transparent, layered structure with a smooth surface. Typically, the specific surface area of the solid adsorbent has a significant impact on the adsorption process. The specific surface area of the GNPs must therefore be determined using nitrogen adsorption/desorption isotherms. The obtained adsorption isotherms were categorized as type IV isotherms. The GNPs' specific surface area was discovered to be 635.2 m^2/g. It was studied how the mass of GNPs affected the adsorption patterns of ASA, CAF, and APAP. It found that, when an adsorbent mass of 15.0 mg was used, it was generally observed the percentage of ASA, CAF, and APAP adsorption rose almost linearly with the increase in GNPs mass. This development is mostly attributed to the rise in adsorption surface area brought on by the increased mass of GNPs, which made more active adsorption sites for the molecules ASA, CAF, and APAP molecules available. For the first 10 minutes, the adsorption of these three pharmaceutical pollutants increased over time. At this stage, equilibrium had been reached, with the amounts of ASA and CAF adsorbed being 63.5%, 94.3%, and 87.6%, respectively. The first stage of ASA, CAF, and APAP adsorption took place during the first 10 min of adsorption and was characterized by the high number of active binding sites on the GNPs surface at this time. Adsorption happened fast in this step, which suggests that it was controlled by the process by which the molecules of ASA, CAF, and APAP moved from the bulk phase to the surface of the GNPs. Because there were less active sites available for the ASA, CAF, and APAP molecules on the surface of the GNPs in the second stage, adsorption was probably an attachment-controlled process. It was investigated how pH affected the effectiveness of ASA, CAF, and APAP removal by GNPs. In the case of ASA and CAF,

the pH of the solution did not generally affect the removal of pharmaceutical compounds by GNPs; the percentage of adsorption (70 and 80, respectively) was not considerably affected by changing the pH value. In the case of APAP, raising the pH from 2.0 to 8.0 had no effect on the percentage of adsorption, while raising the pH to 11.0 was linked to a sharp drop in the percentage from 88.7% to 73.8%. The GNPs covered by the negatively charged hydroxide ions and the negatively charged APAP ions, whose pKa value is 9.9, may repel one another due to electrostatic attraction [76].

The electrostatic and hydrophobic interactions between the adsorbate and the solid adsorbent may be influenced by the ionic strength. Therefore, it is essential to research on how ionic strength affects the way that ASA, CAF, and APAP bind to GNPs. Ionic strength has a significant impact on the adsorption of pharmaceutical compounds because it generates a variety of adsorption conditions in which the electrostatic interactions between the pharmaceutical compounds and the surface of the GNPs are either appealing or repellent. An increase in the ionic strength of the solution had no effect on the percentage of ASA adsorption by GNPs. This suggests that the overall adsorption process is not affected by electrostatic contact. Increasing the ionic strength of the solution did, however, significantly increase the percentage of CAF adsorption, which suggests that - stacking between the surface of the GNPs and neutral CAF (pKa = 14.0) has a stronger electrostatic attraction. Pseudo-first-order and pseudo-second-order kinetic models have been proposed in order to understand the mechanisms of adsorption. The pseudo-second-order model was found to have the highest R^2 value for accurately describing the adsorption of ASA, CAF, and APAP by GNPs. The fundamental cause of the adsorption is a contact between the GNPs and the ASA, CAF, and APAP molecules that acts as an electron donor-acceptor. By computing the thermodynamic parameters, the feasibility and spontaneity of the process of ASA, CAF, and APAP adsorption by GNPs were investigated: Changes in enthalpy, entropy, and Gibbs free energy. Enthalpy change values for the adsorption of ASA, CAF, and APAP by GNPs from aqueous solution were negative; 5.42 kJ/mole, 46.6 kJ/mole, and 25.4 kJ/mole, respectively. The negative numbers demonstrate that ASA, CAF, and APAP are adsorbed by GNPs in an exothermic nature which explains for the decrease in adsorption at higher temperatures. The strength of the enthalpy change points to physical adsorption as compared to chemical adsorption as the likely mechanism for the weak bonding between ASA, CAF, and APAP by GNPs. When ASA, CAF, and APAP were adsorbed onto the surface of the GNPs, the negative values of entropy change, 13.1 J/mole K, 123.0 J/mole K, and 67.3 J/mole K, indicated a decrease in randomness at the GNP/solution interface. The decrease in the degree of freedom of the drug molecules may be the cause of the negative entropy of ASA, CAF, and APAP's adsorption and immobilization on the surface of GNPs. As would be expected from a product-favoured and spontaneous reaction, the free energy change was negative. The adsorption of ASA, CAF, and APAP by GNPs from aqueous solution is represented by the negative values of ΔG^o, which are 1.54 kJ/mole, 10.2 kJ/mole, and 5.42 kJ/mole, respectively [76].

Zaka et al. [80] were using a response surface modelling technique to analyse the effect of four distinct parameters on the elimination of levofloxacin (LFX) using GNPs. Extremely acidic and alkaline conditions diminish the effectiveness marginally. It can be noticed that both dosage and time have a positive effect on removal efficiency. If one of the variables is held constant, the trend remains unchanged. This is due to the fact that an increase in dosage will result in a greater number of accessible sites, hence increasing the removal. The change in elimination due to dosage is more important than the change in effect due to time. At any given time, a rise in concentration will result in a decrease in removal efficiency, which could be attributed to active site saturation. Zaka et al. [80] conducted five trials under optimal conditions: contact time = 77 minutes, GNP dosage = 2.1 g/L, pH = 5, and levofloxacin concentration = 10.5 mg/L. These five studies yielded removal efficiencies of 98.29 %, 98.15 %, 98.55 %, 97.97 %, and 98.59 % respectively. To fit the experimental data, three different isotherm models Langmuir, Freundlich, and Temkin were applied. It can be seen that the Langmuir isotherm model, which has an R^2 value of 0.996, best describes

the adsorption of LFX. This shows that the adsorption is monolayer- and homogeneous-based in nature. The experimental model for the removal of LFX using GNPs was fitted using pseudo-first order and pseudo-second order kinetic models. The pseudo-second order model's observed R^2 value of 0.999 was determined to be preferable to the pseudo-first order model's R^2 value of 0.880. Thermodynamic properties including change in Gibbs free energy (ΔG^o), change in enthalpy (ΔH^o), and change in entropy (ΔS^o) were calculated in order to explore the energy changes connected with LFX elimination. It can be shown that the free energy change values vary from -20 to 0 kJ/mol. This leads to the conclusion that LFX is physically adsorbing to GNPs. Additionally, the negative sign shows that the process is spontaneous. Additionally, the rise in Gibbs free energy shows that adsorption is less likely to occur at high temperatures. The process is endothermic, according to the positive sign of enthalpy change (ΔH^o). Additionally, the high affinity of the sorbent for the sorbate is linked to the positive value of entropy, which indicates an increase in randomness at the solid/liquid interface [77].

Kerkez-kuyumcu et al. studied the removal of amoxicillin (AA) from aqueous solution using magnetically modified graphene nanoplatelets (M-GNPs). M-GNPs were produced utilizing a selected GNPs by using a co-precipitation technique. The BET specific surface areas of M-GNPs were measured to be 543.2 m^2/g. The specific surface area of the GNPs (677.5 m^2/g) was significantly higher than that of the M-GNPs, which was decreased upon mixing with the Fe_3O_4 nanoparticles. Up until an adsorbent mass of 5.4 mg was used, the removal % of AA rose almost linearly with increase in M-GNPs mass. According to the study's findings, there was no discernible change in the percentage of amoxicillin removed over the pH range of 3.0 to 5.0, however the percentage clearance decreased when pH rose above 5.0. Amoxicillin is well-known for having three main function groups with different pKa values: -COOH (pK_{a1} 2.69), -NH_2 (pK_{a2} 7.49), and -OH (pK_{a1} 7.49). (pK_{a3} 9.63). At different pH values, these functional groups ionise to create negatively charged amoxicillin. As the pH of the solution rises, a stronger electrostatic attraction forms between the positively charged surface of the M-GNPs and the negatively charged amoxicillin. Additionally, competition for the active sites on the surface of the M-GNPs develops as the pH of the solution rises between the negatively charged -OH ions and positively charged amoxicillin ions. A pH of about 5.0 was selected as the ideal value for amoxicillin adsorption onto M-GNPs. Since there are several adsorption circumstances where the electrostatic interactions between the surface of the M-GNPs and the pharmaceutical compounds are either attracting or repulsive, the influence of ionic strength on the adsorption of pharmaceutical compounds was studied. The results show that an increase in KNO_3 concentration from 0.0001 M to 0.001 M did not significantly alter the percentage of adsorption, but an increase to 0.01 M caused a significant decrease in the percentage of adsorption from 68.3% to 33.9%. This happens as a result of the inhibitory effect of a high concentration of K^+ ions. Last but not least, the ionic strength investigation showed that electrostatic interaction caused by π–π stacking influenced the adsorption behaviour of amoxicillin on M-GNPs solution.

Three different isotherm models—the Langmuir, Freundlich, and Temkin models were used to analyse the adsorption of AA on M-GNPs. The average R^2 values for the Temkin isotherm model and the Langmuir isotherm model were nearly identical (R^2 >0.99). Accordingly, the adsorption mechanism included both monolayer adsorption and electrostatic interaction between the surface and adsorbate through the π–π stacking of electrons, which agreed with the results of the study on ionic strength. The pseudo-second-order model, intraparticle diffusion, and Bangham models were used to analyse the adsorption kinetics. It was determined that the use of M-GNPs for the removal of AA from aqueous solution primarily followed a pseudo-second-order kinetic model, as observed by an excellent correlation coefficient (>0.99), which confirms that the major cause of AA's adsorption on M-GNPs is to π–π electron donor-acceptor interaction, which is the rate-determining step. In this study, the thermodynamic parameters were analysed; the negative value of ΔG^o indicated that the adsorption was spontaneous, the negative value of ΔH^o that the process was exothermic, and the negative value of ΔS^o that the surface

randomness was decreased as AA molecules adsorb on the adsorbents. Investigations on the recovery and reusability of the adsorbent revealed that it had a great ability to remove AA repeatedly without losing stability [78].

Ion et al. published the first data on phenol removal utilizing exfoliated graphitic nanoplatelets (xGnPs) as a sorbent. They studied the influence of contact time on phenol adsorption. The results demonstrated that phenol adsorption is slow, with the majority of adsorption occurring within the first 10 hours. The equilibrium was reached following 30 hours of adsorption. In addition, the results demonstrated that phenol is better adsorbed on as-grown xGnP than on oxidized xGnP, but equilibrium is reached after the same contact time. Hydrogen bonding is one mechanism for the sorption of phenol and other organic compounds on carbon-based sorbents, but from the data suggest that this process may not be relevant between the phenolic and functional groups on the xGnPs. Possible hydrogen bonding between surface-adsorbed phenol and dissolved phenol may contribute to the increased sorption capacity values found for xGnPs with high surface areas. Moreover, the dissociation of –OH groups on the phenols may hinder the formation of hydrogen bonds between the surface adsorbed on oxidized xGnPs relative to as-grown xGnPs, hence reducing sorption. The to π–π electron donor–acceptor interactions have been applied to the adsorption of organic molecules on the graphene surface. As an amphoteric adsorbate, graphene could be extremely polarizable. Hydroxyl is an electron-donating functional group that boosts the π -donating strength of the graphene aromatic ring and the sorption affinity of phenol to the surface of xGnPs. The influence of starting phenol concentration on adsorption efficiency at 400 mg/L xGnP when 72.25 percent phenol removal is accomplished. According to the study, the percentage of phenol adsorption increased as pH rose from 2 to 6 and subsequently reduced as pH approached the phenol pKa. The adsorption of phenol on xGnPs was analysed using Langmuir and Freundlich models. Langmuir sorption isotherm is more applicable to describe phenol adsorption to xGnPs. This is also confirmed by the higher correlation coefficient ($R^2 = 0.985$) in the case of Langmuir model as compared to Freundlich model [74].

Banerjee et al. investigated the potency and effectiveness of graphene oxide nanoplatelets (GONPs) as an adsorbent, as well as its application for the efficient uptake of ibuprofen (IBP) from an aqueous solution. In batch adsorption studies, the various process parameters were investigated in order to determine their effect on the relevant process. Maximum IBP removal (98.17%) was found at an initial IBP concentration of 6 mg/L, adsorbent dosage of 1.00 g/L, solution pH of 6, agitation speed of 180 RPM, and temperature of 308K following 60 minutes of treatment. The adsorbent of GONPs exhibited thin, crinkled, overlapping paper-like structures in intimate association, which represented the distinctive property of single-layer graphene oxide sheets, according to SEM pictures of GONPs. The GONP surface's folded structures gave a larger surface area for more effective adsorption. After being used to adsorb IBP, GONPs' sharp edges notably began to soften. TEM was used to show the surface shape of GONPs before and after IBP adsorption. Images from TEM analysis showed the overlapping GONPs and their stable aqueous phase dispersion, which allows for increased adsorption rates [79].

The adsorption isotherm study was carried out using the Langmuir, Freundlich, Temkin, and Dubinin-Radushkevich isotherm models. $R^2 = 0.994$, the highest correlation coefficient, indicates that the Langmuir model best explains IBP adsorption over GONPs. This indicated the homogeneous nature of the GO and implied that each IBP molecule's binding energy to the surface GO was constant. Thus, it can be inferred that GO molecules did not interact with one another, indicating that IBP molecules formed a monolayer covering on the surface of GO. Intraparticle diffusion, pseudo-first-order, pseudo-second-order, and Elovich models were used to examine the reaction's pathway and any potential rate-limiting phases during the adsorption of IBP by GONPs at various temperatures (293–313 K). The pseudo-second order rate kinetics is thought to best describe IBP adsorption by GONPs based on the highest correlation coefficient values ($R^2 = 0.998$). The Arrhenius equation was used to compute the activation energy (E_a), which was found to be 13.49 kJ/mol. IBP adsorption by GONPs is physisorption in nature because

the E_a value obtained is less than 40 kJ/mol. Furthermore, the endothermic nature of the process was revealed by an increase in the adsorption capacity of GONPs (8.217 - 9.165 mg/g) and a concomitant increase in temperature (293 - 313 K). Adsorption thermodynamics was studied, and the results show that the process reached equilibrium by utilizing energy from the system under consideration. The negative values of ΔG^o indicated that the adsorption was spontaneous, while the positive values of ΔH^o indicated that the process was endothermic in nature. The increased randomness at the solid/solution interface was assumed to be caused by the translational entropy of the displaced water molecules being higher than that of the released IBP ions, which was supported by the positive value of ΔS^o. For the removal and recovery of the IBP compounds for solution, investigation of the GONPs' reusability potential is important. The rate of IBP elimination (%) throughout the course of 10 cycles of adsorption and desorption was practically unchanged for eight cycles and slightly reduced for the final two cycles (97.18 and 95.91%) [79].

Rosli et al. conducted research on the use of GNPs to remove the pharmaceutical pollutants sulfamethoxazole (SMX), an antibiotic, and acetaminophen (ACM), an analgesic, from water. The best adsorbent was chosen from among several different types of GNPs, including C750, C300, M15, and M5, each of which has a different surface area. From this study, it was discovered that C750 (738.44 m^2/g) had the maximum surface area, followed by C300 (390.30 m^2/g), M15 (61.51 m^2/g), and M5 (63.55 m^2/g). As mesopores, the pore diameters of C750, C300, M15, and M5 fall within the range of (2–50 nm). A larger zeta potential may indicate better dispersion. Zeta potential measured the electrostatic repulsion between similarly charged particles and thus indicates a degree of dispersion efficiency thus giving information about the tendency of agglomeration. Among the other three GNPs, GNP C300 had the most stable observed zeta potential (50.80 mV). With an absolute value of 20.87 mV, GNP M5 has the lowest tendency to aggregate because it is below the 30 mV threshold. Although C750 has a bigger surface area, the preliminary adsorption investigation of four different types of GNPs indicated that C300 has the maximum removal effectiveness when compared to other forms of GNPs. Based on zeta potential, C300 has the highest level of stability. Further batch adsorption experiments using C300 were conducted with a number of parameters, including solution pH, GNP concentration, initial SMX concentration, and contact time. The pH of the solution had an impact on GNP C300's capacity to adsorb to both SMX and ACM. The initial pH of the solution rose from 2 to 4, eventually raising the adsorption capacity of SMX onto GNP C300. In contrast, ACM's adsorption capacity and removal efficiency progressively increased from acid to neutral before declining as it increased further. For SMX and ACM, maximum adsorption was found at pH 4 (99.27%) and pH 8 (98.38%), respectively. The removal of SMX molecules was hindered by the rising pH of the solution, which led to a poor adsorption capability at higher pH. Since SMX is a well-known acidic organic chemical with a dissociation constant (pKa) between 1.6 and 5.7, acidic circumstances (pH pKa) were preferable to basic conditions (pH > pKa) for the removal of the target compound. In other words, they are present in aqueous solution as a protonated form when solution pH is lower than their pKa values. The elimination efficiency rose with the increase in GNP C300 dosage from 5 mg to 60 mg, but the adsorption capacity for both medications decreased. Adsorption sites were fully accessible at low adsorbent dosages, increasing adsorption capacity. In comparison to lower adsorbent dosages, the active sites of the adsorbent that were ready to bind with the medicinal compounds were not fully utilised at larger GNP C300 amounts. Adsorbent may aggregate and there may be a chance for solid particle collisions as GNP C300 levels rise. The initial concentration of SMX and ACM rose in a nearly linear fashion. More adsorbate molecules are accessible for adsorption the higher the starting concentration. Adsorption of SMX and ACM by GNP C300 started out pretty rapidly before slowing down as contact time increased. For the purpose of determining the adsorption equilibrium between the pharmaceuticals and GNP C300, the Langmuir and Freundlich isotherm models were used. The Langmuir isotherm model was shown to have R^2 values of 0.9952 for SMX and 0.9946 for ACM, indicating a quite better fit and greater suitability for modelling the adsorption of pharmaceuticals onto GNP

C300. This indicated that SMX and ACM adsorption on GNP C300 occurred in a monolayer on a homogeneous surface without contact between the adsorbate. Adsorption kinetics were investigated, and linear regression was used to obtain the kinetic parameters and the correlation coefficient, R^2. Compared to the pseudo-first-order kinetic models, the pseudo-second-order model fitted the data better. According to the pseudo-second-order model, the correlation coefficients (R^2) for both SMX and ACM were 0.9999, which was higher than the correlation coefficients for the pseudo-first order. Thus, in agreement with chemisorption being the rate-controlling phase, the pseudo-second-order model was better fit for modelling the process of SMX and ACM adsorption on GNP C300. To further describe the diffusion mechanism, the intraparticle diffusion model was used. Data multilinearity suggests that intraparticle diffusion influences the early stages of adsorption but was not the rate-determining step for the entire adsorption process [80].

Badhei et al. worked on adsorption of Metronidazole antibiotic drug (MNAD) onto magnetically modified graphene nanoplatelets (MMGN) from aqueous solution. The MMGNs were prepared by mixing GNPs with freshly prepared magnetite nanoparticles and the new characteristics were further observed during the investigation. The effect of different operational parameters which affect the removal process were explored such as; adsorbent amounts, contact time, initial pH, temperature, and the initial concentration of MNAD. The results showed that the MNAD was removed within 120 min using 9.8 mg adsorbent, at pH 5.0 and 293 K. Adsorption equilibrium data were fitted using both Langmuir and Temkin isotherms, and the Langmuir maximum adsorption capacity was found to be 112.48 mg g^{-1}. Adsorption for MNAD was studied kinetically and thermodynamically, and found to be well fitted by the pseudo second order kinetic model, spontaneous and exothermic in nature. The adsorption behavior of MNAD on MMGN involved π-π stacking and electrostatic interaction, and the rate determining step was the π–π electron donor– acceptor interaction. Recovery, and reusability of the adsorbent was investigated, and the adsorbents showed great ability for the removal of Antibiotic drug for many times without losing its stability. Generally, MMGN could be considered a potential and promising adsorbent for the removal of organic pollutants from polluted water [1].

de Assis et al. the synthesis of graphene oxide (GO) nanosheets, to be used as adsorbent for the removal of textile dyes from wastewater, was optimized by the modified Hummers method. The GO nanosheets produced were compared with commercial GNPs. The surface area (BET model) for commercial GNPs presented a value of 90.08 ± 3.01m^2 g^{-1}. No hysteresis was observed, which was expected since the material is nonporous, formed only by nanosheets, often superposed. The surface area of GO synthesized by the modified Hummers method presented a value of 176.00 ± 2.09 m^2 g^{-1}, which indicates that the oxidation of the material is favoring the free surface area. It is estimated that the application of ultrasound techniques can promote exfoliation of the sheets and increase the specific surface area. The results of removal efficiency for the blue dye (SFGL) on the two sorts of adsorbents studied evidenced the anionic behavior of the direct dye, because there was a tendency to the significant increase of the removal efficiency when at pH <4, especially when adsorbed on graphene oxide, reaching efficiency higher than 90% at pH 1.0. This pattern may be due to the functional groups of the dye adsorbed on the surface of the GO which increase its surface complexing ability. Because of the high functionalization of the graphene oxide by hydroxyl (-OH) and carboxylic groups (-COOH), negatively charged in aqueous solution, the presence of available oxygen groups and the arrangement of the active functional groups of the dye species, it is possible to occur stronger chemical bonds, such as hydrogen bonds, between GO and the dyes. The results of the removal efficiency of the dye Red 81 under the two different adsorbents were quite different. When adsorbed on commercial graphene the dye exhibited exceptional high efficiency at low pH, which rapidly decreased at higher pHs. When adsorbed on graphene oxide, the removal efficiency did not reach values higher than 80% for low pH, however for pHs above 7.5 reached efficiency close to 100%. The presence of large amounts of OH- functional groups in the GO may facilitate interaction with the amine -NH functional groups of the dye at higher pHs, resulting in a greater

adsorption at these levels. It suggested that the negatively charged sulfonate groups (SO_3) of dye molecule neutralize the electrostatic interaction with oxygen-containing groups on the GO surface, so that of the π-π interactions and the hydrogen bonds with the GO surface can play a dominant role in the adsorption process. Hence, a pH of 3.5 was set to evaluate the influence of the initial dye concentration. Best concentration of 50 ppm for the GO and 100 ppm for the commercial graphene were selected as it resulted in a maximum adsorption capacity [24].

The adsorption isotherm of the dyes Indosol SFGL direct blue and Red 81 on graphene oxide (GO) were studied. Langmuir isotherm fitting best suited both data points, with monolayer maximum sorption capacity (q_m) of 128.58 and 190.53 $mg \cdot g^{-1}$ for SFGL and Red 81, respectively, and satisfactory coefficient of determination (R^2) above 0.96. The Freundlich model also showed a satisfactory $R^2 = 0.90$. It were observed that the Red 81 dye is better adsorbed onto GO, when compared to SFGL, showing a higher adsorption capacity for all the concentrations studied. This might be related to strong interactions between the oxygenated function groups of OG and the -NH and -OH groups of the Red 81 dye. The adsorption behavior was best fitted by a pseudo-second order kinetic model. A layer of graphene has a large two-dimensional planar structure; its extended, delocalized π– electron system facilitates interaction with the direct dyes through π–π stacking, low electrostatic interaction, or Van der Waals forces. The simultaneous action of the different adsorption mechanisms present in the interaction between dyes and adsorbents are important for the understanding of the evolution of adsorptive capacity through existing functional groups. The structural properties of GO allow interaction with organic molecules via non-covalent forces such as π-π stacking and hydrogen bonds. The GO surface is negatively charged due to the presence of large numbers of oxygen-containing functional groups, such as epoxy, carboxyl and hydroxyl. With the protonation of the GO surface by acid pH, the number of positively charged sites increases, favoring the adsorption of negatively charged dye ions by attraction forces. Hence, the high removal efficiency at lower pHs for SFGL using this adsorbent. This blue dye has four sulfonic acid groups ($R\text{-}SO_3Na$), which, in aqueous medium has the dissociation of sodium ions (Na^+) and sulfonate ($R\text{-}SO_3$). However, these sulfonic groups have pKa less than zero and therefore exhibit negative charges even at lower pHs, which helps in the interaction with the protonated GO surface. This factor also assists in the removal of red dye 81, since it contains two sulfonic acid groups in its structure. Another crucial factor is the presence of carboxyl and hydroxyl groups on the GO surface, which can promote hydrogen bonds with the -OH groups, quite present in the SFGL blue, contributing to a greater adsorption capacity of these dye. Specifically, for the Red 81 dye, the existence of an amine group and a hydroxyl in its structure also allows hydrogen bonds with the -OH and -COOH groups present on the GO surface. At basic pH's the hydroxyl and carboxylic groups of the GO are deprotonated and form their anionic specimens (-ACOO and -AO), which are believed to interact via dipole-dipole bonds with the -RNaO and -RO groups present in this red dye. This explains the high adsorption of the Red 81 dye onto GO, both in acidic and basic pHs. The Red 81 and SFGL blue dyes have five and seven aromatic rings in one molecule, respectively. Its extended, delocalized π–electron system facilitates interaction with the direct dyes through the π–π stacking interaction. As both dyes exhibit a planar structure, we believe that these π- π stacking are a secondary interaction mechanism between both dyes and GO, and a main interaction mechanism between the dyes and the commercial graphene (as few oxidized functional groups are present). The adsorptive process on the commercial graphene nanosheets surface occurs by low electrostatic interaction or Van der Waals forces. The electrostatic affinity is indicated by the pH through the analysis of the zero-charge point of the adsorbent which consists of the neutral point in the interaction surface. The low adsorptive capacity using commercial graphene as an adsorbent for SFGL can be explained by the absence of functional oxygen groups. It was found that the adsorption mechanism of benzene does not occur through hydrogen bonds, resulting in a lower adsorptive capacity. It is assumed that in acid pH solution, both anionic dyes exhibits repulsion to the liquid medium and consequently a higher affinity to the inert sheets of graphene nanoplatelets, enabling a better fixation of the

dye and consequently higher adsorption capacity [24].

ElHussein et al., studied on removal of carbamazepine (CBZ) from water using UiO-66 and UiO-66/graphene nanoplatelet composite. UiO-66 and graphene nanoplatelet (GNP)/UiO-66 composites were prepared by hydrothermal method. Morphologies of UiO-66 and UiO-66/GNP nanoparticles were investigated by SEM analysis. The images of particles observed to have a shape of crystals are suitable to literature. The crystal shapes are due to ratio of used modulator acid. In this study, particle size distribution of UiO-66 nanoparticles is about 200 nm, UiO-66/GNP nanoparticles is about 700 nm. BET adsorption-desorption isotherms of adsorbents at 77 K were applied, and specific surface area for the UiO-66, and UiO-66/GNP were estimated as 730.6 m^2/g, and 910.5 m^2/g, respectively. The BJH pore volume of UiO-66 is 0.0462 cm^3/g, and pore radius of 1.92 nm. Also, BJH pore volume of UiO-66/GNP is 0.0357 cm^3/g, and pore radius of 1.81 nm. UiO-66 and UiO-66/GNP nanoparticles were prepared for CBZ adsorption. Adsorbent dosage is an important adsorption parameter; 1 mg dosage of UiO-66/GNP and 2.5 mg dosage of UiO-66 was selected as optimum dosage adsorbent. 5 mL of adsorbate solution is more appropriate quantity for UiO-66/GNP. CBZ adsorption capacity reaches to 26.46 mg/g if5 mL of adsorbate solution. 10 mL of solution is better for UiO-66. The pH of CBZ solution was investigated, the results observed that neutral media is better for both of the adsorbents. pKa values of CBZ are 2.3−13.9. Between pH 3 and 10, CBZ protects its neutral form. Acidic and neutral pH values have nearly similar CBZ adsorption capacities on UiO-66. But UiO-66/GNP has very high adsorption capacity at neutral pH value. This result can be connected to GNP surface. Heterogeneity and uncharged surface of GNP is suitable for CBZ adsorption, π-π stacking brings functional addition to GNP. So, UiO-66/GNP nanoparticles is better for CBZ adsorption from water. Non-linear pseudo-first order and pseudo-second order kinetic models were applied. Pseudo-first order R^2 values of CBZ adsorption on UiO-66/GNP and UiO-66 were 0.92 and 0.97, respectively. R^2 values of CBZ adsorption on UiO-66/ GNP and UiO-66 for pseudo-second order were 0.96 and 0.98, respectively. Both of the kinetic model can explain kinetic behaviour of the adsorption systems. The reaction mechanism is directly due to chemical reactions between urea functional group of carbamazepine ($C_{15}H_{16}N_2O_3$) and adsorbents. Non-linear Langmuir and Freundlich isotherms was applied in this study. According to adjusted R^2 values, CBZ adsorption on UiO-66 and UiO-66/GNP are compatible with non-linear Langmuir and Freundlich isotherms. Multilayer adsorption occurs between CBZ and adsorbents. And chemical reaction is the main step of adsorption [81].

Luo et al. investigated the efficiency of GNPs as solid-phase extraction (SPE) sorbent for determination of phthalate esters (PAEs) in aqueous solution. To evaluate the enrichment effect of GNPs sorbent, five PAEs including dimethyl phthalate (DMP), diethyl phthalate (DEP), dipropyl phthalate (DPrP), DBP and dicyclohexyl phthalate (DCHP) were selected as model analytes. The operation parameters affecting the extraction efficiency, including eluent solvent and its volume, and the sample volume were optimized. The eluent solvent for SPE operation has important influence on sample recovery. The choice of eluent solvent is mainly based on the chemical property of the target samples and the chromatographic mode used downstream. Since the separation of five PAEs was performed by reverse phase HPLC (RP-HPLC), the eluent solvent should be compatible with common mobile phase used in RP-HPLC, that is, the eluent solvent should be miscible with the mobile phase. It observed that acetonitrile is the most effective eluent for five PAEs, probably resulting from strong interaction between acetonitrile and GNPs due to its property of aprotic solvent. Thus, acetonitrile was selected as eluent in the following studies. In addition, the pH effect on the extraction was also explored and it was found that the pH had no significant influence on the recoveries. To ensure reliable analytical results and high enrichment factor, the maximal sample loading volume of GNPs-based SPE cartridge was explored. It observed that the peak area of each analyte increased with increase of loading sample volume up to 1000 mL, indicating rich adsorbed sites on the surface of GNPs sorbent. 80-101% of recoveries were achieved for the analytes (except DMP) when the sample loading volume was less than 500 mL [82].

Comparison of GNPs sorbent with other commonly used sorbents, including C_{18} silica, HLB Oasis, Active carbon, and MWCNTs, has been made. To ensure the same level of packing sorbent in the cartridge, different amounts of sorbents were used due to their different densities. C_{18} silica (100 mg), HLB Oasis (100 mg), Active carbon (50 mg), MWCNTs (50 mg) and GN (30 mg) were packed in 1 mL SPE cartridge. These cartridges were loaded with 200 mL of sample solutions spiked at 100 ng mL^{-1} five PAEs. To determine the possible breakthrough of sample, the effluent at different stages of loading, washing, and elution was collected and determined by HPLC. Methanol as the eluent solvent was used for C18 silica and HLB Oasis. Active carbon and MWCNTs were eluted by acetonitrile. It highlighted, GNPs sorbent yielded the highest recoveries (85.6-100.9%) among these tested sorbents, although its amount was the smallest (only 30 mg). By comparison, GNPs sorbent observed the best performance in terms of recoveries and adsorption capacity among several sorbents. This is probably due to its unique structure, which results in strong π-stacking interaction with the benzene ring in the molecule of PAEs. In addition, GNPs have some hydrophilic groups such as hydroxyl and carboxyl groups, which can improve the water-wettability of GNPs and enhance the retention of polar compounds. These features make GN an attractive sorbent for PAEs [82].

Al-Khateeb et al. studied on removal of non-steroidal anti-inflammatory drugs (NSAIDs) from water using high surface area graphene nanoplatelets (HSANGs). The NSAIDs drugs; Ketoprofen (KETO), Naproxen (NAP) and Diclofenac sodium salt (DIC), and Ibuprofen (IBU); were used in this study. Adsorption of pharmaceutical pollutants NSAIDs from aqueous solutions by carbon-based adsorbents such as HSANGs might be occurred through the by π-π stacking due to the presence of the π electrons on both of the organic compounds and the HSANGs surface. However, there are many other factors that may affect this type of interaction and consequently affect the removal process. Therefore, the effect of different factors on the interaction between HSANGs and KETO, NAP, DIC, and IBU was explored and studied. The effect of HSANGs mass on the removal of KETO, NAP, DIC, and IBU was observed. It is found that the increase in the % removal of NSAIDs with the increase of HSANGs mass. 10.0 mg of HSANGs was able to remove most of the NSAIDs compounds. Further increase of HSANGs increased the % removal of NSAIDs using 40.0 mg of the HSANGs. Within 5.0 minutes adsorption of the NSAIDs compounds reached equilibrium. After 5.0 minutes, the removal percentage did not change significantly. It was also observed that the affinity of the NSAIDs compounds towards the HSANGs was different and followed the following order DIC>NAP > KETO> IBU. Also, this observation could be because DIC, NAP, and KETO molecules composed of two benzene rings, whereas IBU composed of one benzene ring, which allowed DIC, NAP, and KETO molecules to interact and adsorbed on the HSANGs through the π-π interaction. Another reason for the affinity of the NSAIDs compounds towards the HSNGs could be due to the molecular weight and consequently the size of the molecule, as the molecular weights of the molecules. The large size of the molecule allowed them to compete effectively for the adsorption on the surface of the HSANGs. The dependence of the removal on the solution pH is a crucial physicochemical factor, which infers the adsorption mechanism at the solid-solution interface. Therefore, the effect of solution pH on the removal of NSAIDs by HSANGs was studied. The results observed the % removal was the highest at pH value of 2.0 NSAIDs and this % removal did not change by raising the solution pH to 4.0 [83].

It is important to study the adsorption process kinetically through the observation of the experimental parameters that may affect the rate of adsorption and, as a result, help attain equilibrium in a fair amount of time in order to comprehend the adsorption and remediation process. The most common and well-known kinetic models, the pseudo-first-order model and the pseudo-second-order model, were used to analyze the adsorption experimental data of KETO, NAP, DIC, and IBU by the HSANGs in order to comprehend the nature of the adsorption process. It observed that, the pseudo-first-order model, was applied to fit the data. However, the adsorption of KETO, NAP, DIC, and IBU by HSANGs was studied using the pseudo-second-order rate equation showed an excellent regression coefficients (R^2 >0.99)

and straight lines were obtained, as well as good fitting to the experimental data. Using two separate models, the liquid film diffusion model and the intra-particle diffusion model, the adsorption rate-controlling mechanism for the adsorption of the KETO, NAP, DIC, and IBU by HSANGs from aqueous solution was studied. Another kinetic model that involves the flow of adsorbate molecules through a liquid film around the solid adsorbent is the liquid film diffusion model. The linear regression coefficients and convergence of the liquid film diffusion model applied to the adsorption data of KETO, NAP, DIC, and IBU by HSANGs were very low. This suggests that the rate-determining stage for the entire adsorption process was not the liquid film diffusion. Only the kinetic data after the first minute of the adsorption were well-converged with respectable linear regression coefficients. The data of KETO, NAP, DIC, and IBU adsorption by HSANGs did not converge, and no straight lines that passed through the origin were found. The intra-particle diffusion is not the rate-determining step, but it is a component of the adsorption mechanism for the adsorption of KETO, NAP, DIC, and IBU by HSANGs, which suggests that the adsorption processes occur in two kinetic steps. NSAIDs under research may have a significant impact on the adsorption process onto HSANGs. Therefore, it is evident that the adsorption processes were regulated by more than one kinetic step, including intra-particle diffusion of the KETO, NAP, DIC, and IBU via HSANGs and liquid film diffusion. The adsorption mechanism is a mixed process because none of the steps is the rate-determining step. Instead, the first linear step within the first minute is the fastest step and is attributed to the diffusion of KETO, NAP, DIC, and IBU molecules to the HSANGs. The second linear portion is a slower process that corresponds to the intra-particle diffusion of the KETO, NAP, DIC, and IBU through the HSANGs. The HSANGs' ability to adsorb the NSAIDs KETO, NAP, DIC, and IBU from an aqueous solution mostly in accordance with the pseudo-second-order kinetic model, as demonstrated by the excellent correlation coefficients (>0.99) and convergence of the experimental data, led to this conclusion. Additionally, the removal process involves several processes, including intra particle diffusion and liquid film diffusion, however none of these steps determine the removal process's rate[83].

The spontaneity of the NSAID adsorption process was studied by thermodynamic analysis. The ΔH^o values for the adsorption of KETO, NAP, DIC, and IBU by HSANGs from the aqueous solution were positive; +39.5 kJ/mole, +42.5 kJ/mole, +47.0 kJ/mole, and +27.5 kJ/mole, respectively. The endothermic character of the adsorption of KETO, NAP, DIC, and IBU by HSANGs is confirmed by the positive enthalpy values, which explains why the rate of adsorption increases as the temperature of the solution rises. Additionally, the amount of ΔH^o points to a substantial affinity between the physical characteristics of the adsorption and KETO, NAP, DIC, and IBU by HSANGs. During the adsorption and immobilisation of KETO, NAP, DIC, and IBU, the positive values of ΔS^o, +144.8 J/mole.K, +159.7 J/mole.K, +184.0 J/mole.K, and +97.1 J/mole.K, revealed a rise in the degree of randomness at the HSANGs/solution interface. According to the negative values of the predicted free energy change, ΔG^o, which were, respectively, -3.38 kJ/mole, -4.79 kJ/mole, -7.45 kJ/mole, and -1.23 kJ/mole for the adsorption of KETO, NAP, DIC, and IBU by HSANGs from aqueous solution, the adsorption of KETO, NAP, and DIC The adsorption of KETO, NAP, DIC, and IBU by HSANG's process is proposed to be an entropy-driven process by the negative values of ΔG^o and the positive values of ΔH^o and ΔS^o. To determine whether the suggested solid adsorbent is practical, the removal of by HSANGs from actual environmental water samples was examined. For this study, two actual samples were chosen: KETO, NAP, DIC, and IBU tap water (TW), as well as wastewater from King Abdulaziz University Wastewater (WW). The initial KETO, NAP, DIC, and IBU concentrations were tested and were below the HPLC's detection limit, showing that these pollutants were not present in the chosen real water samples. It demonstrates that the majority of NSAIDs such KETO, NAP, DIC, and IBU were eliminated from the WW, and TW spiking samples support the usefulness of HSANGs for environmental remediation, particularly in the case of NSAID pollution. Using actual water samples containing KETO, NAP, DIC, and IBU, the applicability of the HSANGs for the removal of NSAIDs was tested, and the findings demonstrated the high removal effectiveness [83].

Bhattacharya et al. investigates the potential of graphene oxide nanoplatelets (GONPs) for removal of a common and extensively used drug, Carbamazepine (CBZ) from aqueous solutions. The surface morphology of GONP as recorded using SEM observed that the SEM images of GONP composed of thin, closely associated and highly overlapping platelet-like carbon sheets. The rough surfaces of these crumpled GONPs reportedly facilitate efficient adsorption. These wrinkled and layered structures of GO are reportedly formed as a result of interactions between oxygen containing functional groups. Batch studies were performed to assess the potential of graphene oxide for adsorption of CBZ under different. A maximum adsorbate removal of 99% was recorded from a solution containing 5 ppm of CBZ under optimized conditions of solution pH (2), adsorbent dosage ($1gL^{-1}$), temperature (35ºC) and contact time (120 min). Different isotherms models such the Langmuir, Freundlich, Temkin, and Dubinin-Radushkevich were fitted to the percentage CBZ removal. The values of $R^2 = 0.815$ suggested that the results from batch experiments were the most closely related to the Temkin isotherm. Therefore, it may be assumed that CBZ was uniformly adsorbable by GONP. Additionally, this implied that the adsorbent moieties' heat of adsorption reduced linearly as the process advanced. For the examination of process kinetics, CBZ removals were fitted to various models. The pseudo-second order kinetic model best fit the results from batch investigations. The Arrhenius equation was used to compute the activation energy (E_a), which was discovered to be 78 kJ/mol for the adsorption of CBZ by GONPS. The CBZ adsorption by GONP was likely chemisorption in nature if the E_a value was greater than 40 kJ/mol. According to the findings of the study on process thermodynamics, negative values observed for $\Delta G°$ suggested the process in question was spontaneous. Additionally, the process' endothermic character was confirmed by the positive figure for enthalpy. Additionally, the positive value for entropy indicated that the translational entropy of the released CBZ ions was lower than that of the water molecules that were displaced, leading to a higher level of unpredictability at the interface between the adsorbent and adsorbate. The CBZ adsorption efficiency of GONP was observed to maintain the same for eight consecutive cycles and fall in the last two cycles (95 and 90% removal efficiency, respectively), according to the study's findings on reusability. This had happened because of handling-related bulk loss or repeated regeneration-related adsorbent surface degradation [84].

Khalil et al., studied on nanostructured porous graphene (PG) for efficient removal of emerging contaminants (ECs) pharmaceutical; atenolol (ATL), carbamazepine (CBZ), ciprofloxacin (CIP), diclofenac (DCF), gemfibrozil (GEM) and ibuprofen (IBP) from water. Detailed batch tests were conducted to investigate the effects of adsorption time, initial EC concentration, PG dosage, solution pH, and temperature. A maximum adsorbate removal of ECs >99.9% was recorded from a solution containing 250 ppm of ECs under optimized conditions of solution pH (2), adsorbent dosage (5 mg), and contact time (60 min).To illustrate the sorption mechanism and the role of surface area and active sites, four kinetic models including pseudo-first order, pseudo-second order, Elovich and intraparticle diffusion reaction models were applied to evaluate the rate of adsorption reaction and its rate controlling step. Of the four suggested models, the pseudo-second order rate model best described the kinetics of ECs adsorption onto graphene oxide (GO) and PG with an excellent fit as indicated by the highest correlation coefficient values ($R^2 = 0.99$ for most ECs). The results indicated further affinity of ECs of hydrophilic nature, such as ATL and CIP towards GO, while the other ECs were more attracted to PG. In general, although the adsorption performance of GO was higher for ATL and CIP removal, but, in terms of super hydrophobicity, ease of separation from water, recyclability and chemical stability, PG is a more attractive candidate for ECs removal in water treatment applications [85].

Seven adsorption isotherm models were compared for their potential to best fit the experimental data in order to better clarify. The Freundlich model might be used to represent the adsorption findings of GO for ATL and CBZ in terms of the best match criterion (R^2). The Freundlich isotherm models plausible for explaining heterogeneous multilayer adsorption. The Langmuir isotherm is used to illustrate the IBP adsorption data for GO and PG. This implied that a monolayer coverage

formed in the event of IBP adsorption onto a graphene-based material (GBM) surface, suggesting that the binding energies of each IBP molecule on the surface GO were uniform. Therefore, it can be said that no interactions between GO molecules occurred during the IBP adsorption. Finally, it was discovered that the Langmuir models fairly produced a better fitting than the other models in the instance of DCF adsorbed by GO and PG. The pseudo-second order model was applied as best to described the kinetics of ECs adsorption onto GO and PG with an excellent fit (R^2 = 0.99 for most ECs). In every situation, the type of adsorption may be predicted based on the principal adsorption energy E (kJ/mol), which is connected to the D-R model. The ECs' adsorption process on GO and PG showed physical properties, as evidenced by the low values of the E parameter that were observed. The exothermic character of the adsorption is confirmed by the negative values of ΔH, which explains why adsorption decreases at increasing temperatures. In contrast to chemical adsorption, which has a range of -400 to -80 kJ/mol, the magnitude of ΔH points to a weak type of bonding between ECs by PG, such as physical adsorption (ΔH range between -20 and -40 kJ/mol). The decrease in degree of freedom of pharmaceutical molecules, as indicated by the negative values of ΔS, is thought to be the cause of the decrease in randomness. The free energy change, ΔG, is negative, indicating an enthalpy-driven process and a product-favorable spontaneous reaction. Finally, after being regenerated and used four times to cure pharmaceutically contaminated solutions, PG showed good promise for recycling[85].

Table 1. Summarize of adsorption of EDCs onto graphene nanoplatelets

Adsorbent	Pollutant	Adsorption Isotherm Model	Adsorption Kinetics Model	Adsorption Thermodynamic	Remarks	Ref.
Graphene Nanoplatelets	DCS	Langmuir	Pseudo-second-order	Exothermic and spontaneous process	At pH conditions greater than 4.2, diclofenac sodium ionizes given a negatively charged ion that is electrostatically repelled by GNP surface causes a decrease in the removal efficiency.	[75]
Exfoliated Graphene Nanoplatelets	BPA	Langmuir Freundlich	Pseudo-second-order	Exothermic and spontaneous process	At pH from 3 to 7, the adsorption of BPA slightly increased, than it begins to decrease between 7 and 9.	[29]
Graphene nanoplatelets	ASA, APAP, CAF	BET	Pseudo-second-order	Exothermic spontaneous process and increase in randomness	The percentage of adsorption of CAF was slightly enhanced by increasing the ionic strength of the solution	[76]
Graphene Nanoplatelets	LFX	Langmuir	Pseudo-second-order	Endothermic, spontaneous process and	The dosage and time have a positive effect on removal efficiency.	[77]

				increase in randomness	If one of the variables is held constant, the trend remains unchanged.	
Magnetically modified graphene nanoplatelets	AA	Langmuir Temkin	Pseudo-second-order	Exothermic and spontaneous process and decrease in randomness	These functional groups in AA ionize at various pH levels to produce negatively charged AA; the electrostatic repulsion increases between amoxicillin and M-GNPs surface as the solution pH rises.	[78]
Exfoliated Graphene Nanoplatelets	Phenol	Langmuir			The hydrogen bonding between surface-adsorbed phenol and dissolved phenol may contribute to the increased sorption capacity values for xGnPs.	[74]
Graphene Oxide Nanoplatelets	IBP	Langmuir	Pseudo-second-order	Endothermic, spontaneous process and increase in randomness	Maximum IBP removal was found at an initial IBP concentration of 6 mg/L, adsorbent dosage of 1.00 g/L, solution pH of 6, agitation speed of 180 RPM, and temperature of 308K following 60 minutes of treatment.	[79]
Graphene Nanoplatelets	ACM, SMX	Langmuir	Pseudo-second-order		Maximum adsorption was observed at pH 4 (99.27%) for SMX and ACM at pH 8 (98.38%).	[80]
Magnetically Modified Graphene Nanoplatelets	MNAD	Langmuir Temkin	Pseudo-second-order	Exothermic and spontaneous process	MNAD was removed within 120 min using 9.8 mg adsorbent, at pH 5.0 and 293 K.	[1]
Graphene Oxide (GO) Nanosheets, Commercial	Dyes	Langmuir Freundlich	Pseudo-second-order		Dye adsorbed on commercial graphene shows high efficiency at low pH, which	[24]

Graphene					rapidly decreased at higher pH.	
UiO-66, UiO-66/graphene nanoplatelet composite	CBZ	Langmuir Freundlich	Pseudo-first-order Pseudo-second-order		Neutral pH of CBZ solution is better for both of the adsorbents.	[81]
Graphene Nanoplatelets	PAEs				GNPs sorbent yielded the highest recoveries (85.6–100.9%), although its amount was the smallest (only 30 mg).	[82]
High Surface Area Graphene Nanoplatelets	NSAIDs		Pseudo-first-order	Endothermic, spontaneous process and increase at randomness	Percentage removal was the highest at pH value of 2.0 NSAIDs and this % removal did not change by raising the solution pH to 4.0.	[83]
Graphene Oxide Nanoplatelets	CBZ	Temkin	Pseudo-second-order	Endothermic, spontaneous process and increase at randomness	A maximum adsorbate removal of 99% was recorded from a solution containing 5 ppm of CBZ under optimized conditions of solution pH (2), adsorbent dosage ($1gL^{-1}$), temperature ($35^{o}C$) and contact time (120min).	[84]
Nanostructured Porous Graphene	ATL, CBZ, CIP, DCF, GEM, IBP	Freundlich (ATL, CBZ) Langmuir (IBP, DCF) Toth (CIP, GEM, DCF)	Pseudo-second-order	Exothermic, spontaneous process and decrease at randomness	A maximum adsorbate removal of these pharmaceuticals > 99.9% was recorded from a solution containing 250 ppm of ECs under optimized conditions of solution pH (2), adsorbent dosage (5 mg), and contact time (60min).	[85]

Abbreviations: DCS: diclofenac sodium; BPA: bisphenol A; ASA: aspirin; APAP: acetaminophen; CAF: caffeine; LFX: levofloxacin; AA: amoxicillin; SMX: sulfamethoxazole; ACM: acetaminophen; MNAD: metronidazole antibiotic drug; PAEs: phthalate esters; NSAIDs: non-steroidal anti-inflammatory drugs; ATL: atenolol; CBZ: carbamazepine; CIP: ciprofloxacin; DCF: diclofenac; GEM: gemfibrozil; IBP: ibuprofen

Over the decades, the research involving the usage of GNPs have progressed in a multitude of directions. The literatures published in area of nanomaterials governing graphene-based materials especially GNPs indicate the intensity of research activities being carried with this material. The properties of GNPs have caused the wide range of application such as sorbent material for wastewater treatment. However, more research is needed to improve the capability of GNPs to adsorb adsorbates at even lower concentrations. It can be done by further fabricating the GNPs with other materials.

Conclusion

The effective use of graphene nanoplatelets as an adsorbent material for the removal of heavy metals and endocrine disruptors in wastewaters is summarized in this review paper. Pollutants become harmful when exposed for a long period of time, endangering not just humans and the environment but also aquatic life. The conventional treatment techniques might not be sufficient to completely remove these pollutants. Adsorption using graphene materials can be thought of as a simple and low-cost technique, especially for treating distinctive wastes like heavy metals and EDCs, which may only be present in very low concentrations and are harmful if not completely removed. The use of graphene nanoplatelets and its modifications for the removal of heavy metal pollutants and EDCs have made recent progress, as shown in this review. It is evident that graphene nanoplatelets offer a promising alternative to other commonly used adsorbent materials. It has been demonstrated that graphene nanoplatelets have the potential to be one of the most reliable and versatile materials for wastewater treatment in the future. It is important to understand that the adsorptive capacity of graphene nanoplatelets depends on the conditions of the experiment. The results of the batch experiments indicated that the adsorption process was affected by adsorbent dose, contact time, initial phosphate concentration, and temperature. The kinetic study indicated adsorption was governed by several mechanisms with various processes dominating different stages of adsorption. Isotherm studies showed the adsorption could be described by Langmuir, Freundlich, Temkin, and Dubinin-Radushkevich isotherms. Based on a comparison of the R^2 values, the adsorption onto GNPs adsorbent mostly closely fit Langmuir isotherm, suggesting a monolayer adsorption system on the surface. The kinetic studies included a pseudo-first order kinetic model of a Lagergren curve, a pseudo-second order model and an intra-particle diffusion model to elucidate the adsorption mechanisms and the adsorption control rates was studied. Besides that, the mechanisms of adsorption include chemical and physical interactions was investigated in this review. The present review investigates the significance of thermodynamic parameters, standard free energy change (ΔG^o), standard enthalpy change (ΔH^o) and standard entropy change (ΔS^o) to predict the spontaneity of adsorption of metals and EDCs onto the surface of adsorbents. On the basis of its chemical and structural stability, the GNPs could become a very good adsorbent with applications for water remediation. More studies should be carried out for low-cost adsorption process to promote large scale use of non-conventional adsorbents. Low-cost adsorbents should be used to minimize cost and maximize heavy metal removal efficiency.
